
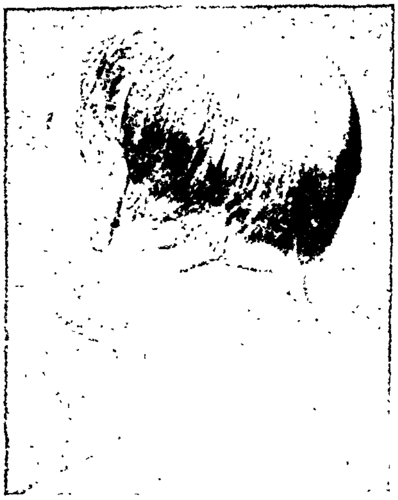

Fig. 2—Subcutaneous lipoma on neck of a man aged 61.

situated on the left arm, left buttock (fig. 3), and right scapula. These are fairly representative sites at which pedunculation occurs, possibly because of the looseness of the subcutaneous tissue and skin, and to the duration of the growth. In these 3 cases the duration was twenty, thirty, and sixteen years. It has been stated that a pedunculated lipoma never grows to a large size (Bland-Sutton 1906), because of its tenuous blood-supply. Though this may be generally true, there are exceptions. The third case of pedunculation in the present series weighed 4 lb. An unusually large lipoma, weighing 24 lb., was described by Duggan (1944); this had started in the neck twenty-six years previously and reached to the waist with a pedicle of skin and hypertrophied platysma as thick as the patient's arm. The patient reported for treatment owing to hæmorrhage from a congested vein at the fundus of the tumour. Secondary changes of this sort are characteristic. Owing to trauma to the surface associated with a stagnating blood-supply, ulceration is liable to occur (fig. 3). As the result of torsion of the pedicle a myxomatous appearance may develop in the tumour, and on rare occasions not only does growth cease but atrophy may occur.

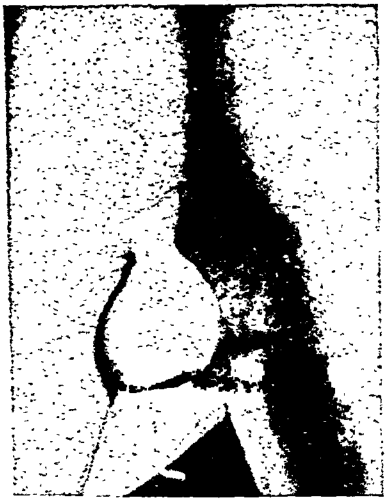

Fig. 3—Pedunculated lipoma of the buttock of a man aged 42. Ulceration has begun on under surface of lipoma.

Multiplicity of lipomas has been commented on already in connection with their possible relationship to subcutaneous nerves. Multiplicity is not uncommon, occurring in 6 cases in the present series, 4 females and 2 males with a total of 18 lipomas, 5 being the most found in one patient (fig. 4). There may be good grounds for placing multiple lipomas in a separate group, especially those cases in which many hundreds are present appearing even in places where fat is not normally found such as the lung and liver, suggesting a dyscrasia of fatty tissues (Virchow). But for those with only a few it seems equally plausible that the same factors are at work which cause a single lipoma to form. A symmetrical distribution was noted in 2 cases, both hips in one, and both deltoid regions in the other.

An important feature of lipomas is recurrence. Whereas for many types of tumour this may be of serious import, for most lipomas this does not apply. Undoubtedly some liposarcomas, as Stout (1944) points out, develop from a pre-existing lipoma—for example, the case he cites of a liposarcoma surrounded by a simple retroperitoneal lipoma. Probably, however, this change is rare. In the present series 4 cases gave a history of removal of a lipoma from a similar site at a previous date. It has not been possible to compare the histology, but on clinical grounds there seems little reason to suppose that a frankly malignant change had taken place. The dates of the previous operations were stated to be fifteen, seventeen, four, and two years previously. Recurrence is most probably due either to incomplete removal of all lobules of the original lipoma or to the persistence of local factors conducent to tumour formation from primitive cells with potential for fat formation. All recurrent tumours should, however, be searched carefully for areas of more primitive cells and more rapid growth.

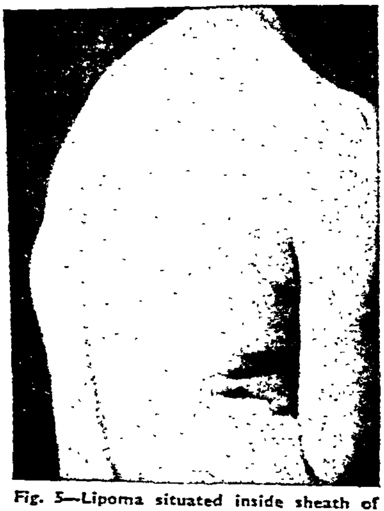

Fig. 5—Lipoma situated inside sheath of sacrospinalis muscle in a woman aged 40.

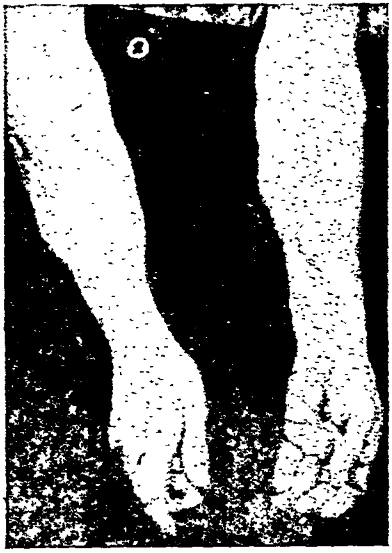

Fig. 4—Multiple lipomas on forearms of a woman aged 52.

In his classification of lipomas, Geschickter (1934) referred to recurrent lipomas as a group, calling them fibrolipomas and embryonic. Myxomatous and xanthomatous appearance may, he stated, be a sign of incomplete differentiation with embryonic cells capable of tumour formation. The term fibrolipoma seems inappropriate since it refers to a mixture of tissues often found in well-differentiated tumours showing no signs of recurrence.

Intermuscular and intramuscular lipomas occur not infrequently (8 in the present series) and do not differ in structure or appearance from their subcutaneous counterparts. They are, however, liable to cause difficulty in diagnosis, and for this reason may require investigation. Characteristically they are symptomless, causing no

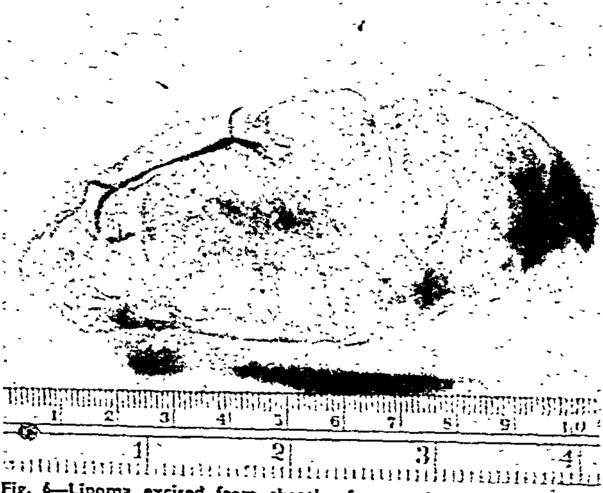

Fig. 6—Lipoma excised from sheath of sacrospinalis muscle (same lipoma as in fig. 5).

interference with function, and forming a soft lump which becomes harder with contraction of the muscle. Lobulation is impossible to define, but a characteristic shape may be produced by the muscle in which they lie—e.g., a spindle shape when the lipoma lies inside the erector spinæ or its sheath (figs. 5 and 6). A cortical depression may be formed by those tumours which are parosteal.

Subsynovial lipomas are less common, arising from the layer of fat which lies external to the joints. Lipoma arborescens, a term coined by Muller (quoted by Bland-Sutton 1906) and said to refer to a true lipoma, has in reality no connection and is associated with chronic and tuberculous arthritis.

It is in relation to the above types of tumour that radiology may prove of value in reaching a correct diagnosis. The basis of soft-tissue radiography depends on the photo-absorption coefficient of the soft tissue concerned. Air has a coefficient of 0, which in relation to that of soft tissue of the body is extremely low. Next to air comes fat. The radiological appearance of an intermuscular lipoma is that of a sharply demarcated semitranslucent lobulated tumour. The lobulated appearance is caused by the fibrous septa. Other tumours with a relatively large content of fat—e.g., dermoid cyst—may produce a similar picture.

Visceral lipomas, although rare, are sufficiently well known to require no introduction. They occur in the gastro-intestinal, respiratory, and genito-urinary tracts, but the first is by far the commonest site. Palazzo (1949) collected 36 cases of lipoma in the gastro-intestinal tract from the files of the Massachusetts General Hospital since 1900. These, as in other series, showed the general trend of increased frequency as the gut is descended: stomach 6, small intestine 16, colon 20. They may be classified as submucous and subserous, with a strong preponderance of the former, both occurring as either sessile or pedunculated tumours. Many intestinal lipomas are symptomless, especially subserous ones, but the 4 cases in the present series will serve well to illustrate the main ways in which they present.

Case 1.—A man, aged 64, who had always enjoyed good health, passed a little bright-red blood per rectum, and a week later some more blood with a mass of fatty tissue enclosed in a capsule.

The spontaneous passage of a submucous lipoma has not often been reported, but its cause is not difficult to understand. Dewis (quoted by Rankin 1926), in a series of 44 cases, included 9 of spontaneous expulsion. As ubserous lipoma may be freed into the peritoneal cavity.

Case 2.—A man, aged 53, was operated on because of a filling defect in the sigmoid colon discovered by radiography after a barium enema during investigation for abdominal pain. The bowel was resected, and the operation specimen contained a lipoma.

The problem of distinguishing a benign from a malignant tumour of the colon at laparotomy or on radiology has been commented on many times. Resection is often the wisest course; but, if accurate diagnosis is possible, simple excision of the lipoma is permissible.

Case 3.—A submucous lipoma was found during an operation for establishing a colostomy in a woman aged 60. It had caused no symptoms.

Case 4.—A woman, aged 49, complained of colicky abdominal pain in the right iliac fossa for two years. At operation the terminal ileum was found to be intussuscepting through the ileocæcal valve, but true intussusception was prevented by a submucous lipoma.

The interior of the thorax is an uncommon site for a lipoma, only about 50 cases having been reported. In this site lipomas give rise to few symptoms apart from those due to pressure on neighbouring structures. They arise from the extrapleural fat either in the mediastinum or subpleurally. Heuer and Andrus (1932), in a comprehensive report on this type, suggested classification into three groups on an anatomical basis: (1) hourglass tumours situated partly intrathoracically and partly subcutaneously; (2) intrathoracic but presenting in the neck; and (3) entirely intrathoracic. The peculiar distribution of the first group has led to the suggestion that they are congenital. Kittle et al. (1950) have described an intrathoracic lipoma of unusual type and histologically resembling glandular adipose tissue.

In the abdomen the retroperitoneal tissues are well known as a site for the formation of lipoma, interest lying in the size and extent to which they may grow as well as the difficulty in diagnosis and the possibility of sarcomatous change. Histologically they are tumours containing a variable mixture of fat and fibrous tissues, and myxomatous changes probably foreshadow not uncommon sarcomatous degeneration and recurrence after excision.

Ockuly and Douglass (1937), who also reviewed this type, record one in an infant only 15 days old. These authors consider that 35% of retroperitoneal lipomas are perirenal in origin, and bilateral examples are not unknown. Perirenal lipomas seem to be an anatomical variant of the retroperitoneal group arising from the renal capsule or the perirenal fat. They surround the kidney and occasionally compress its blood-supply to the point of atrophy. Retroperitoneal lipomas often have an intimate relation to important structures on the posterior abdominal wall and extend forwards into the mesentery of the small intestine. They may rarely occur primarily in this latter situation, as described by S lman and Bender (1948); who discussed the preoperative diagnosis by radiography.

The symptoms are usually those of pressure and mild gastro-intestinal disturbance, but removal by operation is warranted since without it the growth of these tumours leads slowly to death.

The origin of lipomas in the broad ligament, normally free from adipose tissue, has been ascribed to metaplasia of connective tissue or to extension from the retroperitoneal tissues. From the previous discussion on the origin of adipose tissue the former may be discarded. An alternative view, similar to that for some neural lipomas, is the presence of undifferentiated perivascular cells with fat-forming potentialities. This is an uncommon site; 19 cases were collected from the literature and 1 added by Lang and Bland (1940). They were bilateral in a fifth of the reported cases and likely to cause difficulty in diagnosis.

Intracranial or intraspinal masses of adipose tissue are relatively rare and may be separated into several different groups. Undoubtedly they do not all represent tumour formations in the same way as a lipoma of the subcutaneous tissues. An example of this is the collection of adipose tissue found in the lumbosacral region, continuous with the subcutaneous tissues of the gluteal region and penetrating the dura through a bony defect. They may or may not be associated with a meningocele and represent a congenital error in development and closure of the neural tube with overabundant growth of adipose tissue and its inclusion.

Extradural lipomas occurring later in life are not congenital. They have no characteristic segmental distribution and may be associated with obesity or with multiple lipomas. They arise from the extradural fat, a constant layer with a greater vascularity than the subcutaneous tissues. This increase in vessels has its counterpart in many lipomas in this situation which histologically appear as hæmangiolipomas. Other histological variants may also be found.

Intradural lipomas have always been of great interest because of their occurrence in a situation normally regarded as being free from fat. Ehni and Love (1945) collected 2 cases in a comprehensive review of spinal lipomas, and List et al. (1946) collected 30 cases affecting the corpus callosum from about 100 published cases of lipoma of the brain. This latter site is one of the commonest for intracranial lipomas, often being associated with local agenesis of the corpus callosum. A good account of the theories of origin is to be found in the above two papers. The site of origin of intradural lipomas requires consideration. Most if not all are extramedullary. According to Ehni and Love all, with one possible exception, lay in this position. The superficial resemblance to an intramedullary tumour may, however, be striking. A further subdivision, suggested by Cornil and Mosinger (1934) and discussed by Ehni and Love, is the rare tumour associated with nerve-roots and the cauda equina.

In conclusion no discussion on lipomas or their classification would be complete without reference to the wider concept of natural phenomena and pathological disturbances of adipose tissue—conditions which are not widely separated from lipomas or each other.

The naturally occurring phenomena are steatopygy and the sucking-pad of infants. Steatopygy, which has been discussed at length by Shattock (1909), is seen most notably as the prominent buttocks of the Bushmen and the Hottentots—prominent masses of unencapsulated fat. The sucking-pad, or corpus adiposum buccæ, lying isolated in the cheek has been regarded by some as a congenital lipoma. Its function is stated to be that of preventing the cheeks from falling inwards. Like lipomas it remains isolated from the body processes during wasting and becomes prominent in the marasmic infant. Lipomas of the sucking-pad have been reported, and Cameron (1921) collected 15 cases from the literature and added 1 of his own.

Much more has been written about the many types of acquired disturbance of less definite neoplastic nature. Dercum (1892) described adiposis dolorosa, with which his name is associated: painful masses of fat associated with a tendency to obesity, closely related to generalised obesity and to symmetrical diffuse lipomatosis. This latter condition is best known in the form of Madelung's (1888) neck, and although unencapsulated as a whole, it may contain masses of fat closely resembling lipomas in its midst.

Fig. 7 shows a man, aged 46, who four years previously had had removed from his abdominal wall a lipoma which had been growing for some time. Shortly afterwards he noticed a swelling on the right side of his neck; this was followed by another swelling on the left side. These swellings slowly increased until the condition illustrated in fig. 7 was reached. The tumours were removed in four stages.

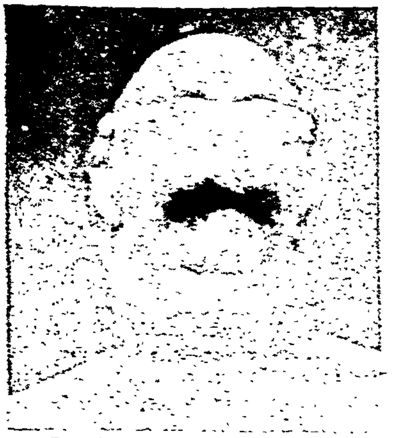

Fig. 7—Diffuse lipoma of neck in a man aged 46.

Recurrence is not usual in this condition except sometimes round the periphery. This condition is not confined to the neck but may also involve the axillæ and upper extremities. Unilateral or asymmetrical lipomatosis of a limb may also occur, as depicted by Adair et al. (1932), associated with hypertrophy of neighbouring tissues such as bone, a feature advanced in support of their view of the relationship of lipoma and nerves on an analogy with neurofibromatosis.

Lyon (1910) studied these conditions comprehensively, and not unnaturally suggested a basic common feature for the whole group. Ewing (1940) thought that the relation of lipoma to other forms of fat hypertrophy may be similar to that of fibroma to fibromatosis. Glandular disturbances, particularly those of the pituitary, thyroid, and genital glands, have often been blamed, and it is well known that the injection of insulin for diabetes may have a profound but diverse effect on the local subcutaneous tissues, producing either atrophy or hypertrophy, a situation reminiscent of that as yet unsolved disease progressive lipodystrophy.

GENERAL ANÆSTHESIA FOR TONSILLECTOMY BY DISSECTION IN CHILDREN*

A TECHNIQUE BASED ON INTRAVENOUS THIOPENTONE

JOHN BULLOUGH

M.B. Lond., D.A.

CONSULTANT ANÆSTHETIST, DARTFORD GROUP OF HOSPITALS, KENT; LATE VISITING ANÆSTHETIST, ORMSKIRK GENERAL HOSPITAL

UNNECESSARY suffering is still being meted out unthinkingly to thousands of children who have their tonsils and adenoids removed. It seems to be assumed that under the age of about 10 a child has no feelings, or none that are important compared with those of adults. Actually, of course, the reverse is true, children being more sensitive and having long memories for emotional experiences.

I believe that today, apart from the casualty department, the crudest and most distasteful forms of induction of anæsthesia are used at the tonsillectomy session. Administration of the anæsthetic is usually delegated to a junior because the seniors consider their own skill to be better used in conjunction with major surgery. My purpose here is to plead for a higher standard in the administration of anæsthetics for tonsillectomy, and more care and respect for these patients.

REQUIREMENTS

The requirements are a quick smooth induction, as pleasant as possible for all concerned: relaxation of the jaw muscles at the beginning of the operation for insertion of a gag; suppression of the pharyngeal and laryngeal reflexes during the operation; and a rapid return of these reflexes at the end of the operation. Recovery again should be as pleasant as possible for all concerned.

---

* Based on a paper read to the Liverpool Society of Anæsthetists on May 23, 1952.

Now let us consider the agents and techniques in present use, and see how they meet these requirements.

PREMEDICATION

The use of atropine is advisable in all cases, but there are two opposing schools of thought on the use of hypnotic or narcotic drugs. Some hold that a child should be sound asleep before the induction of anæsthesia and have no recollection of the event. Others think this unnecessary in most cases; that, if the child is properly looked after by the nurses, it does not matter if he is awake; and that all hypnotics have disadvantages which outweigh their advantages.

Hypnotics.—The hypnotics in general use for these children are pentobarbitone ('Nembutal') and quinalbarbitone ('Seconal'). Both are usually given by mouth because rectal administration has further disadvantages. There may be difficulty in persuading the child to take the drug, in whatever form it is offered. Moreover, absorption of the drug from the stomach is notoriously unreliable in children. Although induction of anæsthesia may be facilitated, the production of the required depth of anæsthesia may be delayed by respiratory depression, and the return of reflexes at the end of the operation may be delayed. There is occasionally extreme restlessness in the immediate postoperative period, during which the child is difficult to control, makes a great deal of noise, and upsets all the other children, some of whom may be waiting to go to the theatre. This can be remedied by the injection of an analgesic such as 'Nepenthe,' but involves further nursing care.

Narcotics.—Some children may be frightened of coming into hospital for an operation. As the time approaches for his turn to go to the theatre, the child may become terrified. He is then very difficult to anæsthetise by any inhalational method, and induction becomes a very crude procedure because it has to be forced on the unwilling child. It is not always possible to tell in advance which child will react in this way. The psychological effect on such a child cannot be other than harmful, and the child's future relationship with doctors will hardly be improved.

Thiopentone has been used since 1941 as a basal anæsthetic (narcotic) given rectally in a dosage of 15–20 mg. per lb. body-weight. In this dosage its action starts rapidly, the child falling into a deep sleep in about ten minutes and remaining thus for an hour or so. During this time the jaw muscles are well relaxed, the jaw may need supporting, and the child requires close supervision. Dosage and timing must be accurately assessed. This technique is not suitable for routine tonsillectomy sessions, although it is very valuable on occasion.

INDUCTION OF ANÆSTHESIA

Ethyl chloride on an open mask has a potent smell, even if disguised by eau-de-cologne, and many children dislike both it and the mask. If a child is asleep after having been given a hypnotic drug he is likely to be wakened by the vapour of ethyl chloride, when he may be more difficult to control than a child who has received no hypnotic. Ethyl chloride has toxic properties, but fatalities appear to be rare; the jaw muscles are not always relaxed; vomiting is common on recovery.

Vinyl ether ('Vinesthene'), although not possessing the toxic properties of ethyl chloride, has an unpleasant smell, and the difficulty of persuading the child to inhale the vapour arises again. If it is given on an open mask, the cost is high. If it is given in a closed inhaler, the child suffers the experience of having a mask firmly applied to his face while conscious. Both ethyl chloride and vinyl ether are better avoided in coöperative children of this age, or children who are already asleep, though they can be very useful for suppressing noisy uncoöperative children.

Nitrous oxide has the advantage that, to all intents and purposes, it is odourless and lacks pungency. If a child is asleep, the gas may be blown over his face until he is unconscious, with very little likelihood of waking him. It is probably the most useful drug for induction in children who are already asleep. Its action, however, is very weak, and the oxygen intake must necessarily be somewhat restricted during induction. In an uncoöperative child induction may be prolonged and will often be followed by a short period of anoxia.

MAINTENANCE OF ANÆSTHESIA

Anæsthesia during tonsillectomy is usually maintained with diethyl ether, often supplemented by trichlorethylene ('Trilene'). The use of trilene during the first half of the anæsthesia seems to produce moderate post-operative analgesia and to decrease the incidence of post-operative restlessness after tonsillectomy. This matter is being investigated. Trilene is turned off half-way through the operation because it delays the return of the laryngeal reflex for a few minutes.

POSSIBLE OBJECTIONS TO INTRAVENOUS THIOPENTONE

Veins.—The difficulty of finding a suitable vein may be fairly common in children under the age of 5; but even at this age a surprisingly large number of children have accessible veins—probably more than half of them.

Needles.—Children are said to dislike needles. This difficulty can largely be overcome by starting each session with two brand-new needles size 16–18. Only about 10% of children have any appreciable objection to the use of these needles, if properly handled; and if the alternative is a face-mask many of them will prefer the needle.

Sensitivity to Thiopentone.—A child's respiratory centre has been said to be very sensitive to thiopentone. I have found that, provided thiopentone is given at a proportionately slower rate and in proportionately smaller dosage, the effect is very little different from that in the adult. The smaller blood volume in a child should be borne in mind, with consequently less dilution of thiopentone on its passage to the brain. I am not alone in believing that thiopentone can safely be given to children; for instance, Stephen (1952), in the U.S.A., writes:

> "There is no anatomic, physiologic, or biochemical contra-indication to the employment of barbiturates or curare in children, provided that the anaesthetist is sufficiently trained to take the same precautions as he would in an adult."

Recovery of Reflexes.—It might be thought that there is a danger of delay in recovery of reflexes at the end of the operation, but this is not so (see below).

TECHNIQUE WITH NITROUS OXIDE, TRILENE, AND ETHER

Before describing the technique when thiopentone is used, I will describe the technique when induction is by nitrous oxide, followed by trilene and ether. The method of administration of the inhalation anæsthetic following a thiopentone induction differs only slightly from the one now to be described.

Premedication in every case is an injection of atropine gr. $^1/_{100}$.

Induction takes place on the operating-table, because there is no anæsthetic room. The child is carefully laid on the table with as little disturbance as possible. A high flow of nitrous oxide is blown over the child's face from a Boyle's apparatus, using the by-pass. After about fifteen breaths, or one minute, the child loses consciousness; the face-mask is then gently placed over the face, and the inhaled mixture is 9 litres (90%) of nitrous oxide and 1 litre (10%) of oxygen. Trilene is immediately added in a concentration of about $^1/_4$% (lever at top of second division of Boyle's bottle). Ether is next cautiously added, with an attempt to prevent any coughing or straining, because this increases operative bleeding. When the child is coming under the influence of the ether, the oxygen is increased to 25% (nitrous oxide 6 litres, oxygen 2 litres). After an average of four minutes from the start of induction the child is settled in upper plane 2, the gases now passing over the surface of the ether (lever full on)—a concentration of about 25%. The child's head is raised to allow towels to be placed, no respiratory obstruction being allowed. The surgeon inserts a Boyle-Davies gag, and the same gases are insufflated through the gag. Only three or four breaths of air are allowed during insertion of the gag.

Discontinuance.—When the first tonsil has been removed, the trilene is turned off. When the second tonsil has been removed, the ether is turned off. When the adenoids have been curetted, the nitrous oxide is turned off. Oxygen alone is now being given, while the pharynx is cleared by suction. After a minute or two the bleeding has stopped and the pharyngeal reflex is active.

Postoperatively the child is placed in the semi-prone position on a trolley, with an airway in place if tolerated, and returns to bed. After half an hour or so he sits up in bed to minimise postoperative oozing from the tonsillar bed.

Carbon Dioxide.—A flow of 100 ml. per minute of carbon dioxide may very usefully be added to the inhaled mixture throughout—concentration 1–2%. This hastens induction, prevents hypocapnia during insufflation, and hastens recovery. Bleeding during the operation, however, may be increased.

TECHNIQUE WITH THIOPENTONE

I first thought of using intravenous thiopentone as a combined agent for basal anæsthesia and induction of anæsthesia in these children about two years ago. I had long been using small doses of thiopentone as a prelude to nasal gas-oxygen in adults for dental extraction, after the manner described by Macintosh and Bannister (1950), and it occurred to me that this technique could be applied to children for tonsillectomy, nitrous oxide being supplemented by trilene and ether. I have found no published account of similar techniques, but they have doubtless been used.

Induction.—The dosage of thiopentone is 25 mg.—i.e., 0·5 ml. of the usual 5% solution—per year of age. This is injected at the rate of 1 ml. every five seconds until the child is unconscious, or until the whole dose has been given, usually the latter. If it is injected more quickly, apnœa is likely to follow for fifteen to forty-five seconds; if more slowly, the child may not lose consciousness. No apology is made for basing the dose on age, or for using a 5% solution, because the results are satisfactory. A $2^1/_2$% solution has to be injected at twice the rate, and its effects are almost identical with those of a 5% solution.

When the child is unconscious, a face-mask is immediately placed over his face, and nitrous oxide (85–90% with oxygen), followed by trilene and later by ether, is administered very much the same as already described. Here is the time-table in a typical case, a boy aged 6 years:

Min.	*Sec.*	
0	0	Venepuncture.
0	15	Thiopentone injected.
0	30	Nitrous oxide 6 litres per min., oxygen 1 litre per min., trilene $^1/_4$ on.
1	0	Ether added, concentration slowly increased.
2	0	Ether full on, over surface. Oxygen increased to 2 litres per min.
4	0	Towels applied; gag inserted; gases insufflated through gag.
6	0	First tonsil removed; trilene turned off.
8	0	Second tonsil removed; ether turned off.
9	0	Adenoids curetted; nitrous oxide turned off.
10	0	Pharyngeal toilet.
11	0	Pharyngeal reflex returns; child placed on trolley in semi-prone position.

This dosage of thiopentone produces one or two minutes' anæsthesia, followed by about ten minutes' basal narcosis and rapid recovery. There is no delay in the return of reflexes. In fact, in this series, the average time from induction of anæsthesia to the return of the pharyngeal reflex was slightly shorter than when no thiopentone was given. The average time for those receiving thiopentone was 11·1 minutes; for those receiving nitrous oxide induction it was 11·4 minutes. This is presumably because the children receiving thiopentone required less volatile anæsthetic. These figures are given only to show that recovery time was not prolonged.

The explanation of the rapid recovery emerges if we compare the dosage of barbiturate given in this technique with that given by other methods. A child aged 6 years and weighing 3 stone would receive an oral dose of gr. 2 of nembutal, gr. $2^1/_4$ of seconal, or 0·8 g. of rectal thiopentone as premedication. By the present technique he receives only 0·15 g. of thiopentone, which dosage is equal to that of the longer-acting barbiturates, or a fifth of the dose of rectal thiopentone. The action of the dose might thus be expected to be about a fifth as long, and this appears to be so in practice, because the action of thiopentone has largely worn off by the end of the operation.

RESULTS

Of 172 children operated on by one surgeon, Mr. E. Lewis Reid, at one hospital in twelve months, thiopentone was used in 98; thialbarbitone ('Kemithal') was used in 3 for comparison; and 71 received nitrous oxide induction as controls. Some of the latter had no accessible veins; 3 of them had declined injection; in 7 the injection had failed because the needle became dislodged, usually through the child moving his arm (a point to be guarded against). If the needle became dislodged, a second venepuncture was not attempted, lest the child's confidence be lost. The children were otherwise unselected. No appreciable difference was found between thialbarbitone and thiopentone, the dosage being doubled. The average quantity of ether used for each case was 1 oz. The average age of the children was 7·9 years; the commonest age was 6 years, 31 children being of this age. There were 102 boys and 70 girls. 6 children were crying softly when they came to the theatre; 2 of these were coöperative enough to receive thiopentone. One child was very upset and was induced with nitrous oxide in the ward. There was no case of failed venepuncture in a child over the age of 5, when visible or palpable veins were present. The average turnover was 1 patient every twelve minutes. There was 1 case of prolonged postoperative oozing in the series, unrelated to anæsthesia; this patient did not require ligation of the bleeding vessel.

CONCLUSIONS

The advantages of the technique are as follows:

(1) It is pleasant for the patient. The child's only recollection of his visit to the theatre is the prick of a needle. In the vast majority of cases children, like adults, appreciate this, and there seems to be no reason for withholding the technique. The children have been heard talking enthusiastically at outpatient clinics about "the needle." Many of the children learn from other children, or from the nurses, what is in store for them, and, perhaps for this reason, very few of them are particularly nervous about coming to the theatre awake.

(2) It is pleasant for the anæsthetist.

(3) It is pleasant for the surgeon; induction is quickly achieved, with little straining or coughing, and operative bleeding is slight.

(4) It is pleasant for the nurses. There has been no comparable restlessness in the postoperative period, such as not uncommonly occurs after the use of the other barbiturates. The explanation of this is not known.

reflexes during the operation; and a rapid return of these reflexes at the end of the operation. Recovery again should be as pleasant as possible for all concerned.

Now let us consider the agents and techniques in present use, and see how they meet these requirements.

PREMEDICATION

The use of atropine is advisable in all cases, but there are two opposing schools of thought on the use of hypnotic or narcotic drugs. Some hold that a child should be sound asleep before the induction of anæsthesia and have no recollection of the event. Others think this unnecessary in most cases; that, if the child is properly looked after by the nurses, it does not matter if he is awake; and that all hypnotics have disadvantages which outweigh their advantages.

Hypnotics.—The hypnotics in general use for these children are pentobarbitone ('Nembutal') and quinalbarbitone ('Seconal'). Both are usually given by mouth because rectal administration has further disadvantages. There may be difficulty in persuading the child to take the drug, in whatever form it is offered. Moreover, absorption of the drug from the stomach is notoriously unreliable in children. Although induction of anæsthesia may be facilitated, the production of the required depth of anæsthesia may be delayed by respiratory depression, and the return of reflexes at the end of the operation may be delayed. There is occasionally extreme restlessness in the immediate postoperative period, during which the child is difficult to control, makes a great deal of noise, and upsets all the other children, some of whom may be waiting to go to the theatre. This can be remedied by the injection of an analgesic such as 'Nepenthe,' but involves further nursing care.

Narcotics.—Some children may be frightened of coming into hospital for an operation. As the time approaches for his turn to go to the theatre, the child may become terrified. He is then very difficult to anæsthetise by any inhalational method, and induction becomes a very crude procedure because it has to be forced on the unwilling child. It is not always possible to tell in advance which child will react in this way. The psychological effect on such a child cannot be other than harmful, and the child's future relationship with doctors will hardly be improved.

Thiopentone has been used since 1941 as a basal anæsthetic (narcotic) given rectally in a dosage of 15–20 mg. per lb. body-weight. In this dosage its action starts rapidly, the child falling into a deep sleep in about ten minutes and remaining thus for an hour or so. During this time the jaw muscles are well relaxed, the jaw may need supporting, and the child requires close supervision. Dosage and timing must be accurately assessed. This technique is not suitable for routine tonsillectomy sessions, although it is very valuable on occasion.

INDUCTION OF ANÆSTHESIA

Ethyl chloride on an open mask has a potent smell, even if disguised by eau-de-cologne, and many children dislike both it and the mask. If a child is asleep after having been given a hypnotic drug he is likely to be wakened by the vapour of ethyl chloride, when he may be more difficult to control than a child who has received no hypnotic. Ethyl chloride has toxic properties, but fatalities appear to be rare; the jaw muscles are not aways relaxed; vomiting is common on recovery.

Vinyl ether ('Vinesthene'), although not possessing the toxic properties of ethyl chloride, has an unpleasant smell, and the difficulty of persuading the child to inhale the vapour arises again. If it is given on an open mask, the cost is high. If it is given in a closed inhaler, the child suffers the experience of having a mask firmly applied to his face while conscious. Both ethyl chloride and vinyl ether are better avoided in coöperative children of this age, or children who are already asleep, though they can be very useful for suppressing noisy uncoöperative children.

Nitrous oxide has the advantage that, to all intents and purposes, it is odourless and lacks pungency. If a child is asleep, the gas may be blown over his face until he is unconscious, with very little likelihood of waking him. It is probably the most useful drug for induction in children who are already asleep. Its action, however, is very weak, and the oxygen intake must necessarily be somewhat restricted during induction. In an uncoöperative child induction may be prolonged and will often be followed by a short period of anoxia.

MAINTENANCE OF ANÆSTHESIA

Anæsthesia during tonsillectomy is usually maintained with diethyl ether, often supplemented by trichlorethylene ('Trilene'). The use of trilene during the first half of the anæsthesia seems to produce moderate postoperative analgesia and to decrease the incidence of postoperative restlessness after tonsillectomy. This matter is being investigated. Trilene is turned off half-way through the operation because it delays the return of the laryngeal reflex for a few minutes.

POSSIBLE OBJECTIONS TO INTRAVENOUS THIOPENTONE

Veins.—The difficulty of finding a suitable vein may be fairly common in children under the age of 5; but even at this age a surprisingly large number of children have accessible veins—probably more than half of them.

Needles.—Children are said to dislike needles. This difficulty can largely be overcome by starting each session with two brand-new needles size 16–18. Only about 10% of children have any appreciable objection to the use of these needles, if properly handled; and if the alternative is a face-mask many of them will prefer the needle.

Sensitivity to Thiopentone.—A child's respiratory centre has been said to be very sensitive to thiopentone. I have found that, provided thiopentone is given at a proportionately slower rate and in proportionately smaller dosage, the effect is very little different from that in the adult. The smaller blood volume in a child should be borne in mind, with consequently less dilution of thiopentone on its passage to the brain. I am not alone in believing that thiopentone can safely be given to children; for instance, Stephen (1952), in the U.S.A., writes:

> "There is no anatomic, physiologic, or biochemical contra-indication to the employment of barbiturates or curare in children, provided that the anaesthetist is sufficiently trained to take the same precautions as he would in an adult."

Recovery of Reflexes.—It might be thought that there is a danger of delay in recovery of reflexes at the end of the operation, but this is not so (see below).

TECHNIQUE WITH NITROUS OXIDE, TRILENE, AND ETHER

Before describing the technique when thiopentone is used, I will describe the technique when induction is by nitrous oxide, followed by trilene and ether. The method of administration of the inhalation anæsthetic following a thiopentone induction differs only slightly from the one now to be described.

Premedication in every case is an injection of atropine gr. $^1/_{100}$.

Induction takes place on the operating-table, because there is no anæsthetic room. The child is carefully laid on the table with as little disturbance as possible. A high flow of nitrous oxide is blown over the child's face from a Boyle's apparatus, using the by-pass. After about fifteen breaths, or one minute, the child loses consciousness; the face-mask is then gently placed over the face, and the inhaled mixture is 9 litres (90%) of nitrous oxide and 1 litre (10%) of oxygen. Trilene is immediately added in a concentration of about $^1/_4$% (lever at top of second division of Boyle's bottle). *Ether is next cau-*

tiously added, with an attempt to prevent any coughing or straining, because this increases operative bleeding. When the child is coming under the influence of the ether, the oxygen is increased to 25% (nitrous oxide 6 litres, oxygen 2 litres). After an average of four minutes from the start of induction the child is settled in upper plane 2, the gases now passing over the surface of the ether (lever full on)—a concentration of about 25%. The child's head is raised to allow towels to be placed, no respiratory obstruction being allowed. The surgeon inserts a Boyle-Davies gag, and the same gases are insufflated through the gag. Only three or four breaths of air are allowed during insertion of the gag.

Discontinuance.—When the first tonsil has been removed, the trilene is turned off. When the second tonsil has been removed, the ether is turned off. When the adenoids have been curetted, the nitrous oxide is turned off. Oxygen alone is now being given, while the pharynx is cleared by suction. After a minute or two the bleeding has stopped and the pharyngeal reflex is active.

Postoperatively the child is placed in the semi-prone position on a trolley, with an airway in place if tolerated, and returns to bed. After half an hour or so he sits up in bed to minimise postoperative oozing from the tonsillar bed.

Carbon Dioxide.—A flow of 100 ml. per minute of carbon dioxide may very usefully be added to the inhaled mixture throughout—concentration 1–2%. This hastens induction, prevents hypocapnia during insufflation, and hastens recovery. Bleeding during the operation, however, may be increased.

TECHNIQUE WITH THIOPENTONE

I first thought of using intravenous thiopentone as a combined agent for basal anæsthesia and induction of anæsthesia in these children about two years ago. I had long been using small doses of thiopentone as a prelude to nasal gas-oxygen in adults for dental extraction, after the manner described by Macintosh and Bannister (1950), and it occurred to me that this technique could be applied to children for tonsillectomy, nitrous oxide being supplemented by trilene and ether. I have found no published account of similar techniques, but they have doubtless been used.

Induction.—The dosage of thiopentone is 25 mg.—i.e., 0·5 ml. of the usual 5% solution—per year of age. This is injected at the rate of 1 ml. every five seconds until the child is unconscious, or until the whole dose has been given, usually the latter. If it is injected more quickly, apnœa is likely to follow for fifteen to forty-five seconds; if more slowly, the child may not lose consciousness. No apology is made for basing the dose on age, or for using a 5% solution, because the results are satisfactory. A $2^{1}/_{2}$% solution has to be injected at twice the rate, and its effects are almost identical with those of a 5% solution.

When the child is unconscious, a face-mask is immediately placed over his face, and nitrous oxide (85–90% with oxygen), followed by trilene and later by ether, is administered very much the same as already described. Here is the time-table in a typical case, a boy aged 6 years:

Min.	*Sec.*	
0	0	Venepuncture.
0	15	Thiopentone injected.
0	30	Nitrous oxide 6 litres per min., oxygen 1 litre per min., trilene $^{1}/_{4}$ on.
1	0	Ether added, concentration slowly increased.
2	0	Ether full on, over surface. Oxygen increased to 2 litres per min.
4	0	Towels applied; gag inserted; gases insufflated through gag.
6	0	First tonsil removed; trilene turned off.
8	0	Second tonsil removed; ether turned off.
9	0	Adenoids curetted; nitrous oxide turned off.
10	0	Pharyngeal toilet.
11	0	Pharyngeal reflex returns; child placed on trolley in semi-prone position.

This dosage of thiopentone produces one or two minutes' anæsthesia, followed by about ten minutes' basal narcosis and rapid recovery. There is no delay in the return of reflexes. In fact, in this series, the average time from induction of anæsthesia to the return of the pharyngeal reflex was slightly shorter than when no thiopentone was given. The average time for those receiving thiopentone was 11·1 minutes; for those receiving nitrous oxide induction it was 11·4 minutes. This is presumably because the children receiving thiopentone required less volatile anæsthetic. These figures are given only to show that recovery time was not prolonged.

The explanation of the rapid recovery emerges if we compare the dosage of barbiturate given in this technique with that given by other methods. A child aged 6 years and weighing 3 stone would receive an oral dose of gr. 2 of nembutal, gr. $2^{1}/_{4}$ of seconal, or 0·8 g. of rectal thiopentone as premedication. By the present technique he receives only 0·15 g. of thiopentone, which dosage is equal to that of the longer-acting barbiturates, or a fifth of the dose of rectal thiopentone. The action of the dose might thus be expected to be about a fifth as long, and this appears to be so in practice, because the action of thiopentone has largely worn off by the end of the operation.

RESULTS

Of 172 children operated on by one surgeon, Mr. E. Lewis Reid, at one hospital in twelve months, thiopentone was used in 98; thialbarbitone ('Kemithal') was used in 3 for comparison; and 71 received nitrous oxide induction as controls. Some of the latter had no accessible veins; 3 of them had declined injection; in 7 the injection had failed because the needle became dislodged, usually through the child moving his arm (a point to be guarded against). If the needle became dislodged, a second venepuncture was not attempted, lest the child's confidence be lost. The children were otherwise unselected. No appreciable difference was found between thialbarbitone and thiopentone, the dosage being doubled. The average quantity of ether used for each case was 1 oz. The average age of the children was 7·9 years; the commonest age was 6 years, 31 children being of this age. There were 102 boys and 70 girls. 6 children were crying softly when they came to the theatre; 2 of these were coöperative enough to receive thiopentone. One child was very upset and was induced with nitrous oxide in the ward. There was no case of failed venepuncture in a child over the age of 5, when visible or palpable veins were present. The average turnover was 1 patient every twelve minutes. There was 1 case of prolonged postoperative oozing in the series, unrelated to anæsthesia; this patient did not require ligation of the bleeding vessel.

CONCLUSIONS

The advantages of the technique are as follows:

(1) It is pleasant for the patient. The child's only recollection of his visit to the theatre is the prick of a needle. In the vast majority of cases children, like adults, appreciate this, and there seems to be no reason for withholding the technique. The children have been heard talking enthusiastically at outpatient clinics about "the needle." Many of the children learn from other children, or from the nurses, what is in store for them, and, perhaps for this reason, very few of them are particularly nervous about coming to the theatre awake.

(2) It is pleasant for the anæsthetist.

(3) It is pleasant for the surgeon; induction is quickly achieved, with little straining or coughing, and operative bleeding is slight.

(4) It is pleasant for the nurses. There has been no comparable restlessness in the postoperative period, such as not uncommonly occurs after the use of the other barbiturates. The explanation of this is not known.

Dr. Robert [illegible]

The disadvantages of the technique are few. There is a possibility of laryngospasm immediately after induction, or when ether vapour is given; this should be guarded against by keeping the airway absolutely clear throughout, and by adding ether cautiously. Trilene paves the way for ether very conveniently. Some skill is required for venepuncture. An apparatus capable of delivering oxygen under pressure must, of course, be to hand. The children are usually less active in the postoperative period than children who have received no hypnotic drug whatever, and require reasonable supervision. No analgesics were used in this series, but, if they were to be used, more supervision would be required.

This technique is offered to those anæsthetists with the skill and experience to carry it out, who do not for some reason wish to give a preoperative hypnotic but wish to prevent children from becoming frightened, and who desire a rapid recovery of reflexes and avoidance of postoperative restlessness and the necessity to administer a postoperative analgesic.

The surgeon with whom I developed this technique, a man of over twenty years' experience, and who has probably seen every available type of anæsthetic given for this operation, is of the opinion that it is the best, both from his and the children's point of view, that he has ever seen. We await the reaction of other surgeons and anæsthetists who care to give it a trial.

SUMMARY

A brief survey is made of the requirements for anæsthesia for tonsillectomy in children aged 4–12 years.

Premedication is briefly discussed, and the commoner techniques of induction of anæsthesia are criticised. Possible objections to the use of intravenous thiopentone for these children are considered.

A method of anæsthesia by nitrous oxide, trilene, and ether is described. The technique with thiopentone differs from this only at induction. A time-table of a typical case is given. The rapid recovery is explained.

Some figures from a series of 172 cases are given. The advantages and disadvantages are enumerated.

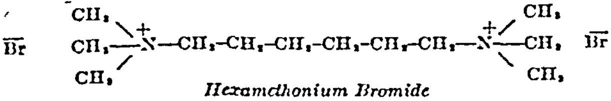
HYPOTENSIVE ACTIONS OF HEXAMETHONIUM BROMIDE AND SOME OF ITS HOMOLOGUES

THEIR USE IN HIGH BLOOD-PRESSURE

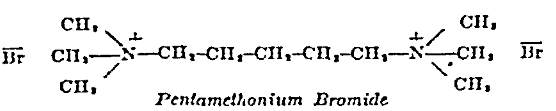
F. HORACE SMIRK
M.D. Manc., F.R.C.P., F.R.A.C.P.
PROFESSOR OF MEDICINE IN THE UNIVERSITY OF OTAGO, DUNEDIN, NEW ZEALAND

IN this paper the action of hexamethonium bromide (H.M.B.) is compared with those of two new ganglion-blocking agents, 'Ciba 9295' (N,N,N′, N′, 3-pentamethyl-N, N′-diethyl-3-aza-pentylene-(1,5)-diammonium-dibromide) and 'M. & B. 1863' (hexamethylene bisethyldimethylammonium bromide). The close chemical relation between these compounds is apparent from the structural formulæ:



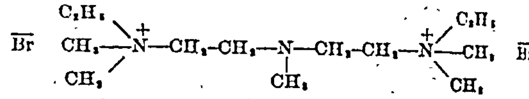
$\overline{\mathrm{Br}}\ (CH_3)_3\overset{+}{N}-CH_2-CH_2-CH_2-CH_2-CH_2-CH_2-\overset{+}{N}(CH_3)_3\ \overline{\mathrm{Br}}$

Hexamethonium Bromide



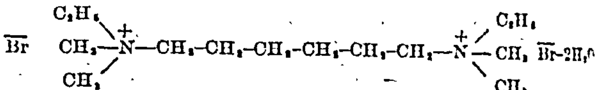
$\overline{\mathrm{Br}}\ (CH_3)_3\overset{+}{N}-CH_2-CH_2-CH_2-CH_2-CH_2-\overset{+}{N}(CH_3)_3\ \overline{\mathrm{Br}}$

Pentamethonium Bromide



$\overline{\mathrm{Br}}\ (C_2H_5)(CH_3)_2\overset{+}{N}-CH_2-CH_2-N(CH_3)-CH_2-CH_2-\overset{+}{N}(C_2H_5)(CH_3)_2\ \overline{\mathrm{Br}}$

Ciba 9295 (Pendiomide)



$\overline{\mathrm{Br}}\ (C_2H_5)(CH_3)_2\overset{+}{N}-CH_2-CH_2-CH_2-CH_2-CH_2-CH_2-\overset{+}{N}(C_2H_5)(CH_3)_2\ \overline{\mathrm{Br}}\cdot 2H_2O$

M. & B. 1863 (Gaplegin)

The ganglion-blocking action of pentamethonium and hexamethonium salts, leading among other effects to fall of blood-pressure, is mentioned by Paton and Zaimis (1948, 1949), Organe et al. (1949), Arnold and Rosenheim (1949), Arnold et al. (1949), Burt and Graham (1950), Kay and Smith (1950), Enderby (1950), Paton (1951), and Restall and Smirk (1952). The use of methonium compounds in the treatment of high blood-pressure has been described by Restall and Smirk (1950), Saville (1950), Turner (1950), Campbell and Robertson (1950), Smirk (1950), Locket et al. (1951), Freis (1951a and b), Smirk and Alstad (1951), Smirk (1951a and b), Mackey and Shaw (1951), Kilpatrick and Smirk (1952), Campbell et al. (1952), and Locket et al. (1952).

Observations on Ciba 9295 ('Pendiomide') by Bein and Meier (1950, 1951) and Bernsmeier et al. (1951) show that this substance behaves essentially like H.M.B. The pharmacology of M. & B. 1863 ('Gaplegin') has been described by Wien and Mason (1951), and clinical studies have been reported by Campbell et al. (1952) and Locket et al. (1952). Campbell et al. (1952) indicate that M. & B. 1863 is about twice as active as H.M.B. in lowering the blood-pressure.

The effects of H.M.B. injections have now been observed here in more than 300 hypertensive patients, and only 2 or 3 of these did not exhibit an appreciable fall of blood-pressure with adequate dosage, provided the observations were made with the patient *sitting* or standing, in which postures blood-pressure falls more. More than 170 patients have now been treated for from two to thirty-two months, with similar results to those reported earlier (Restall and Smirk 1950, Smirk and Alstad 1951). Effective and well-controlled treatment by subcutaneous (not intramuscular) injections produces good results in a much larger proportion of patients than receive benefit either from oral H.M.B. (Kilpatrick and Smirk 1952) or from oral administration of veratrum alkaloids (Smirk and Chapman 1952). The results reported here indicate that M. & B. 1863 is useful in some patients in whom the side-effects from H.M.B. are sufficient to keep the dose of H.M.B. below *the optimal* level for control of blood-pressure.

ADMINISTRATION

Subcutaneous Injection

Ciba 9295, M & B. 1863, and H.M.B. may be administered either orally or subcutaneously. Simple 5–10% aqueous solutions are non-irritant when injected; 0·5% chlorbutol is a suitable preservative.

Patients vary in the dosage of H.M.B. which they require to lower the blood-pressure (Smirk and Alstad 1951), and there is wide variation also in the hypotensive responses of different patients to a first dose of 15 mg. of Ciba 9295 or 7·5 mg. of M. & B. 1863. Thus, after initial subcutaneous injections of 15 mg. of Ciba 9295, the blood-pressure in the sitting posture fell by 60/36 mm. Hg in one patient and 14/20 mm. Hg in another. After 7·5 mg. of M. & B. 1863, given before the development of toleration, the blood-pressure in the sitting posture fell by 78/35 mm. Hg in a third patient and 28/12 mm Hg in a fourth.

Though sensitivity to the hypotensive action of these ganglion-blocking agents differs from patient to patient, in any given patient a high (or low) degree of sensitivity to one of the drugs is usually accompanied by a high (or low) sensitivity to the others. Suitable initial doses which (in the absence of developed tolerance) produce approximately equal falls of blood-pressure are 15 mg. of H.M.B., 17 mg. of Ciba 9295, and 7·5 mg. of M. & B. 1863. The relation between the effective doses of H.M.B. and M. & B. 1863 seems rather stable, and the ratio is preserved throughout the development of drug toleration (see below). With Ciba 9295 the relation seems less precise, and sometimes, with the development of full toleration, the effective dose of Ciba 9295 becomes considerably larger than the effective dose of H.M.B.

Oral Administration

Trials with various doses show that with Ciba 9295 and M. & B. 1863, as with H.M.B., the effective oral dose is 10 or more times as great as an equally hypotensive dose given subcutaneoulsy (see table). It is important to compare only tests made at about the same stage in the development of drug toleration.

The effective subcutaneous dose of Ciba 9295 before toleration is about 17/15 of the dose of H.M.B., and the effective oral dose is also rather greater than the oral dose of H.M.B. The effective subcutaneous dose of M. & B. 1863 is about half that of H.M.B., and the effective oral dose of M. & B. 1863 is about half that of H.M.B. (see table). Apparently there is no great difference between the three substances in the proportion of oral doses that is absorbed.

COMPARISON OF EFFECTS OF SUBCUTANEOUS AND ORAL ADMINISTRATION OF CIBA 9295 AND M. & B. 1863

Drug	Case no.	Subcutaneous			Oral		
		Dose (mg.)	Greatest fall in blood-pressure (mm. Hg)	Duration of effect (hr.)	Dose (mg.)	Greatest fall in blood-pressure (mm. Hg)	Duration of effect (hr.)
Ciba 9295	268	25	36/2	2½	750	14/15	Short and indefinite
	262	80	30/10	4	500	42/22	1
	Average	52·5	33/6	3¼	625	28/19	1
M. & B. 1863	262	25	70/32	3	375	40/6	5
	23	10	56/24	2	375	46/36	6
	229	38	84/50	5	250	30/4	4½
	137	50	104/36	5½	525	44/18	3
	110	7·5	112/52	5	325	30/4	1
	Average	26·1	85/39	4	370	38/14	4

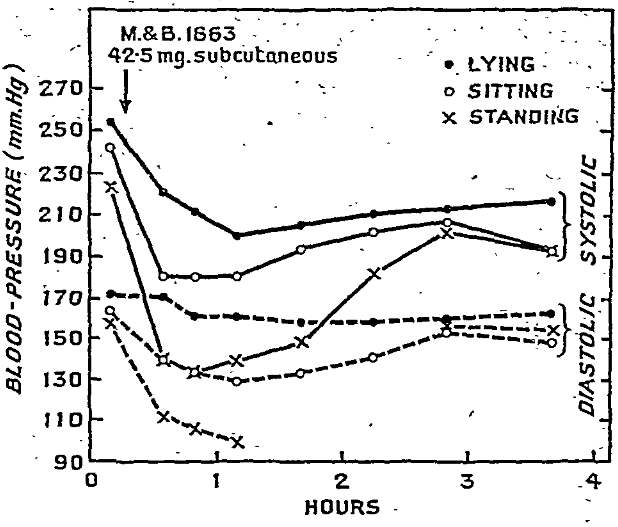


Fig. 1—Systolic and diastolic blood-pressures in lying, sitting, and standing postures after subcutaneous injection of 42·5 mg. of M. & B. 1863.

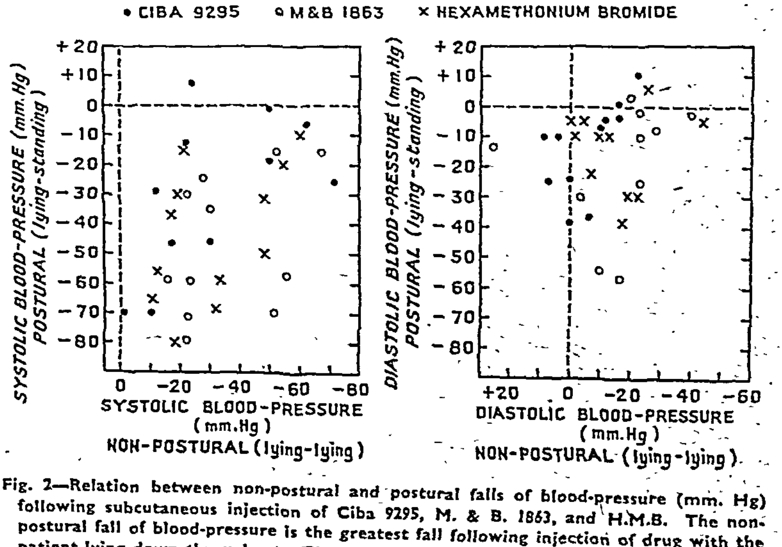

Fig. 2—Relation between non-postural and postural falls of blood-pressure (mm. Hg) following subcutaneous injection of Ciba 9295, M. & B. 1863, and H.M.B. The non-postural fall of blood-pressure is the greatest fall following injection of drug with the patient lying down throughout. The postural fall of blood-pressure is the difference between the blood-pressures in standing and lying postures, measured when the blood-pressure fall is greatest. It will be noted that in some tests the non-postural fall was associated with a small postural rise, or vice versa.

COURSE OF HYPOTENSIVE ACTION OF CIBA 9295, M. & B. 1863, AND H.M.B. AFTER SUBCUTANEOUS INJECTION

Fig. 1 shows the fall of blood-pressure after an injection of M. & B. 1863; and the fall is similar in the two other substances. After an effective subcutaneous dose the blood-pressure falls in ten to twenty minutes. The time taken after the injection to reach the lowest level of blood-pressure varies from twenty minutes to two hours. The duration of the hypotensive action is greater with larger doses but ordinarily is two to five hours (average about three hours). In these respects there is no consistent or important difference between the three substances, provided the doses given are adjusted to produce about equal decreases of blood-pressure at the trough of the fall.

The decrease in the systolic pressure is often about, or slightly more than, twice the fall in diastolic pressure. This relationship holds for the averages of the results with the three substances. Some of the results are set out in fig. 2. The blood-pressure fall produced by Ciba 9295 is less than that produced by an equivalent dose of H.M.B. A marked postural hypotension is present in the standing posture with both drugs, and there is no notable difference in the amount of postural hypotension relative to the extent of non-postural fall in blood-pressure. Non-postural falls in blood-pressure are measured by noting the difference between the blood-pressures, both taken in the lying posture, before and after giving the drug. The postural hypotension is studied by noting the difference between the blood-pressure in the standing and lying postures when, as the result of the drug action, the blood-pressure has reached its lowest level for the lying posture. It can be seen from fig. 2 that the postural element in the fall of blood-pressure differs from patient to patient, but in most instances the postural fall is greater than the non-postural fall. There is no difference between the three drugs in the importance of the postural effect relative to the non-postural effect on the blood-pressure.

The effects of M. & B. 1863 and Ciba 9295 on the pulse-rate are variable and similar to those already described for H.M.B. (Smirk and Alstad 1951, McMichael 1952). The additional fall in blood-pressure after meals, which is caused by H.M.B., is caused also by M. & B. 1863 or Ciba 9295 and is probably due to reduced ability, after the administration of methonium, to compensate for splanchnic dilatation. Although patients treated with methonium salts or with veratrum alkaloids vary in the extent to which they show blood-pressure falls after meals, the response of a given patient may be consistently of sufficient magnitude to determine postponement of a second injection until an hour after the meal. Ordinarily such postponement is unnecessary.

ACQUIRED TOLERANCE TO CIBA 9295, M. & B. 1863, AND HEXAMETHONIUM SALTS

It has been shown already that repeated administration of pentamethonium or hexamethonium bromide leads to toleration, noticeable sometimes even on the first day of administration, and with regular dosage toleration continues to increase for weeks or months, until ultimately the dose required becomes stable. The degree of toleration acquired varies from patient to patient, and the eventual dose needed to reproduce the initial response may be only 2 or 3 times the first dose, but ordinarily it is 6 or 12 times. Among patients whose reaction to the drug appears to have become stable some manage on subcutaneous H.M.B. 30–40 mg. thrice daily, and at the other extreme is a patient who receives 450 mg. thrice daily. Side-effects are no more pronounced in this last patient than in many of those on small doses. Side-effects on a good régime are comparatively slight in most patients. Fortunately the acquisition of toleration seems to become more complete to parasympathetic side-effects than to sympathetic effects. Dryness of the mouth and blurring of vision, though they seldom disappear, may become less prominent in time, even though equally effective falls of blood-pressure are maintained. Delay in emptying the bladder may be observed with early doses but tends to pass off as toleration develops.

The present observations show that toleration is also acquired rapidly on repeated administration of Ciba 9295 and M. & B. 1863. Where patients have been given doses (sometimes of Ciba 9295, sometimes of M. & B. 1863, and sometimes of H.M.B.) and have been observed for weeks or months, it is clear that toleration to all three substances has developed concurrently. 6 patients who had never received M. & B. 1863 before, but who had already acquired a tolerance to H.M.B., were given an equivalent dose of M. & B. 1863. Thus in case 206 the optimal subcutaneous dose of H.M.B. was 150 mg. When 75 mg. of M. & B. 1863 was substituted it had about the same effect on the blood-pressure. This would happen only if, concurrently with the acquisition of toleration to H.M.B., there had developed a corresponding degree of toleration to M. & B. 1863. 75 mg. of M. & B. 1863 given without the previous acquisition of tolerance would be an excessive dose causing fainting in the sitting posture.

Similar investigations made with Ciba 9295 gave similar results.

To see if toleration for homologues can be acquired in the reverse direction, we first gave a patient M. & B. 1863 and continued with this substance until a good measure of toleration to it had developed. We then administered H.M.B. in twice the dose and found that its effect was about the same as that of M. & B. 1863, indicating that, when toleration was acquired to M. & B. 1863, a corresponding degree of toleration was also acquired to H.M.B.

Two other tests were made by giving Ciba 9295 until a toleration was acquired. Then, although no H.M.B. had been given beforehand to these patients, the responses indicated that a considerable measure of toleration to it was acquired as the result of giving Ciba 9295. Evidently when, as the result of repeated administration, toleration has been acquired to one of the methonium compounds studied, simultaneously toleration is acquired to certain other methonium compounds, even though these have not been administered previously.

M. & B. 1863 AND CIBA 9295 AS ALTERNATIVES TO H.M.B. IN TREATMNET OF ARTERIAL HYPERTENSION

Ordinarily there is little difference in the side-effects produced by Ciba 9295, M. & B. 1863, and H.M.B. There has been slightly less dryness of the mouth and blurred vision from M. & B. 1863 for equal hypotensive action. The difference is quantitative, and no qualitative difference has been observed with either of these substances. A minority of patients have appreciable trouble with side-effects from H.M.B. Some of these patients have compared the effects of H.M.B. and M. & B. 1863 and noted that, for equal hypotensive effects, there have been fewer side-effects from M. & B. 1863.

In 14 patients treated for periods of from one to four months with M. & B. 1863 it has been possible in all instances to obtain as good control over the arterial level as with H.M.B., using approximately half of the dose. Of 8 patients given both drugs, 2 could distinguish no symptomatic difference between their actions, 1 could distinguish a difference but had no preference, and 5 claimed that they were more comfortable on M. & B. 1863 because side-effects were less pronounced.

ILLUSTRATIVE CASE-RECORDS

CASE 207.—A man, aged 57, had malignant hypertension with severe headache and breathlessness on exertion. The average arterial blood-pressure was reduced by subcutaneous H.M.B.; papillœdema cleared entirely, headaches and breathlessness disappeared, and he returned to his occupation as an engineer without restriction of activity. Adequate control of arterial blood-pressure by H.M.B. injections caused occasional diarrhœa at night. On control with M. & B. 1863 the patient felt generally better, and diarrhœa, dryness of the mouth, and blurring of vision were less than with H.M.B. His treatment with H.M.B. lasted four months and with M. & B. 1863 one month. The first effective dosage of subcutaneous H.M.B. was 75 mg. thrice daily; but, as toleration developed, the effective dosage increased to 210 mg. thrice daily. The treatment was next changed to 102 mg. of M. & B. 1863 thrice daily, which had a similar effect on the blood-pressure. The blood-pressure was initially about 220/146 mm. Hg and seldom fell below 170/120 mm. Hg in the early weeks of treatment, but latterly with H.M.B. the blood-pressure usually was 122/80–190/130 mm. Hg. On M. & B. 1863 the blood-pressures were in the same range.

CASE 228.—A woman, aged 43, with essential hypertension, had had hemiplegia before treatment but when first seen by us was otherwise symptomless, and treatment with H.M.B. was prophylactic. As a side-effect of H.M.B. she had considerable colicky pain 1½–2 hours after the injection and was relieved to some extent by atropine gr. 1/100. She had not experienced such discomfort before treatment with H.M.B. M. & B. 1863 in doses which produced about the same amount of hypotension did not cause colicky pain. Dryness of the mouth and blurring of vision were also less. After two weeks H.M.B. injections were resumed without recurrence of the pain, but dryness of the mouth and blurring of vision were accentuated, and the patient could distinguish between equal hypotensive doses of H.M.B. and M. & B. 1863. The dosage of H.M.B. increased from 15 to 60 mg. thrice daily. The treatment was then changed to 35 mg. of M. & B. 1863 thrice daily for three weeks. The blood-pressure recorded before treatment was 240/150 mm. Hg, which fell under basal conditions to 188/138. With H.M.B. the blood-pressure in the sitting posture fell to 132/110. Between injections the pressure did not ordinarily rise much above 182/130. On M. & B. 1863 the blood-pressure was usually 132/98–180/130.

CONCLUSION

H.M.B. has now been tried here for two years and eight months and has given very little indication of toxicity other than that which arises as a temporary phenomenon from overdosage. So far it has not caused any adverse permanent tissue change, but no doubt in the course of time occasional instances will be reported. Ciba 9295 and M. & B. 1863 have not been tried as long, but they behave like H.M.B.

SUMMARY

Hexamethonium salts and the ganglion-blocking homologues Ciba 9295 and M. & B. 1863 are qualitatively similar in reducing blood-pressure, causing postural hypotension, and inducing toleration after repeated administration.

The administration of any one of these substances induces toleration to its homologues.

All these substances when given orally require ten or more times the subcutaneous dose.

By subcutaneous injection, before toleration has developed, approximately equal falls of blood-pressure are induced by 7 mg. of M. & B. 1863, 15 mg. of H.M.B., and 17 mg. of Ciba 9295. After toleration has developed, Ciba 9295 is usually much less effective than either H.M.B. or M. & B. 1863.

In a few hypertensive patients M. & B. 1863 is rather better tolerated than H.M.B. in the sense that, for equal falls of blood-pressure, side-effects are less prominent.

Thanks are due to Miss M. Poppelwell for secretarial work, and to Miss J. Rivers, Miss N. Hoggan, and Miss B. Stanton for technical assistance. Messrs. May & Baker Ltd. supplied the hexamethonium bromide and M. & B. 1863, and Ciba Laboratories Ltd. the Ciba 9295. The expenses of the work were defrayed in part by the Medical Research Council of New Zealand.

"... It is a convenient working rule to assume our fellow men, if not our equals, are at least in general not very much more stupid or wicked than we are ourselves. If that be admitted, then the more reprehensible their conduct appears the greater should our curiosity become. The quality that the academic mind can bring to the conduct of affairs is that of reasonableness. There are no short cuts and no cure-alls, but there is a great deal of inaccurate thinking. The call is for hard work, full and precise knowledge, clear exposition, and refusal to accept a comfortable evasion of unpalatable conclusions."—Prof. H. H. BELLOT, addressing the students of Hull University College, reported in the *Manchester Guardian*, Nov. 3, 1952, p. 9.

A "HARLEQUIN" COLOUR CHANGE IN THE NEWBORN

G. A. NELIGAN
B.M. Oxfd, M.R.C.P.
LECTURER, DEPARTMENT OF CHILD HEALTH, UNIVERSITY OF DURHAM

L. B. STRANG
M.B. Durh., M.R.C.P.
PEDIATRIC REGISTRAR, PRINCESS MARY MATERNITY HOSPITAL

From the Princess Mary Maternity Hospital, and the Department of Child Health, King's College, Newcastle upon Tyne

ON a day in March, 1951, each of us on separate occasions saw a particular baby in the nursery of this hospital undergo a most bizarre and striking colour change with which we were previously unfamiliar. At the age of 3 days she was lying naked on her right side in an oxygen box, when the left half of her body became much paler than usual, although the right half remained the usual pink. The dividing line between the two halves was as sharp and straight as if it had been drawn with a pencil and ruler, and it ran exactly in the midline—down the centre of the forehead, nose, chin, and trunk, through the centre of the umbilicus and genitalia, and up the back over the tips of the vertebral spines. This surprising appearance passed off spontaneously after a few minutes on both occasions, the whole body reverting to its usual colour.

The sister in charge of the nursery remembered having seen a similar colour change in two babies in the nursery during the previous year, and the case-notes confirmed this. Accordingly, the nursing and medical staffs of the nursery began to watch for such attacks in case these might have some pathological significance, and during the next twelve months a further 21 babies were observed to be affected (each on one or more occasions). These observations were made by the sister-in-charge, four staff midwives, and ourselves. In addition, we observed 2 instances elsewhere, and had 3 further instances reported to us by interested colleagues from other hospitals.

THE ATTACKS

There is always a clear-cut line of demarcation running exactly in the midline of the body, and gravity determines the distribution of colour between the two halves of the body, the side which is uppermost always being the paler. The intensity of the attack varies considerably from one baby to another, the pallor being much more striking in some than in others, and in some of the mildest attacks there has been no line of demarcation visible on the skin of the face and genitalia. Even in severe attacks, no difference is apparent in the colour of the two halves of the lips and tongue. Respiration, responsiveness to stimuli, and muscle tone appear to be normal during the attack; and a single observation of the state of the pupils showed them to be of equal size. If the baby is left undisturbed, the attack passes off spontaneously after anything from thirty seconds to twenty minutes, and the baby then looks quite normal again.

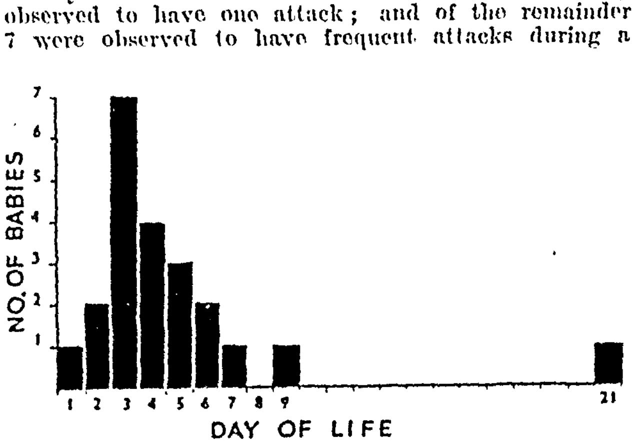
The attacks may occur with the baby in almost any posture, so long as he is more or less turned on one side: he may be lying horizontally, his feet may be above or below the level of his head, or he may even be almost sitting in the nurse's arms. In several cases we have confirmed the effect of gravity; for the whole picture has been reversed by turning the baby on to the opposite side during an attack, without disturbing his sleep. The previously pale half gradually becomes suffused with blood till the whole baby is a uniform colour for a few seconds; then the previously darker half, now uppermost, gradually goes pale. The time taken for this reversal to be completed is between a half and one minute. If, instead, the baby is simply turned on to his back, the attack is brought to an end in about a quarter of a minute. We have tried to find out if it is the position of the baby's trunk, or head, or both, that determines the distribution of colour, but have so far failed to make convincing observations on this point.

One of the reasons for this difficulty is that attempts to rotate the baby's head and trunk independently usually disturb him; and, if he becomes too active, the pale half begins to flush irrespective of posture. If he actually cries, of course, the intense flush which results rapidly obliterates the whole picture. These effects of posture and activity also, in part, explain the difficulty of getting satisfactory photographs of the colour change in these attacks. We have so far failed to obtain one good enough for reproduction in black and white.

INCIDENCE OF ATTACKS

The minimum incidence of the condition has been estimated by recording every attack observed in the selected group of 250 babies admitted to the nursery, rather than to the lying-in wards with their mothers, from mid-March, 1951, to mid-March, 1952. This group included all babies with a birth weight of 5 lb. or less, and babies above this weight who showed clinical evidence of cerebral damage, or whose obstetric history suggested that they were particularly liable to develop it, together with a few severe cases of hæmolytic disease and hæmorrhagic disease. Of the 250 babies admitted only 126 spent more than the first forty-eight hours of life in the nursery, since the rest had either died or been discharged to the lying-in wards by that age. These babies in the nursery were under closer observation than the normal babies in the lying-in wards: for they were examined relatively frequently by the doctors, they were hand-fed by nurses who were familiar with the harlequin colour change, and many of them spent days or weeks naked in oxygen boxes.

Of the 250 babies admitted, 22 were observed to have one or more of these attacks (see figure). In only 3 babies was the first attack observed in the first forty-eight hours of life; the remaining 19 instances were observed in the 126 babies who stayed in the nursery longer than forty-eight hours, giving an incidence among them of 15%. The true incidence is presumably higher, since other babies must have had attacks without their being observed. This infrequency of recorded attacks during the first forty-eight hours of life surprised us, but we have no reason to believe that attacks at that stage were less likely to be observed (rather the reverse, if anything). Most of the first attacks were observed on the third or fourth day of life, but one was observed on the twenty-first. 12 of the affected babies were only observed to have one attack; and of the remainder 7 were observed to have frequent attacks during a single period of twenty-four hours (the greatest number recorded for any one baby being twelve).



Age at time of first recorded harlequin attack in 22 nursery babies.

An analysis to discover whether any particular group of babies has a special tendency to these attacks suggested that this might be true of the smaller prematures, but the difference in incidence between those weighing less than 4 lb. and the larger premature babies (6 out of compared with 13 out of 98) is not regarded as statistically significant.

Since the year covered by these observations, an attack has been observed in a mature baby about a minute after delivery; and in a premature baby fifty-four attacks were observed in the first two weeks of life.

SIGNIFICANCE OF ATTACKS

These attacks seem to have no pathological significance. During the year in question, they were observed in babies with very varied and apparently unrelated pathological states in the nursery, and in 6 apparently normal premature babies. We have also observed attacks elsewhere in 2 mature babies: one on the sixth day of life in a baby with scaphocephaly, and the other on the sixteenth day in a baby convalescent from pneumonia. Finally, we have received reports from colleagues of attacks in a perfectly normal mature baby on the day and in 2 normal premature babies in other hospitals.

DISCUSSION

We have not found any previous description of the phenomenon. Our own limited speculations about the mechanism involved are based on the observations described. We have deduced that the essential asymmetry, or incoördination, must occur at a level of the central nervous system where there are centres controlling the tone of the skin blood-vessels in each half of the body separately. This is the only way in which we can explain the precise distribution and demarcation of the colour changes (the fact that the lips and tongue do not show these changes, even in severe attacks, and that the face and genitalia are unaffected in the mildest attacks might perhaps be due to the greater vascularity of the skin over these parts). Richards (1946) suggests that there are such centres in the hypothalamus, and that the vasomotor centres in the medulla are concerned only with the "more vital activities of the heart and great vessels." The existence of cortical centres seems to be open to doubt. Instability of these hypothalamic centres in the neonatal period would accord well with the accepted view that the unstable heat-regulating mechanism of the newborn is controlled from centres at the same level of the nervous system. The apparently greater susceptibility of smaller premature babies to attacks, if confirmed, would also correspond well to their less stable heat-regulating mechanism. What is less easy to explain is the relative infrequency of attacks in the first forty-eight hours of life, when any such instability would be expected to be at its height.

Our view that the attacks have no pathological significance is without conclusive support as yet; our own observations have all been made in babies who were abnormal in some way (if only because of prematurity or a recent infection), and only one of the observations reported by our colleagues concerned a completely normal baby. We feel that this is merely an index of the sort of babies we tend to look at most closely and frequently during our normal day's work; and we have certainly failed to trace any logical connection between the various abnormalities of the affected babies. Conclusive proof, however, awaits the observation of attacks in a sufficient number of perfectly normal mature babies.

A better interpretation of these attacks may come from future observations in the clinical field. Part of our object in presenting this report is the that it may interest others working in more experimental fields.

SUMMARY

In the premature and sick nursery of a maternity hospital it has been noted that the babies are liable to attacks, of short duration, in which one exact half of the body becomes much paler than the other half. The clinical features of these attacks are described.

In a single year, of 250 babies admitted to the nursery, 22 had one or more of these attacks. The attacks seem to be more liable to occur after the first forty-eight hours of life; and of the 126 babies who spent more than their first forty-eight hours in the nursery 19 (15%) had one or more attacks at that stage. The true incidence is presumed to be higher than this.

No connection has been found between these attacks and any particular pathological state. The attacks are believed to be of no pathological significance.

The mechanism involved in the attacks remains purely conjectural; but the precise distribution of the colour changes suggests a temporary imbalance in the central nervous system (possibly in the hypothalamus).

We wish to thank Sir James Spence and Dr. Donald Court for their interest and for their advice about the preparation of this report; and Dr. E. G. Knox, Dr. T. C. Noble, and Dr. J. M. Stansfeld for letting us know about cases in other hospitals.

PRIMARY CARCINOMA OF THE LIVER FOLLOWING VIRAL HEPATITIS

REPORT OF TWO CASES

J. M. WALSHE
M.R.C.P.

STOTHERT RESEARCH FELLOW OF THE ROYAL SOCIETY, AT THE MEDICAL UNIT, UNIVERSITY COLLEGE HOSPITAL, LONDON

H. H. WOLFF
M.D. Camb., M.R.C.P.

SENIOR MEDICAL REGISTRAR, ST. HELIER HOSPITAL, CARSHALTON, SURREY

ALTHOUGH primary carcinoma of the liver is one of the commonest forms of malignant disease in certain African and Asiatic races it is generally agreed to be a rare tumour in Western Europe. In the Bantu (Berman 1951) and in China (Tull 1932) it appears to be secondary to dietary cirrhosis and parasitic infestations of the liver. In European races, however, dietary cirrhosis of the liver is rare. Primary carcinoma of the liver, when it does occur, is usually found in association with cirrhosis, either diffuse hepatic fibrosis (Schupbach and Chappell 1952) or nodular hyperplasia (Muir 1908, Himsworth 1950). Although the ætiology of hepatic cirrhosis, in this country, is often obscure, many cases are probably due to viral hepatitis; certainly hepatic fibrosis is now a well-recognised sequel to this disease (Stokes and Miller 1947, Watson and Hoffbauer 1946, Havens 1948, Post et al. 1950). It is therefore surprising that the sequence of events—infective hepatitis, cirrhosis of the liver, carcinoma of the liver—has not been described more frequently. Sherlock (1952) was able to cite only one published report, by Sheldon and James (1948), in which 5 cases of hepatic cirrhosis are described; 2 of these developed primary carcinoma of the liver. The cause of the cirrhosis in all 5 was stated to be viral hepatitis, although both patients in whom a carcinoma was found were chronic alcoholics.

We believe that the 2 cases described here began with a viral hepatitis, and proceeded to postnecrotic scarring, nodular hyperplasia, and finally tumour formation. In the first case the hepatitis was either of the epidemic infective or of the serum variety and the carcinoma was diagnosed during life. In the second case the hepatitis was probably of the epidemic variety and the carcinoma was an incidental finding at necropsy.

THE FIRST CASE

A man, aged 35, was admitted to St. Helier Hospital on Aug. 10, 1951.

History

He had joined the Army in 1940 and had been sent to India in 1942. In 1943 he was treated for benign and malignant tertian malaria. In May, 1944, he contracted syphilis, for which he was treated with neoarsphenamine and bismuth injections. In December, 1944, after having two courses of antiluetic treatment, he developed anorexia, nausea, and upper abdominal discomfort, followed by jaundice. His stools became pale and his urine dark. He was on active service in Burma at that time, and there was an epidemic of infective hepatitis among the troops serving in the area.

From December, 1944, to January, 1946, he was treated in various military hospitals, at first in India and later in England. Throughout this period he had persistent jaundice, with enlargement of the liver and spleen. His Wassermann reaction which had been positive in May, 1944, had become negative by December of the same year. He was discharged from the Army with the diagnosis of subacute hepatitis. He returned to work as a clerk; but, except for a short period in 1948, his jaundice never subsided completely.

In August, 1949, he developed increasing lassitude and his jaundice became more intense. He was admitted to Dulwich Hospital and was found to have an enlarged liver and spleen and several pulsating arterial telangiectases on his arms and trunk. Investigation at that time gave the following results: hæmoglobin 94%, serum-bilirubin 6·8 mg. per 100 ml., thymol turbidity 15 units, alkaline phosphatase 21 King units, serum-albumin 2·92 g. per 100 ml., and serum-globulin 4·39 g. per 100 ml. He was discharged, after three weeks, still slightly jaundiced. Subsequently he developed œdema of his legs. By May, 1950, the thymol turbidity had risen to 30 units with flocculation, but the serum-bilirubin level had fallen to 2·0 mg. per 100 ml. In August, 1951, he suddenly developed severe pain in the right side of his chest, worse on breathing, and six days later he was again admitted to hospital. There was no history of alcoholism either before or after the beginning of his illness in 1944.

Condition on Admission

He looked ill, was moderately icteric, and complained of severe right-sided pleuritic pain. His temperature was 99·2°F. There was a large pulsating arterial telangiectasis on his left shoulder, and there were several smaller ones on the arms and on the chest wall. Both thenar and hypothenar eminences showed the erythema of "liver palms." A firm and slightly tender liver edge was palpable 1 in. below the right costal margin. The spleen was considerably enlarged and firm, extending 2 in. below the left costal margin. There was pitting œdema of both legs and thighs, but there was no demonstrable ascites. A pleural friction rub was audible in the right axilla, and there were râles at both bases. The cardiovascular and central nervous systems were normal.

Investigations

His hæmoglobin was 98%, and the white-cell count 3100 per c.mm. (polymorphs 86%, lymphocytes 14%). The serum-bilirubin was 4·5 mg. per 100 ml., the thymol turbidity 5 units with flocculation, and the serum-alkaline-phosphatase 18·5 units. The total serum-proteins were 7 g. per 100 ml. (albumin 2·8 g., globulin 4·2 g.), and the Wassermann reaction negative.

Radiography of the chest revealed scattered areas of consolidation at both bases, and several rounded opacities, in both lung fields, suggestive of secondary malignant deposits. The primary growth was thought to be in the liver.

Course

The patient continued to have low-grade pyrexia up to 100°F. He became more deeply jaundiced, the œdema of his legs increased, and he developed ascites. His condition gradually deteriorated until he died a month after admission.

Post-mortem Findings

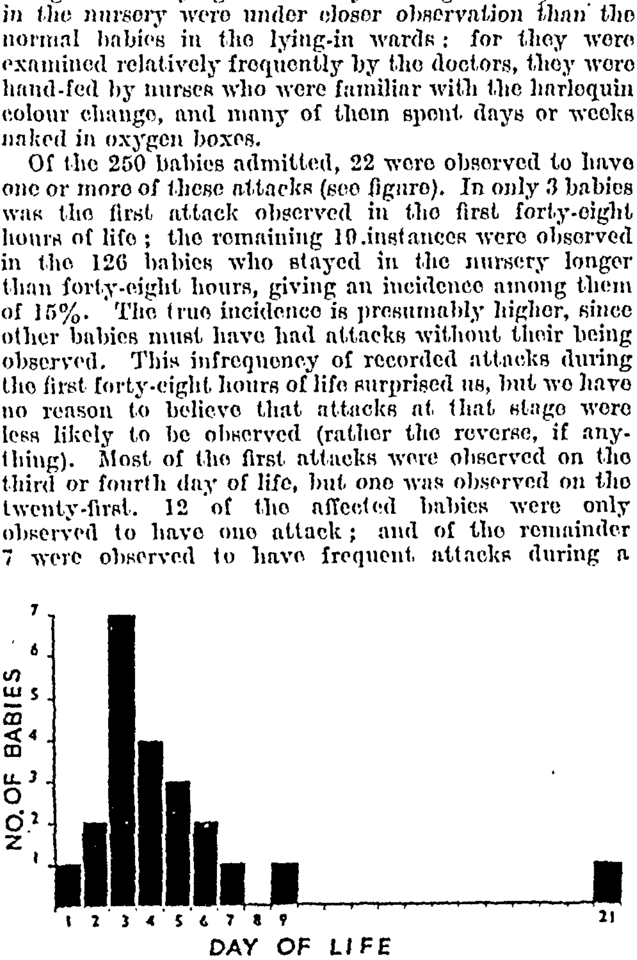
Necropsy (Dr. T. E. W. Goodier).—The liver, of normal size, contained a yellow mass of tumour tissue 5·0 cm. in diameter in the right lobe, and several smaller yellow nodules reversal to be completed is between a half and one minute. If, instead, the baby is simply turned on to his back, the attack is brought to an end in about a quarter of a minute. We have tried to find out if it is the position of the baby's trunk, or head, or both, that determines the distribution of colour, but have so far failed to make convincing observations on this point.

One of the reasons for this difficulty is that attempts to rotate the baby's head and trunk independently usually disturb him; and, if he becomes too active, the pale half begins to flush irrespective of posture. If he actually cries, of course, the intense flush which results rapidly obliterates the whole picture. These effects of posture and activity also, in part, explain the difficulty of getting satisfactory photographs of the colour change in these attacks. We have so far failed to obtain one good enough for reproduction in black and white.

INCIDENCE OF ATTACKS

The minimum incidence of the condition has been estimated by recording every attack observed in the selected group of 250 babies admitted to the nursery, rather than to the lying-in wards with their mothers, from mid-March, 1951, to mid-March, 1952. This group included all babies with a birth weight of 5 lb. or less, and babies above this weight who showed clinical evidence of cerebral damage, or whose obstetric history suggested that they were particularly liable to develop it, together with a few severe cases of hæmolytic disease and hæmorrhagic disease. Of the 250 babies admitted only 126 spent more than the first forty-eight hours of life in the nursery, since the rest had either died or been discharged to the lying-in wards by that age. These babies *in the nursery were under closer observation than the* normal babies in the lying-in wards: for they were examined relatively frequently by the doctors, they were hand-fed by nurses who were familiar with the harlequin colour change, and many of them spent days or weeks naked in oxygen boxes.

Of the 250 babies admitted, 22 were observed to have one or more of these attacks (see figure). In only 3 babies was the first attack observed in the first forty-eight hours of life; the remaining 19 instances were observed in the 126 babies who stayed in the nursery longer than forty-eight hours, giving an incidence among them of 15%. The true incidence is presumably higher, since other babies must have had attacks without their being observed. This infrequency of recorded attacks during the first forty-eight hours of life surprised us, but we have no reason to believe that attacks at that stage were less likely to be observed (rather the reverse, if anything). Most of the first attacks were observed on the third or fourth day of life, but one was observed on the twenty-first. 12 of the affected babies were only observed to have one attack; and of the remainder 7 were observed to have frequent attacks during a single period of twenty-four hours (the greatest num recorded for any one baby being twelve).



Age at time of first recorded harlequin attack in 22 nursery babies.

An analysis to discover whether any particular g of babies has a special tendency to these attacks sugg that this might be true of the smaller premature, the difference in incidence between those weighing than 4 lb. and the larger premature babies (6 out of compared with 13 out of 98) is not regarded statistically significant.

Since the year covered by these observations, attack has been observed in a mature baby about minute after delivery; and in a premature baby fi four attacks were observed in the first two weeks life.

SIGNIFICANCE OF ATTACKS

These attacks seem to have no pathological significa During the year in question, they were observed in babies with very varied and apparently unrelated pat logical states in the nursery, *and in 6 apparently* norm premature babies. We have *also observed* atta elsewhere in 2 mature babies: one on the sixth day of in a baby with scaphocephaly, and the other on t sixteenth day in a baby convalescent from pneumo Finally, we have received reports from colleagues attacks in a perfectly normal mature baby on the fi day and in 2 normal premature babies in other hospit

DISCUSSION

We have not found any previous description of t phenomenon. Our own limited *speculations* about t mechanism involved are based on the observati described. We have deduced that the essential asy metry, or incoördination, must occur at a level of t central nervous system where there are centres contr ling the tone of the skin blood-vessels in each half of *body separately. This is the only way in which* we explain the precise distribution and demarcation of t colour changes (the fact that the lips and tongue do show these changes, even in severe attacks, and that face and genitalia are unaffected in the mildest attack might perhaps be due to the greater vascularity of t skin over these parts). Richards (1946) suggests th there are *such centres* in the hypothalamus, and th the vasomotor centres in the medulla are conc only with the "*more vital* activities of the heart a great vessels." The existence of cortical centres se to be open to doubt. Instability of these hypothalamic centres in the neonatal period would *accord* well with th accepted view that the unstable heat-regulating mech ism of the newborn is controlled from centres at the level of the nervous system. The apparently gr susceptibility of smaller premature babies to atta if confirmed, would also correspond well to their stable heat-regulating mechanism. What is less *to explain is the relative* infrequency of attacks in first forty-eight hours of life, when any such instab would be expected to be at its height.

Our view that the *attacks* have no patholo significance is without conclusive support as yet; own observations have *all* been made in babies who abnormal in some way (if only because of prematu or a recent infection), and only *one* of the observat reported by our colleagues concerned a compl normal baby. We feel that this is merely an ind the sort of *babies we tend to* look at most closely frequently during our normal day's work; and we certainly failed to trace any logical connection bet the various abnormalities of the affected babies. clusive *proof*, however, awaits the observation of att in a sufficient number of *perfectly normal* mature ba

A better *interpretation* of these attacks may *from future* observations in the clinical field. part of our object in presenting this report is the

plasma infusions did not relieve his ascites, and repeated tappings were necessary. He got steadily worse and died in coma six weeks after admission.

Post-mortem Findings

Necropsy (Dr. R. H. D. Short).—The liver was small and coarsely scarred. It weighed 1180 g., and contained multiple regeneration nodules up to 2 cm. in diameter. In the right lobe one nodule was yellowish and appeared to be infiltrating the surrounding liver. The spleen was enlarged and weighed 520 g. Apart from ascites and dilated œsophageal veins there were no significant abnormalities in any other organ.

Histologically the liver showed coarse bands of fibrous tissue intersecting regeneration nodules of different sizes. In some of the nodules the relation of the central vein to the portal triads appeared to be undisturbed, and the nodules seemed to be composed of groups of apparently normal liver lobules. In other areas the normal liver architecture was completely distorted and there were small groups of cells cut off by fibrous tissue. The yellowish nodule from the right lobe showed irregular columns of cells of different sizes, in some areas almost syncytial, with many multinucleate cells, irregular-sized nuclei, and many mitoses. There was a well-marked transition from the normal to the abnormal cells. The appearance was typical of a primary liver-cell carcinoma arising in a cirrhotic liver, probably in postnecrotic scarring (toxic cirrhosis of Mallory) (figs. 3 and 4).

DISCUSSION

It is clear that the initial illness in both these cases was a viral hepatitis. In case 1 the hepatitis started during an epidemic of infective hepatitis in Burma, and the patient was receiving antiluetic treatment with arsenic and bismuth at the time. The illness could therefore have been either epidemic infective hepatitis or homologous serum jaundice. In case 2 there was an initial episode of liver injury, probably serum hepatitis contracted during the course of arsenotherapy. This was followed fourteen years later by a severe attack of hepatitis which was almost certainly of the epidemic variety because the patient's wife had a similar though milder illness at the same time.

After the attack of viral hepatitis both patients developed cirrhosis of the liver. In case 1 the acute illness passed directly into the stage of subacute hepatitis, and some jaundice persisted almost without interruption until his death seven years later. In case 2 there was a latent period of five years between the attack of infective hepatitis and the first appearance of symptoms of portal hypertension. This long latent period has also been described by Kunkel and Labby (1950), who recorded the development of cirrhosis in 5 patients from two to six years after an attack of infective hepatitis. In both our cases the histological appearances were more in keeping with those of postnecrotic scarring than those of Laennec's diffuse fibrosis, although it is admitted that the histological differentiation between these two types of cirrhosis is often difficult if not impossible (Hoffbauer 1947).

Though there is a history of syphilis in both our cases, there is no evidence that this played any direct part in the ætiology of the cirrhosis. Prolonged oral administration of arsenic may predispose to fibrosis of the liver (Himsworth 1950), but the short courses of parenteral arsenic which these two patients had received are unlikely to have played any part in the development of the cirrhosis.

It seems probable that the neoplastic change was a consequence of the process of continuous regeneration of liver cells that is known to take place in cirrhosis due to other causes (Muir 1908). It is possible, however, that the virus had remained active and had in some way caused the regenerating liver cells to undergo malignant change. On the other hand, it is known that dietary factors can influence the formation of hepatic tumours. Miller et al. (1941) and Cramer (1942) showed that casein and riboflavine partially protected rats against hepatoma induced by butter yellow. Opie (1944) showed that rice, in some unexplained way, favoured the formation of hepatic tumours. Copeland and Salmon (1946) produced hepatoma-like tumours in rats maintained for a long time on choline-deficient diet. Though such abnormal diets are common among the native populations in those parts of the world where hepatic cancers are

0·5–2·0 cm. in diameter in the remainder of the right and in the left lobe. The intervening portions of the liver had the appearance of a coarse nodular cirrhosis. The spleen was firm and enlarged to three times its normal size. The lungs contained numerous bile-stained secondary deposits. There was no significant abnormality in any other organ.

Histological examination of the liver showed complete disorganisation of its architecture. Dense tracts of fibrous tissue divided groups of parenchymal cells into lobules of different sizes. Bile-duct regeneration was conspicuous. Many of the liver cells showed fatty infiltration. Scattered throughout the section were irregular areas consisting of neoplastic cells. In many places these were arranged to form alveolar spaces of different sizes, whereas in other places the cells formed solid columns and irregular syncytial masses. Multinucleate cells, irregularity of nuclear size, and mitotic figures were all common. Most of the cells surrounding the alveolar spaces were cuboidal; some were flattened, and the alveolar spaces were filled with a homogeneous pink-staining material. Broad bands of fibrous tissue separated the irregular collections of neoplastic cells. The appearances were those of a mixed bile-duct and liver-cell carcinoma arising in a liver which was the site of a multilobular cirrhosis (figs. 1 and 2).

THE SECOND CASE

A man, aged 40, was admitted to University College Hospital on Feb. 7, 1949.

History

The first six years of his life were spent in India, and during that time he had both typhoid fever and malaria. In 1928 he contracted syphilis, which was treated with intravenous arsenic. Eighteen months later, while still under treatment, he had a transient attack of jaundice lasting only a few days. He was then well until 1942, when he had an illness starting with malaise and anorexia and followed by jaundice. He was treated at home with a low-protein low-fat high-carbohydrate diet. The jaundice lasted three months; during this time his wife also had an attack of jaundice, which lasted two weeks.

For two months after the jaundice had cleared he had frequent attacks of sore throat and fever, which caused him to leave his work as a type moulder and seek lighter employment. From the end of 1942 he was well until January, 1948, when, after passing black stools for two days, he had a large hæmatemesis. He was admitted to the West Middlesex Hospital, where his hæmoglobin was found to be 45%. He was treated by blood-transfusion and improved, but after a few days he developed ascites and intermittent pyrexia. Investigations showed an erythrocyte-sedimentation rate of 25 mm. in 1 hour, a negative Wassermann reaction, and strongly positive serum-flocculation reactions. Chest radiography was normal, and a barium swallow did not show any œsophageal varices. Gastroscopy also failed to reveal any source of hæmorrhage. The ascitic fluid was reabsorbed spontaneously, and it then became possible to feel a firm liver and an enlarged spleen. He was discharged after two months in hospital.

He returned to work and was well until December, 1948, when his abdomen began to swell and he developed bilateral inguinal herniæ. During January, 1949, he was troubled by occasional nose-bleeds, swelling of the ankles, and breathlessness on effort. There was no history of alcoholism at any time.

Condition on Admission

He was wasted and anicteric, with temperature 99°F and pulse-rate 100. He had no complaints apart from the discomfort of his greatly distended abdomen. There were several pulsating arterial telangiectases on his neck, and he also showed well-developed "liver palms." There was no clubbing of the fingers, and no abnormal veins were visible on the abdomen or flanks. There was pitting œdema of the ankles. The abdomen was grossly distended with fluid, and it was impossible to palpate the liver or the spleen. The lungs and cardiovascular system were normal.

Investigations

The hæmoglobin was 88% and the white-cell count normal. The prothrombin concentration was 50% of normal. The serum-flocculation tests were all strongly positive, and the thymol turbidity was 20 units with flocculation. The Wassermann reaction and Kahn test were negative. The serum-albumin level was 3·7 g. per 100 ml. and serum-globulin 4 g. per 100 ml. Later the serum-albumin fell to 1·9 g., while the serum-globulin remained constant. A barium swallow showed œsophageal varices.

Course

After the ascites had been drained, a firm irregular liver edge could be felt in the epigastrium and the tip of the spleen was palpable. The patient had continued irregular pyrexia up to 102°F while in hospital, and this was not influenced by sulphonamides or by penicillin. Intravenous

only in Yemenite Jews but also in Oriental Jews and in Jews from Central Europe. The significant facts were that it could not be obtained regularly by the moist-stasis technique and never by using any of the conventional reducing agents (Dreyfuss et al. 1951). Yet in the single case of sickling discovered in a survey of Arabs (Dreyfuss and Benyesch 1952) the drepanocytes could be produced regularly by using ascorbic acid as recommended by Daland and Castle (1948).

On the occasion of the visit of one of us (H. L.) to Israel blood from some 30 unrelated Oriental Jews other than Yemenites was examined chemically for sickle cells, and none were found. Blood from 3 Central European Jews who had previously produced sickle cells in moist-stasis tests were re-examined chemically and found negative; they were also negative when tested by the moist-stasis technique on this occasion.

We next examined 59 unrelated Yemenites, all being recent immigrants living at Zorah. None of the samples showed sickle cells. The method used was incubation with 2% sodium metabisulphite. The reducing agent was dissolved in boiled distilled water on the day of use. Solutions similarly prepared from the same batch of the salt had been efficacious in producing sickle cells in numerous Veddians only a few days before in India.

Several weeks later one of us (F. D.) collected a further 27 blood samples in Zorah, 6 of them being from people whose blood had been examined on the first occasion. The blood was flown to London and examined within five days for the sickle-cell trait. The following reducing agents were used: sodium metabisulphite 2%, sodium dithionate 2·4%, and sodium hydrosulphite 2·1%. On this occasion African sickle cells from Uganda, which had been collected seven days before and were sent to us by courtesy of Dr. P. W. Hutton, were used as a control. In none of the Yemenite samples was sickling found, although it was demonstrated readily with each of the reagents in the African blood. A third consignment of 24 specimens, all from hospital patients, was sent two months later; 19 specimens were examined within three days, and the rest within four days of collection. Again no sickle cells could be produced by chemical means. Altogether 104 blood samples of unrelated Yemenites were examined with negative results.

Sickle cells are formed when the relatively insoluble reduced sickle-cell hæmoglobin crystallises intracellularly (Perutz et al. 1951), but they can also be produced by extracellular stress on normal cells (Isaacs 1950). A possible explanation of the earlier findings of Dreyfuss and Benyesch (1951) is that, on prolonged moist-stasis incubation, compounds were formed in the plasma which caused the red cells to sickle. The sera of the 3 Central Europeans whose blood had on previous occasions shown sickling were examined in London for numerous possible abnormalities, but the only remotely significant finding was a raised β-globulin content shown on filter-paper electrophoresis (by courtesy of Dr. W. G. Dangerfield). Experiments aiming at converting normal red cells into sickle cells by incubating them in β-globulin solutions of different strengths, however, gave negative results. One of us (F. D.) is continuing to investigate the possible causes—both extracellular and intracellular—of the observed phenomenen.

BLOOD-GROUPS

From all the people whom sickling tests were done in Israel samples were taken for blood-grouping and flown to London for testing at the Blood Group Reference Laboratory. Subsequent consignments sent by air to London for sickling tests were also examined for blood-groups. All the samples were tested with anti-A, anti-A_1 where relevant, anti-B, anti-C, anti-C^w, anti-D, anti-E, anti-c, anti-M, anti-N, anti-S, and anti-Henshaw. Positives with anti-E were tested with anti-e. Specimens negative with a saline anti-D were examined by means of the indirect anti-human-globulin test with a strong incomplete anti-D serum to detect the D^u antigen. In view of the exceptionally high frequency of D^u found in the first batch, second samples from several people were sent from Israel, and, apart from one which arrived in poor condition on the second occasion, all the results agreed with those found the first time. As an additional precaution D^u bloods of the second and third batches, and the repeat samples, were submitted to a direct anti-globulin test; they gave negative results. Hence the high D^u frequency found may be accepted with confidence.

The results of the blood-group tests are shown in tables I–III. Gene frequencies were calculated by the methods which have been briefly described by Chalmers et al. (1949) and Prasad et al. (1949) and are to be more fully described by A. E. Mourant (in the press).

frequently found, there is no evidence that they played any significant part in our two cases.

SUMMARY

Two cases are described in which viral hepatitis was followed by cirrhosis and finally by primary carcinoma of the liver. Reference to the literature suggests that carcinoma of the liver is a rare complication of viral hepatitis.

Our thanks are due to Dr. J. B. Harman for permission to publish case 1; to Sir Harold Himsworth for permission to publish case 2; to Prof. G. R. Cameron for confirming the histological diagnosis; and to Mr. A. Bligh for the photomicrographs.

THE modern Jew is not necessarily a close racial relation of the people of the Bible some 3000 years ago. Furthest removed from them are probably the Ashkenazim (Central and Eastern European), less so the Sephardim (Spanish and Mediterranean), and least the Oriental Jews of Asia Minor and Arabia.

There was undoubtedly a period in Roman times when the Jews made proselytes, an activity which waned when Christianity became fully established. It was also the custom for a slave on becoming a free man to accept the religion of his former master. Thus there must have been an influx of non-Semitic blood into the Jewish community in those times. Moreover in Eastern Europe whole communities, such as the Chazars near the Black Sea, embraced the Jewish faith.

There exist still, however, the Jews of Yemen, who have lived in isolation for nearly 2000 years. They are a deeply religious community among whom miscegenation with the surrounding Arabs must have been very rare. These Yemenite Jews have recently migrated to the new state of Israel and thus become much more readily accessible for anthropological investigation.

BLOOD-GROUPS OF JEWS

Broadly, the Jews resemble their neighbours in their ABO-group frequencies but tend to have a higher B frequency than peoples in the West of Europe, and a higher A frequency than the indigenous populations in Eastern Europe, including Russia.

In their Rh groups the Jews tend to a somewhat low frequency of the Rh-negative group and of the cde (r) chromosome, and a relatively high frequency of CDe (R_1), in both respects resembling the peoples of southern rather than Central and Northern Europe. The Jews also have rather more of the cDe (R_0) chromosome than have most Europeans. This chromosome is typical of Africa, but frequencies above the normal European level of 2% are found in various peoples near the Mediterranean Sea, especially the Egyptians and Iraq Arabs. There can be little doubt that the Jews have derived this chromosome ultimately from an African source. There was contact with that continent during the sojourn in Egypt; Moses's wife was an Ethiopian and was therefore resented by Miriam and Aaron (*Numbers*, XII). It is also probable that the Jews, like other Mediterranean groups, received some African blood in Roman times.

The Yemenite Jews present a rather special local problem. Their ABO blood-group frequencies differ from those of most other Jewish peoples. With a high frequency of O, a moderate frequency of A, and a low frequency of B they closely resemble, rather surprisingly, those of the Yemenite Arabs, of the white Berbers and Touaregs of North Africa, and of the "Celtic" peoples of the British Isles. On the other hand, their high frequency of M is typically Asiatic rather than European or African. A preliminary Rh survey of Yemenite Jews showed the very low frequency of 2·3% of Rh-negatives (D-negatives) (Gurevitch et al. 1947). A more recent and detailed study of 500 Yemenite Jews showed 10% of Rh-negatives, together with 5% of the ccDee (R_0) phenotype or more than 6% of the cDe chromosome, suggesting a small but appreciable African component in the population (Brzezinski et al. 1952). Dreyfuss and Benyesch (1951) made sickling tests in Israel on newly arrived immigrants from Yemen and reported positive results in 17 children. This trait has hitherto been found almost exclusively in African Negroids and, sporadically, in Mediterranean peoples among whom it was not unreasonable to expect contributions from an occasional African ancestor. The trait has also been found in Veddians in South India (Lehmann and Cutbush 1952a and b); hence it becomes possible for the trait to be derived from non-Negroids. However it still holds for practical purposes that sickle cells, in the first place at any rate, suggest connections with Africa.

The history and traditions of the Yemenite Jews and the major features of their blood-group picture thus gave no indications of any African ancestry; but the reported presence of sickling and of a somewhat raised cDe frequency showed that the presence of an African component had to be considered. To investigate a possible African connection, two of us (F. D. and H. L.) met in Israel to look for the sickle-cell trait and to collect blood for grouping.

SICKLE-CELL TRAIT

Dreyfuss and Benyesch (1951) had seen the sickle-cell trait when they incubated blood samples by the moist-stasis method of Scriver and Waugh (1930). It could not be shown regularly in the same persons, and often consisted only in the conversion into the sickle shape of a very few cells after prolonged incubation, though in some instances there was a very full development of the abnormal cell configuration over the whole field of the sample. This phenomenon was eventually noted not only in Yemenite Jews but also in Oriental Jews and in Jews from Central Europe. The significant facts were that it could not be obtained regularly by the moist-stasis technique and never by using any of the conventional reducing agents (Dreyfuss et al. 1951). Yet in the single case of sickling discovered in a survey of Arabs (Dreyfuss and Benyesch 1952) the drepanocytes could be produced regularly by using ascorbic acid as recommended by Daland and Castle (1948).

On the occasion of the visit of one of us (H. L.) to Israel blood from some 30 unrelated Oriental Jews other than Yemenites was examined chemically for sickle cells, and none were found. Blood from 3 Central European Jews who had previously produced sickle cells in moist-stasis tests were re-examined chemically and found negative; they were also negative when tested by the moist-stasis technique on this occasion.

We next examined 59 unrelated Yemenites, all being recent immigrants living at Zorah. None of the samples showed sickle cells. The method used was incubation with 2% sodium metabisulphite. The reducing agent was dissolved in boiled distilled water on the day of use. Solutions similarly prepared from the same batch of the salt had been efficacious in producing sickle cells in numerous Veddians only a few days before in India.

Several weeks later one of us (F. D.) collected a further 27 blood samples in Zorah, 6 of them being from people whose blood had been examined on the first occasion. The blood was flown to London and examined within five days for the sickle-cell trait. The following reducing agents were used: sodium metabisulphite 2%, sodium dithionate 2·4%, and sodium hydrosulphite 2·1%. On this occasion African sickle cells from Uganda, which had been collected seven days before and were sent to us by courtesy of Dr. P. W. Hutton, were used as a control. In none of the Yemenite samples was sickling found, although it was demonstrated readily with each of the reagents in the African blood. A third consignment of 24 specimens, all from hospital patients, was sent two months later; 19 specimens were examined within three days, and the rest within four days of collection. Again no sickle cells could be produced by chemical means. Altogether 104 blood samples of unrelated Yemenites were examined with negative results.

BLOOD-GROUPS

From all the people whom sickling tests were done in Israel samples were taken for blood-grouping and flown to London for testing at the Blood Group Reference Laboratory. Subsequent consignments sent by air to London for sickling tests were also examined for blood-groups. All the samples were tested with anti-A, anti-A_1 where relevant, anti-B, anti-C, anti-C^w, anti-D, anti-E, anti-c, anti-M, anti-N, anti-S, and anti-Henshaw. Positives with anti-E were tested with anti-e. Specimens negative with a saline anti-D were examined by means of the indirect anti-human-globulin test with a strong incomplete anti-D serum to detect the D^u antigen. In view of the exceptionally high frequency of D^u found in the first batch, second samples from several people were sent from Israel, and, apart from one which arrived in poor condition on the second occasion, all the results agreed with those found the first time. As an additional precaution D^u bloods of the second and third batches, and the repeat samples, were submitted to a direct anti-globulin test; they gave negative results. Hence the high D^u frequency found may be accepted with confidence.

The results of the blood-group tests are shown in tables I–III. Gene frequencies were calculated by the methods which have been briefly described by Chalmers et al. (1949) and Prasad et al. (1949) and are to be more fully described by A. E. Mourant (in the press).

TABLE III—PHENOTYPES OF YEMENITE JEWS (RHESUS)

Our blood-group results are in fair agreement with those of previous workers cited above, but in certain respects the disagreement is sufficient to suggest that our specimens and theirs are not drawn from a single homogeneous population. As regards ABO, whereas we found rather lower frequencies of O and higher frequencies of A than did either Younovitch (1933) or Brzezinski et al. (1952), there is still a considerable resemblance to the Yemenite Arabs, the white North Africans, and the inhabitants of the British Isles (rather to the English than to the Scots, Irish, and Welsh). The frequency found by us for the A_2 gene is higher than any other reported for Asia, and compares closely with those found in the extreme West of Europe.

Our frequencies for the MN groups are extremely close to those of Brzezinski et al. (1952), the frequency of M being very high. We also found a relatively high frequency of S, mainly associated with M. The whole of this MNS picture is similar to that found in Northern India, Anglo-Egyptian Sudan, and Abyssinia (but not in Egypt or in Negro Africa). High frequencies of M are found throughout Eastern Europe and Western Asia, but only in the above-mentioned cases has S been tested for. S frequencies are high among Europeans and western Asiatics but low in most other races.

Tests were made for the Henshaw antigen (Ikin and Mourant 1951) so far known almost solely in Negroes. Had it been found it would have been important evidence of African connections; but, since it is only present in 3% of Africans so far tested, its absence from the Yemenite Jews means little.

The most interesting feature of the blood-groups of the Yemenite Jews is their Rh picture. Like most other series of Jews hitherto examined, they show relatively high CDe (R_1) and low cDE (R_2) and cde (rr). They do not, however, show the usual cDe (R_0) frequency of 5–10%. They have only 1·3% of this chromosome, but they show the quite exceptional frequency of 20% of cD^ue. When the first batch of specimens gave this surprising result, arrangements were made, as stated above, to repeat the tests on the blood of some of the people concerned, and in the subsequent batches special control tests were made, including direct anti-human-globulin tests. There is thus no doubt that the phenomenon is genuine. Possibly the discrepancy in the frequency of Rh-negatives in the two previous series of tests on Yemenite Jews is due to this high frequency of D^u, since cells with the D^u antigen (and without D) might give positive results with one anti-D serum and negative results with another.

Everywhere outside Africa the chromosome cD^ue is extremely rare or unknown. In most Negro populations its frequency is about 1%, and it had hitherto been supposed that this represented mutations from the commonest Negro chromosome cDe (and that in Europe mutation from CDe had similarly produced CD^ue). One other group of people has, however, recently been found which appears to have a frequency of cD^ue comparable to that of the Yemenite Jews. These are the Touaregs of Agades, one of the most southerly Touareg peoples. In this case only 71 persons have yet been tested, and the specimens were several days old—rather older than is desirable for such critical examinations. Hence the results need confirmation. The Northern Nigerians all have about 7% of cD^ue; this may well be due to mixing with white peoples of the Sahara, and possibly a high frequency of cD^ue will prove to be an important characteristic of a series of white peoples in North Africa and the near East.

The genetical picture revealed by an examination of the blood of Yemenite Jews thus shows resemblances to Europe, Asia, and white North Africa. Negro characters, such as sickling of cells on deoxygenation and a raised cDe frequency, are absent.

SUMMARY

Among 104 unrelated Yemenite Jews no sickle-cell trait was found when their blood was reduced by chemical means.

Their blood-group picture resembles that of the peoples of Europe and Western Asia and the white peoples of North Africa.

Their Rh chromosome cDe has a frequency of 1·4%, compared with about 2% in Europe and more than 50% in Negroes.

Their chromosome cD^ue has the exceptionally high frequency of 20%. The only other known community with a comparable frequency is that of the Touaregs (North-African whites).

We are grateful to Dr. R. N. Salaman, F.R.S., for pointing out that, although most of the experts assume that the Yemenite Jews arrived in South Arabia at the time of the destruction of the second temple, others hold the view (unpublished) that there were but few of them, and that the present-day Yemenite Jews are descended from Arab converts. Even then they would represent a "Semitic" group which did not experience the miscegenation of the Jews of Europe. One of us (F. D.) was helped by the Research Council of the Government of Israel and one (H. L.) by the Nuffield Foundation. We are indebted to these two organisations and would also like to acknowledge gratefully the help of Mrs. A. C. Kopeć, D.SC., of the Nuffield Blood Group Centre of the Royal Anthropological Institute, London, in calculating the frequencies reported here.

ISONIAZID IN LEPROSY

JOHN LOWE
M.D. Birm., M.R.C.P.
SENIOR SPECIALIST, NIGERIA LEPROSY SERVICE,
UZUAKOLI, NIGERIA

THE link between tuberculosis and leprosy is perhaps most obvious in the similarity of the causative organisms, and in the fact that some chemotherapeutic agents seem to act on both organisms. Indeed the two groups of drugs most effective in leprosy (sulphones and thiosemicarbazones) were originally designed for use in tuberculosis; and the promising early reports on the action of isoniazid in tuberculosis have naturally led to its trial in leprosy.

A trial began here in April, 1952, and lasted 5½ months. The reports of the action of isoniazid in tuberculosis suggested that it might be of value in leprosy in two ways; it might be effective as a basic treatment of the disease itself; or it might be of value in the treatment of the acute and subacute complications of leprosy. The trial was therefore planned to study both these aspects of the chemotherapy of leprosy.

ISONIAZID IN UNCOMPLICATED LEPROSY

Newly diagnosed and completely untreated cases of leprosy were selected. Moreover, patients were chosen who showed easily visible lesions in which clinical improvement could be readily detected. There were 20 patients in this trial: 10 had "lepromatous" disease, in which the prognosis without treatment is poor and improvement with treatment is slow; 10 had "tuberculoid" leprosy, in which prognosis is relatively good, in which slow spontaneous improvement is often seen, and in which improvement under treatment is often rapid.

Dosage

At the start of the trial the *initial* dose of isoniazid was 50 mg. a day, rising to 100 mg. and 150 mg. in the second and third weeks respectively. As the trial progressed it became clear that isoniazid was very well tolerated but the response to treatment was poor, so an attempt was made to improve the response by starting with doses of 200 or even 300 mg. a day. The highest dosage given was 300 mg. a day.

Results in Tuberculoid Leprosy

The 10 patients were treated for periods varying between eight and nineteen weeks. In all cases the disease was active, with thickened raised red lesions in the skin, and often with thickening and inflammation of nerves, including the cutaneous nerves supplying the lesions and the nerve-trunks of the affected parts, particularly the ulnar and peroneal nerves. Ordinary bacteriological examination of the lesions for leprosy bacilli was usually negative, and the assessment of results had to be made on clinical grounds alone.

As I have previously pointed out (Lowe 1936), these lesions often subside slowly without treatment, and they usually respond to sulphones or thiosemicarbazones in a few weeks (Lowe 1950, 1952, Lowe and Davey 1951).

Under treatment with isoniazid, only 1 patient out of the 10 showed any definite improvement; 3 showed possibly a slight improvement; 5 showed no change whatever; and 1 became definitely worse.

These results are very disappointing, for they could easily have been just the same with no treatment at all. They were in no way comparable to those regularly obtained with sulphones and thiosemicarbazones in similar cases. The therapeutic action of isoniazid in such cases seems negligible.

Results in Lepromatous Leprosy

The 10 lepromatous patients had had no previous treatment; the disease was not too severe, and there were easily visible lesions in which clinical improvement could be quickly detected. These patients were treated for periods up to twenty-three weeks, and only 1 had less than fourteen weeks' treatment. They were all very suitable cases for chemotherapy. The general condition of the patients and the appearance of the lesions were watched for signs of improvement, and repeated bacteriological examinations of the lesions were made to detect any decrease in the number of bacilli or any change in their morphology.

At the end of the trial, not a single patient showed definite improvement; there were 4 who might have improved very slightly; 4 showed no change; and 2 were clearly worse. In no case were bacilli definitely less, and no distinct morphological change in bacilli was observed.

In this form of leprosy, the disease usually gets worse without treatment, but very slowly, and improvement under treatment is also very slow. It may, therefore, seem difficult or impossible to assess the value of isoniazid in such cases after only twenty-three weeks or less. Nevertheless, I have no hesitation in saying that in this group of very favourable cases, sulphone or thiosemicarbazone would have produced definite clinical and some bacteriological improvement in a considerable number within this time. These findings, while not proving that isoniazid is inactive in lepromatous leprosy, strongly suggest that it has little or no action.

ISONIAZID IN THE COMPLICATIONS OF LEPROSY

Some reports of the use of isoniazid in tuberculosis have emphasised its value in the control of acute and subacute manifestations, suggesting that it might have a similar action in leprosy.

To investigate this point, 7 patients were chosen in whom treatment with sulphone or thiosemicarbazone had become difficult because of acute and subacute complications. They were all lepromatous cases. The complications, which had probably been precipitated by the previous treatment, took the form of repeated "reactions," with fever, erythema nodosum, neuritis, and other acute or subacute manifestations. Such attacks are well known during chemotherapy; they usually subside slowly when treatment is stopped, but they often recur if treatment is resumed, or even if it is withheld indefinitely. Isoniazid was tried in the hope that it might diminish the frequency and severity of these attacks.

All 7 patients were given isoniazid for the first time during an attack, and the acute symptoms subsided in 6 of them. Thus the early results were good, but the late results were very variable. After treatment for from fifteen to twenty-three weeks, 3 of the 7 patients were relatively free from acute symptoms; 2 were perhaps slightly better; 1 was no better; and 1 (with ulnar neuritis) had responded only to surgical treatment. These results are very similar to those obtained simply by stopping chemotherapy, and they again suggest that isoniazid is inactive in leprosy. None of the patients showed any evidence of definite improvement in the underlying infection.

CONCLUSIONS AND SUMMARY

Isoniazid has produced no significant improvement in 27 patients with leprosy who were treated for periods of from fourteen to twenty-three weeks. The patients were chosen as particularly suitable for showing the results of chemotherapy.

Isoniazid is possibly of slight benefit in leprosy, but its action is much less than that of sulphone or thiosemicarbazone in comparable cases. It may have some value in the treatment of acute and subacute manifestations of the disease, but the findings in this trial were not at all conclusive.

My thanks are due to Miss F. McNulty, laboratory superintendent, for her help with this work; to Dr. K. S. Seal, of the Nigeria Leprosy Service, for supervising the work during my absence; to Dr. T. F. Davey, Leprosy Adviser to the Nigeria Government, and Dr. S. L. A. Manuwa, Inspector-General of Medical Services, Nigeria, for permission to publish these results; and to Dr. R. Forgan of Messrs. May & Baker for supplies of izoniazid.

DIETARY LIVER NECROSIS

INFLUENCE OF ENVIRONMENTAL TEMPERATURE AND MODE OF FEEDING ON ITS PRODUCTION IN THE RAT

J. M. Naftalin
M.B. Glasg., D.P.H.
PATHOLOGIST, ROWETT RESEARCH INSTITUTE, ABERDEEN

In a previous paper (Naftalin 1951) I showed that, when young male albino rats were offered a low-protein diet deficient in vitamin E, the incidence of acute liver necrosis depended on the environmental temperature and on the mode of feeding—i.e., whether the rats were allowed to eat to appetite or not. On comparing the results of three separate experiments it was *postulated* that the same degree of food restriction would give different results at different environmental temperatures. Experiment 4 described below was designed to test this postulate in one experiment. Littermates were used so that the ratios of food eaten by the different groups would be directly comparable. Two degrees of restriction and two environmental temperatures were studied. This experiment and experiment 5 define the lower and upper limits of favourable environmental temperatures for the production of acute dietary liver necrosis in the rat.

METHODS

Male albino rats were studied in both experiments. The procedures of rearing, management, and acclimatisation were as previously described (Naftalin 1951).

Environments

In both experiments the dry-bulb air-temperature was recorded on seven-day thermographs placed in the centre of one wall in the room:

Experiment 4 (November, 1950–February, 1951).—Two environments were studied: (1) heated animal-house, usual range of temperature 70°–78°F, extreme range 64°–80°F (groups A, B, and C, of 12 rats each); (2) heated animal-house, usual range 60°–64°F, extreme range 58°–70°, each extreme on one occasion for short period of half a day (groups D, E, and F, each of 12 rats).

Experiment 5 (March–June, 1951).—Two environments were studied: (1) heated animal-house, extreme range 72°–76°F (group H of 9 rats); and (2) heated animal-house, extreme range 88°–92°F (groups I of 10 rats, J of 6 rats, and K of 9 rats). The temperatures remained within these ranges throughout the experiment.

Food

The *diets* used in experiment 4 were those previously described—i.e., diet no. 51 containing 16% casein (Glaxo 'Vitamin-Free') and 3% yeast from the 18th day of age till the 37th day, and diet no. 47 containing 8% casein and 3% yeast from the 38th day. In experiment 5 choline chloride (200 mg. per 100 g. of diet) was added to both diets to prevent an acute hæmorrhagic lesion of the kidneys. This lesion was found in experiment 4 when 8 rats died aged 25–28 days—i.e., in the pre-experimental period—but was not encountered in the three previous experiments with diet no. 51.

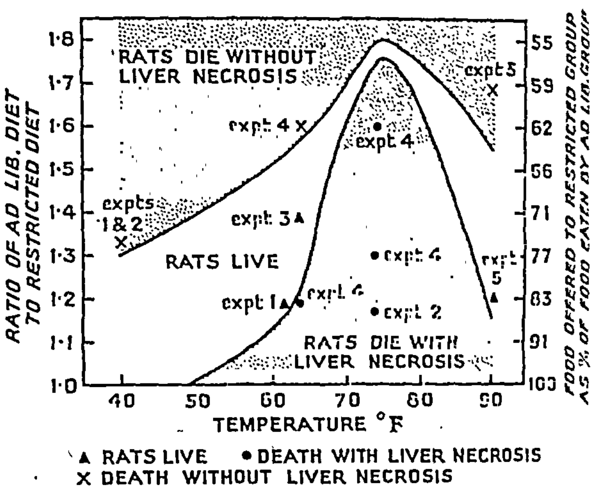
Feeding.—Groups A and D of experiment 4 and groups H and I of experiment 5 were allowed to eat according to appetite. The food consumption of each rat in both experiments was measured at about 10 A.M. daily.

"*Restricted*" *feeding.*—Groups B, C, E, and F of experiment 4 and groups J and K of experiment 5 were not fed to appetite. The degree of food restriction aimed at was such that in experiment 4 the ratio of food eaten by group A to group B was 1·2; A/C 1·5; D/E 1·2; and D/F 1·5; and in experiment 5 I/J 1·2; and I/K 1·6. The ratio was determined daily by taking the average food intake of the rats in the corresponding groups fed to appetite and then feeding to the "restricted" groups the calculated amount. At the conclusion of the experiment a calculation for the *group* average degree of food restriction for groups B, C, E, or F was made by taking the average of the food eaten daily by the rats in the groups fed to appetite (group A or D) and dividing by the average amount of food offered daily to these "restricted" groups. These ratios differed slightly from the ratios aimed at, because after a rat died its average food intake was not taken into account in the feeding of the "res[illegible]" [illegible]. These final ratios are indicated in the [illegible].

RESULTS AND DISCUSSION *

Optimum Environmental Temperature for Production of Liver Necrosis

In experiment 4, in the rats fed to appetite in the environmental temperature of 60°–64°F the incidence of acute liver necrosis was 4 among 12 rats (group D); in the environmental temperature of 70°–78°F (group A) the incidence of acute liver necrosis was 12 among 12 rats. The probability of such a difference in incidence between groups A and D arising by chance is less than 1 in 100.



The values "food restriction/environmental temperature" obtained in experiments 1–5 have been plotted and two curves drawn round them. These curves are appoximate, and the exact values may not hold for other diets of different percentage composition. It has been assumed that optimal temperature for the production of dietary liver necrosis is about 75°F.

In experiment 5, in group H, environmental temperature of 72°–76°F, the incidence of acute liver necrosis was 9 among 9 rats, with a median survival-time of 15 days, whereas at 88°–92°F, group I, 9 of 10 rats died of acute liver necrosis, the median survival-time being 29 days, a difference which did not quite reach the 5% level of significance.

It is thus evident that 60°–64°F is too low, and 88°–92°F too high for the optimum environmental temperature for the production of liver necrosis. As the range of 80°–88°F has not yet been studied, the optimum temperature has not been defined within narrower limits. Meanwhile it can be said that an environmental temperature of about 75°F is suitable for the production of a high incidence of dietary liver necrosis in rats.

Degree of Food Restriction

The results obtained with different degrees of food restriction depend on the environmental temperature.

At 70°–78°F the greater degree of restriction, 1·6, was insufficient to prevent liver necrosis in every rat in group C, 3 of 12 rats dying from liver necrosis, whereas a similar degree of restriction led to deaths without liver necrosis at 60°–64°F and 88°–92°F (group F, 3 deaths; group K, 7 deaths). This supports the postulate put forward previously. When the temperature fell below about 45°F, even a moderate degree of restriction, 1·3–1·4, led to death without liver necrosis (experiment 1). With a lower degree of restriction, 1·2–1·3, the incidence of liver necrosis at 70°–78°F was the same as in the groups fed "ad lib." (experiments 2 and 4). This high incidence of liver necrosis in group B, experiment 4, took place despite a fall in temperature to about 68°F (lowest 64°F for half a day) from Dec. 26, 1950, to Jan. 11, 1951. During this period there were no deaths in group B, the median survival-time thus being exaggerated (group B, 50 days; group A, 15 days).

In contrast with these results, at an environmental temperature of about 63°F in experiment 1 liver necrosis was prevented by a low degree of food restriction (1·15). The rats survived the experiment. However, in the corresponding group fed to appetite the food intake of only 2 rats was studied for a week. In experiment 3 the degree of food restriction of 1·6 was used at the beginning, but, though this was dropped to 1·25–1·4, liver necrosis did not result, the rats again surviving the experiment. However, in experiment 4, group B environmental temperature 60°–64°F, 6 of 12 rats died from acute liver necrosis when the group average degree of food restriction was 1·2, the median survival time being 64 days. It thus seems that a group average degree of food restriction of 1·2 is too low at 60°–64°F to prevent liver necrosis in every rat. In group D of this experiment the wide range of food eaten, 7·2 g. to 12·1 g. per rat per day made it difficult to assess the degree of food restriction in individual rats. Again, at 88°–92°F a small degree of restriction of 1·2 sufficed for protection against liver necrosis.

---

* Multigraphed tables showing the results in detail may be had on application to the office of THE LANCET, 7, Adam Street, Adelphi, London, W.C.2.

The evidence from studying the degree of food restriction thus confirmed that the optimum temperature for production of the disease was above 64°F and below 88°F. Further, from the study of the amount of food eaten it was shown that it was the manner of feeding and the degree of food restriction in relation to the environmental temperature and not the amount of food eaten per se that determined whether a rat survived or died of liver necrosis or of inanition.

For experiments 1–5 the degree of food restriction was plotted against environmental temperature, and two curves were drawn by hand, separating the groups which died from necrosis from the survivals and from those which died from inanition. This is shown in the accompanying figure which brings out clearly the relation between food restriction and environmental temperature. The base-line represents the rats which ate to appetite. It has been assumed that their sensitivity to liver necrosis is greatest in the region of 75°F. The values are not to be taken as absolute, because sufficient points have not been obtained experimentally. Furthermore, these ratios are based on observations on young male albino rats weaned on their 24th day of life, given the experimental low-protein diet about their 38th day when they weighed 60–80 g., and fed on the diet described in this paper and the previous one. Although the trend is clear, the exact values may not hold for diets of other percentage composition or with ingredients of different make.

The biochemical significance of these changes in ratios is not yet clear. The prevention of necrosis by low environmental temperature or the increased survival-time at a high temperature may not be an expression of the same changes in metabolism as those due to a "restricted" method of feeding. These results support the view that different pathways of metabolism are followed under different conditions, and the manner in which the liver functions depends on the total body metabolism.

SUMMARY

A high incidence of acute liver necrosis was produced in young male albino rats when they were housed in a suitable environment and allowed to eat to appetite of a diet containing 8% casein (Glaxo 'Vitamin-Free'), 3% yeast (Pharmaco-Chemical Products), 7% lard, 2% cod-liver oil (B.P.), 76% sucrose, and 4% McCollum's salt and B vitamins, but without added vitamin E.

Of the three ranges of environmental temperature studied—60°–64°F, 70°–78°F, and 88°–92°F—the best temperature for the production of acute liver necrosis was 70°–78°F.

A sufficient degree of food restriction prevented liver necrosis at all environmental temperatures studied, but a too severe degree of food restriction led to death without liver necrosis. Whether a rat survived or died of necrosis or of inanition depended on the degree of food restriction in relation to the environmental temperature and not on the amount of food eaten.

I am indebted to Mr. A. W. Boyne, of the Rowett Institute, for the statistical design of the experiments and for much helpful discussion.

RICKETS AND AMINO-ACIDURIA

J. H. P. JONXIS P. A. SMITH

T. H. J. HUISMAN

From the Kinderkliniek, Academisch Ziekenhuis, Groningen, and the Zuiderziekenhuis, Rotterdam

SMALL amounts of amino-acids, peptides, and conjugates are found in the urine of healthy children. The quantities of these depend to some extent on the composition of the food (Dunn et al. 1947, Harvey and Horwitt 1949), but the concentration of the free amino-nitrogen in the 24-hour urine of a normal child seldom exceeds 20 mg. per 100 ml. This is approximately equivalent to a concentration of free amino-acids of 200 mg. per 100 ml. When the amino-acid composition of the diet is incomplete or when certain drugs are taken—e.g., salicylates—which are partly excreted as glycine-conjugates, the urinary output of amino-acids is considerably greater. Of the individual amino-acids it is normal for the urine of adults and infants to contain some glycine and histidine, smaller amounts of serine, threonine, alanine, and lysine, and only a trace of many others. Acid hydrolysis may free considerable amounts of glutamic acid and aspartic acid, and generally also additional glycine.

When investigating the differences in the amino-acid excretion of infants fed on breast-milk or cow's milk Jonxis (1951) noticed that some children with incipient rickets excreted considerably more amino-acids than the others, and this observation led to a more detailed study of the amino-aciduria in rachitic children. Little is known about this. Abnormal amino-aciduria is part of the Toni-Fanconi-Debré syndrome (McCune et al. 1943), but this form of osteomalacia is not thought to be due primarily to a vitamin-D deficiency.

MATERIAL AND METHODS

Nine children with uncomplicated rickets have been examined. Their ages ranged from 6 to 15 months, and none of them had been given any vitamin D. The X-ray pictures of their bones showed the usual abnormalities. After admission to the hospital the children were given a diet suitable to their age and weight and containing about 2·5 g. of protein per kg. of body-weight. The main source of this protein was cow's milk, of which 500 ml. daily was given to each child. Since a deficiency of vitamin C may cause an increased output of amino-acids (Jonxis and Wadman 1951) 100 mg. of ascorbic acid was given daily to each child during the first few days after admission. A sample of blood was withdrawn for the determination of calcium, phosphate, and phosphatase, and the urine was collected for 72 hours. Vitamin D 300,000 I.U. dissolved in 3 ml. of arachis oil, was then given by mouth, and 8–35 days later the levels of calcium, phosphate, and alkaline phosphatase in the serum were again determined, and the urine was again collected over 72 hours. Further radiographs were also taken. The amino-acid excretion of 10 healthy children of ages similar to those with rickets was also studied over 72 hours. In addition to this, siblings and other relatives of some of the rachitic children were examined clinically and biochemically.

The urine was stored at −20°C till it could be examined for amino-acids. The simple copper method of Albanese and Irby (1944) was used to get a general impression of the extent of the amino-aciduria, but the more accurate ninhydrin and carbon dioxide method of van Slyke et al. (1941) was also usually applied before and after acid hydrolysis. The increase of the percentage of amino-nitrogen after hydrolysis gave a measure of the quantity of amino-acids which had been present as peptides and conjugates. In addition to this, two-

dimensional paper chromatograms were made by the technique described by Dent (1949).

RESULTS

Table I shows the findings in the serum and in the urine of the rachitic children before and after treatment, and table II the quantities of amino-acids and peptides excreted by normal children. It will be seen that the excretion of free amino-acids and of peptides and conjugates by children with florid rickets was much greater than normal. During recovery the excretion both of free and bound amino-acids decreased, and in some of the children—e.g., case 4—the fall in the excretion of bound amino-acids was the greater. Six other children were examined less completely, and the findings in them were essentially similar. If the changes in the serum are compared with those in the urine, it will be noted that the decrease of the amino-acid excretion, like that of the phosphatase activity in the serum, was relatively slow, requiring about a month to be complete. Before this time the serum-calcium and serum-phosphorus levels had reached their normal values, and an improvement could be demonstrated radiologically in the bones. Serial findings in case 4 are shown in table III.

From tables I and II it seems that, even after recovery, the urinary output of amino-acids of some of the patients remained greater than that of normal healthy children. An older brother of patient no. 5 had already been under treatment for severe rickets, and this led us to investigate the excretion of amino-acids by all the members of this family. Table IV shows that two of the brothers (aged 5 and 13) and the mother of patient no. 5 excreted an increased amount of amino-acids in the urine and had signs of former rickets. The mothers of three other patients (nos. 4, 7, and 9) also showed signs of having had severe rickets and excreted abnormally high concentrations of amino-acids in their urine.

DISCUSSION

There is still much to be learnt about the increased excretion of amino-acids, which has been found to be part of the rachitic syndrome and to persist throughout life in persons who have had rickets. The indications at present are that the fault lies in the kidneys, because the level of amino- nitrogen in the plasma of these patients is within the normal range and does not exceed 7 mg. per 100 ml. Results of two-dimensional paper chromatography of the urine indicate that the amino-acids excreted are those which are normally present in urine in appreciable quantities (glycine, histidine, alanine, lysine, serine, and threonine), and not those which would be expected if the levels in the plasma were to rise abnormally after a meal (arginine, lysine, and

* Had severe rickets.

glutamic acid). The paper chromatograms have not suggested the presence in the urines of any amino-acids not normally found there.

It is known that in rickets some of the renal functions are not normal, for the reabsorption of phosphate is diminished (Harrison and Harrison 1941). According to some investigators (Albright and Reifenstein 1948) this is caused by a secondary hyperparathyroidism, which may in its turn be the result of a deficiency of serum-calcium. Zetterström (1951) holds that the defect in the reabsorption of phosphate is a primary result of the vitamin-D deficiency. Possibly the defective reabsorption of phosphate and that of amino-acids, peptides, and conjugates are interrelated and may even be due to a fault in the same part of the trouble. Under treatment, however, the phosphate in the blood of rachitic children reaches its normal level before the amino-acid excretion does (table III), and the fall in the latter has a time-relation more in keeping with that of the alkaline-phosphatase activity.

Until now simple rickets has not been thought to be heriditary, although resistant rickets has long been known to be so (Gill 1939, Freeman and Dunsky 1950). The present results suggest that there may be important hereditary factors in the genesis of uncomplicated rickets, and further study may throw light on the mechanisms of this inheritance.

SUMMARY

Children with rickets excreted much more amino-nitrogen in free and bound form than did normal children.

Within a month after treatment with calciferol the excretion was reduced, but not as a rule to a strictly normal level.

Members of a family with rickets or signs of old rickets excreted more amino-acids than did the others.

Preliminary Communication

ESTIMATION OF BLOOD-DEXTROSE BY A RAPID OPHTHALMOSCOPIC METHOD

THIS note describes a method of estimating the blood-dextrose by means of an adapted ophthalmoscope. This method gives an approximation to the blood-dextrose within ± 20 mg. per 100 mg. per 100 ml.

The ophthalmoscope is fitted with a device for measuring the intensity of illumination of the retina when a beam of light is shone through the pupil. Originally the ophthalmoscope was fitted with two polaroid screens, one of which could be rotated over a scale, and a monochromatic light filter to give a sharp cut-off. The red reflex was observed and the analyser rotated till extinction occurred. An alternative device achieves the same end using neutral graded wedges, but the polarising ophthalmoscope is more accurate.

The unit area illumination intensity of the retina so measured, using the pupil as a stop, is found to vary quantitatively with the blood-dextrose. This illumination change is probably due to alteration in the refraction of the eye. It is already known that eye refraction is affected by changes in blood-dextrose.[1] This is in keeping with the observation of many patients that their vision is impaired when the blood-dextrose changes. Experiments are proceeding to investigate the nature of this alteration which may be due to a physicochemical effect on the lens protein.

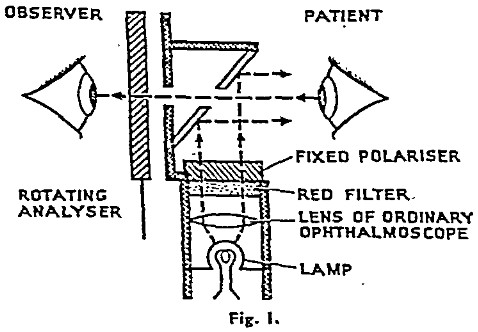

Fig. 1.

When suitable corrections for diffusion-rate of dextrose, pupil size, and refractive error are applied, a reading of the blood-dextrose can be given from the analyser rotation and a calibration curve, within ± 20 mg. per 100 mg. per 100 ml. of the laboratory finding in the Folin-Wu tube. A reading takes 45 seconds to complete. The correlation coefficient of 100 readings with the laboratory estimations is 0·954.

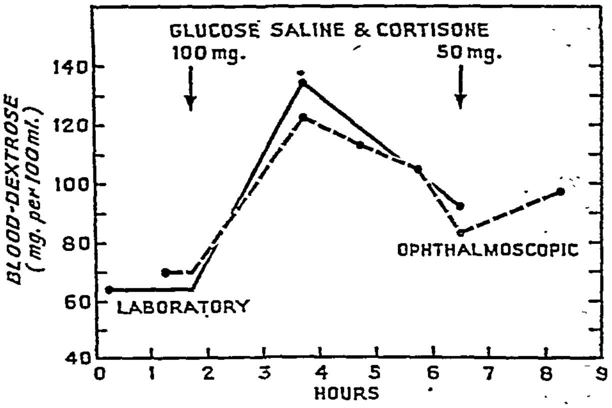

Fig. 2—Comparison between Folin-Wu and optical methods. The 100 mg. and 50 mg. refer to oral doses of cortisone.

This method has an obvious practical value, since in the diabetic clinic an approximate estimation of the blood-dextrose can be made within one minute of the patient's arrival, or at the bedside serial readings can be taken at short intervals, without taking blood. The necessary attachments are readily mounted on an ordinary ophthalmoscope.

Fig. 1 illustrates the principle of the instrument. Fig. 2 shows a comparison between Folin-Wu and optical methods under conditions of varying blood-sugar in a patient during an addisonian crisis.

It must be emphasised that this device is still experimental and that its use requires care and practice.

Medical Societies

MANCHESTER MEDICAL SOCIETY

Research in General Practice

AT a meeting on Oct. 27 of the Manchester Medical Society's section of general practice, Prof. ROBERT PLATT discussed Opportunities for Research in General Practice. He regretted the lack of articles by general practitioners in medical journals. This was partly due, he thought, to a wrong attitude towards research which assumed that it could only be carried out by whole-time workers with special facilities. The conventional idea of a research-worker was of an austere man in a white coat with a background of complicated glassware. His idea of a research-worker, on the other hand, was of a man who cleaned his teeth only on the left side so as to use the right side as a control to see if tooth-brushing had any effect on the incidence of caries. In other words, research depended largely on an attitude of mind. It need not be time-consuming but involved the design of a policy in order to answer a question. With very little added work one could plan a campaign—for use, for instance, in an influenza epidemic, when it could be quickly proved whether a certain line of treatment had any effect in reducing complications. In a dysentery epidemic during the late war he had done a similar research which had demonstrated the uselessness of sodium sulphate and the value of sulphaguanidine. Such observations could not be made in hospitals; for cases were highly selected before admission. It was important to think statistically; but this did not mean that one had to be highly trained in statistical theory.

Certain subjects particularly lent themselves to investigation by general practitioners—for instance, the incidence of common diseases such as migraine and hypertension, and the treatment of common disorders including neuroses. Other disorders in which plenty of problems awaited solution included rheumatism, obesity, sciatica, emphysema, and constipation. Every attempt at therapy was in fact an experiment. All who had the necessary attitude could engage in research.

New Inventions

A STRETCHER CHAIR WITH MANY USES IN HOSPITAL AND HOME NURSING

PREVIOUSLY we used the "Swedish chair"[1] on the neurosurgical ward, and this made bathroom privileges easier for hemiplegic, paraplegic, and other crippled patients. However, it was still a great feat of strength and ingenuity to lift a heavy paralysed patient into the Swedish chair. In addition, we looked for a contrivance that would hasten early convalescence. In the first two models (aided by a research grant from the Department of Veterans Affairs) we converted a stretcher into a chair by an elevator mechanism.[2] Later it was suggested that a mobile parallelogram might be the solution to the problem. This required balancing the stretcher with heavy weights. A sliding plane was then introduced into the parallelogram. With this third model we met with continued enthusiasm from many different groups of nurses and medical people who hope to discard the bedpan in modern nursing.[3] Many other uses were suggested—as a reading-chair, in the X-ray department for evacuation of enemas, as an X-ray stretcher, as a demonstration chair in amphitheatre clinics, and as a Swedish chair or hospital commode.

The stretcher chair is 6 ft. long. In the stretcher position it is 20 in. wide. In the sitting position the seat drops to 18 in. from the floor. The frame is of welded aluminium tubing, which rides on ball-bearing swivel wheels 5 in. in diameter with foot locks. The foam-rubber cushions are covered with sturdy 'Fabricoid' of good quality. Two handles, one on either side of the frame, are conveniently located. Thirty-five turns of the handle will raise or lower the chair from a sitting position at normal chair height (18 in. from the floor) to a stretcher position at hospital-bed height. The smooth action of the gearbox, located in the back of the frame, and the durable stainless-steel cables operate a parallelogram. The gearbox is self-locking; its action can take place by turning the handle in a clockwise or an anticlockwise direction. This mechanism effects the change of position of the back rest, the seat rest, and the leg rest. It is possible to stop the motion of the chair at any position between the full stretch and the sitting position or to provide a reclining position. A removable foot rest is provided for comfort in the sitting position; it is adjustable and designed to suit both very short and very tall people. The seat cushion is removable. There is a slide under the toilet seat where a stainless-steel bedpan can be inserted.

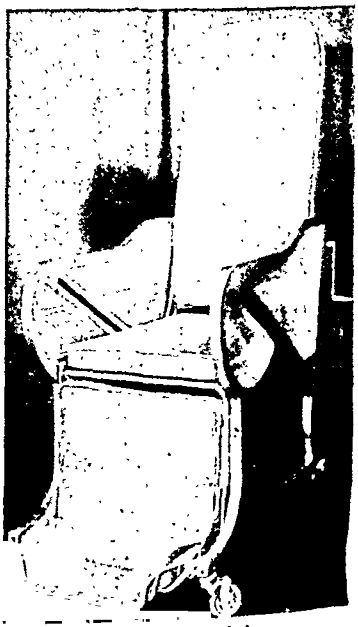

Fig. 2—As chair.

Under the name of the 'Stretchair,' the chair can be obtained from the Robert Mitchell Co., Ville St. Laurent, Montreal, who have made its construction possible. We are particularly indebted to Mr. St. C. Holland and Mr. G. A. Johnson of their research division.

Reviews of Books

Westminster Hospital 1719-1948

JOHN LANGDON-DAVIES. London: John Murray. 1952. Pp. 274. 21s.

ON Jan. 14, 1716, four citizens, Henry Hoare, Robert Witham, William Wogan, and Patrick Coburn, met at St. Dunstan's Coffee House to discuss their concern over the sick poor of Westminster. A banker, a brewer, a writer on religious subjects, and an ex-curate, they were a strange quartet with only vague conceptions of how to reduce the human misery in their midst. Yet from that meeting came eventually the founding of the first modern voluntary hospital in London. Starting with the nucleus provided by the four Westminster philanthropists, Mr. Langdon-Davies traces the development of research and therapy through the dark days of insanitation and all the evils consequent upon ignorance and poverty, step by step to the present day. If in dealing with such advances as antisepsis, anæsthesia, and nursing reforms he emphasises the part played by Westminster this is natural in the writer of a hospital history. He has had access to the complete set of minutes preserved by the hospital authorities and to the comprehensive outline of the hospital's history contributed by Mr. Walter Spencer to the Reports in 1924. His other sources included manuscripts in the Wellcome Medical Museum Library and the files of THE LANCET, and his biographical details include THE LANCET's venomous attack upon Sir Anthony Carlisle in 1838. The animosity displayed towards their colleagues by members of a staff makes strange reading today. Mr. Langdon-Davies's biographical sketches end in 1893 with an account of Mr. Spencer's attempt to ensure surgical efficiency; and, while recognising the difficulties, one cannot help regretting the lack of references to later members of the staff, some of whom have made substantial contributions to medicine. Apparently, too, the medical school was regarded as outside Mr. Langdon-Davies's terms of reference, for he says very little about its interesting vicissitudes and remarkable development. His book, however, has the advantage of being the work of a skilled journalist, able to grasp essentials and present them attractively. In describing the new hospital building it pays well-deserved tribute to the "key men on the Executive Building Committee," Mr. Charles Power with his great experience of hospital organisation and administration, and Sir Ernest Rock Carling with his genius for understanding other people's techniques.

Diabetes and Pregnancy

RALPH A. REIS, M.D., F.A.C.S., professor of obstetrics and gynæcology, Northwestern University Medical School; EDWIN J. DECOSTA, M.D., F.A.C.S., assistant professor of obstetrics and gynæcology, Northwestern University Medical School; M. DAVID ALLWEISS, M.D., associate in medicine, Northwestern University Medical School. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1952. Pp. 78. 18s.

IN this addition (no. 158) to the American Lecture Series the authors express what they term the "in between view" on strict control of diabetes during pregnancy and induction of labour; but analysis suggests that their standards of diabetic control are as high as any in this country. They conclude that the only proven way in which diabetes may affect pregnancy is by giving rise to an oversize fœtus. Their figures do not support White's view that fœtal malformations are prevalent in pregnancies associated with diabetes. They ascribe their unusually low incidence of toxæmia to their custom of warning patients with vascular and renal complications against bearing children, and to the small proportion of their patients who had been juvenile diabetics. They deny that, with our present knowledge, hormones other than insulin can be usefully given to pregnant diabetics. The monograph draws attention to the danger of early postnatal hypoglycæmia in the infants of diabetic mothers. The authors are on less firm ground when they attempt to state the probabilities of diabetes developing in the children of diabetic mothers as precisely as if dealing with the inheritance of hæmophilia.

Handbook of Tropical Dermatology and Medical Mycology

Vol. I. Editor: R. D. G. Ph. SIMONS, M.D., senior lecturer, dermatological clinic, University of Leyden, Netherlands. Amsterdam and London: Elsevier Publishing Co. 1952. Pp. 845. £5.

IN this work a team of 80 contributors have attempted to cover every tropical skin affection with a completeness never before achieved; and it can be said straight away that they have succeeded. Not only have they dealt with an extensive range of subjects, but they have given a balanced picture of the many diseases involving other systems besides the skin. The subject matter has been critically selected, and the work is up to date, authoritative, and well documented. The lavish illustrations are all excellent.

To translate into homogeneous English contributions from so many Continental and other authorities was a formidable task, which has been carried out well, though the inevitable occasional error has slipped in here and there. Dr. Simons hopes that the volume will be of use to dermatologists and physicians in all parts of the tropics. It may well be more than this, for those practising in the temperate regions will also find it a valuable work of reference.

The Forgotten Language

ERICH FROMM. London: Gollancz. 1952. Pp. 224. 16s.

AS an elementary introduction to dream interpretation this book fulfils its purpose; it takes from well-known sources historical and expository quotations, links them together with an easy commentary, and persuades the ingenuous reader that the language of symbolism in dreams can be learnt without great effort: indeed, the author urges that the understanding of symbolic language should be taught in schools "just as other 'foreign languages' are part of their curriculum."

He appends a lengthy final chapter on symbolism in myths, fairy-tales, and ritual: the Œdipus myth is reconsidered in the light of Bachofen's theory of the transition in ancient religions and societies, with the result that Dr. Fromm discerns in Sophocles's trilogy not the theme of incest and hate through jealousy which Freud has stressed, but a tragic fight between the matriarchal and the patriarchal principle, exemplified in the hostility between father and son. This excursion, and others that examine the creation myth, Little Red Riding Hood, the Sabbath, and Kafka's *The Trial*, has less coherence and point than general readers might expect in a primer of the universal symbolic language which Dr. Fromm is convinced we should all learn to understand.

International Review of Cytology

Vol. 1. Editors: G. H. BOURNE, D.SC., London Hospital Medical College; J. F. DANIELLI, D.SC., zoology department, King's College, London. New York: Academic Press. 1952. Pp. 368. $7.80.

THIS volume has been issued under the auspices of the International Society for Cell Biology, and the editors hope to publish succeeding volumes annually. They intend to keep the scope of the review as wide as possible so that all aspects of cell biology may in due course be represented. The growth of new physical and micro-techniques during the last few years has led to many advances in knowledge of cytochemistry and micro-structure of cells.

A. F. Hughes briefly relates the history of cell biology. C. L. Huskins deals with nuclear reproduction. G. W. Kidder reviews enzyme capacities and their relation to cell-nutrition in animals; and L. G. E. Bell contributes a valuable article on the application of freezing and drying techniques to cytology. The chapter by Rosenberg and Wilbrandt on enzymatic processes in cell-membrane penetration is mainly physiological; yet, since it may throw light on the cell-membrane, this work also extends the range of cytology. Bisset's review of bacterial cytology is also valuable. R. Brown gives a short account of the problems of absorption of sugar by plant tissues in relation to protoplast surface enzymes. A. D. Hershey's excellent account of the reproduction of bacteriophage, in which the genetical, cytological, and chemical aspects are related to each other, is some indication of the intrinsic value of the whole volume and of the wisdom of the editors in keeping the range of subject-matter as wide as possible. Goldacre's article on the folding and unfolding of protein molecules as a basis of osmotic work is one of the few misfits of the volume. The ideas presented may be valuable; but they are not at present fully substantiated. Fankhauser's useful paper on nucleo-cytoplasmic relations in amphibian development gives an important place to embryological cytology. Swann discusses structural agents in mitosis, chiefly from the evidence of polarised light experiments. M. Singer's informative account of the factors which control the staining of tissue sections with acid and basic dyes is restricted to colouring proteins, and leaves out the attempts at rationalising staining reactions and cytochemistry. The method of estimating the iso-electric point of a tissue protein by finding the pH of minimal retention of acidic and basic dyes is interesting.

Lord Rothschild describes the behaviour of spermatozoa in the neighbourhood of ova. W. Montagna's conscientious review of the cytology of mammalian epidermis and sebaceous glands will probably be of more interest to the cytologically minded medical histologist than to general cytologists. L. H. Bretschneider's contribution on the use of the electron microscope in the investigation of tissue sections is of dubious value; fig. 3 (p. 312) is a good example of maltreated cells, and many of the objects shown could have been photographed with a higher numerical aperture light or ultraviolet microscope to show the same features. Glass knives are not mentioned. G. Gomori ends the book with a valuable account of the histochemistry of esterases. The index is useful though incomplete.

Physiologie normale et pathologique du métabolisme de l'eau

JEAN HAMBURGER, professeur agrégé à la Faculté de Médecine des Hôpitaux de Paris; GEORGES MATHÉ, interne médaille d'or des Hôpitaux de Paris. Paris: Flammarion. 1952. Pp. 502.

THE first half of this book is a well-written and up-to-date account of the amount and distribution of water in the body, and the regulation of water-balance, and can be recommended to the general reader as well as to the specialist. The second part, although equally lucid and well written, is more alien to prevalent notions on body-fluid imbalance.

Excellent features of the physiological section are the clear diagrams, adequate accounts of experimental methods, and a useful conversion table from mg. per 100 ml. to m.eq. per litre, and milli-osmols per litre for the different ions. The authors are aware that osmotic forces are not the sole determinant of water distribution, and they describe interesting experimental work showing that depression of cell metabolism leads to an accumulation of water in the cell. Perhaps the title of the book, with its stress on water, has led to some disproportion of emphasis, for little space is given to electrolyte balance, which often determines water-balance.

In the second half of the book, dealing with pathological water metabolism, we become more conscious that in France they order this matter, if not better, at least differently. Cellular dehydration and overhydration are contrasted with extracellular dehydration and overhydration; whereas in the English and American literature the emphasis is either on electrolyte deficit and excess, or on water depletion or excess which affects extracellular and intracellular fluid alike. Our more detailed analysis perhaps gives more definite guidance to treatment. The authors discuss therapeutic principles, but they have not found space for details, and there are some omissions, such as the use of sodium lactate in patients with diarrhœa, and osmotic diuretics in the treatment of œdema. The international bibliography contains 2536 references.

Spread of Tumours in the Human Body

2nd ed. R. A. WILLIS, M.D., D.SC. Melb., F.R.C.P., professor of pathology, Leeds University. London: Butterworth. 1952. Pp. 447. 63*s*.

THE first edition of this book when it was published in 1934 established Professor Willis's reputation as an authority on neoplastic disease. In its new form the work is a companion volume to his *Pathology of Tumours.* The general arrangement of the subject-matter is the same as in the first edition, but many sections have been revised and some rewritten. About 260 references have been added to the bibliography; and the appendix of case-notes on necropsies which Professor Willis has performed is increased by 177. The figures, mostly photomicrographs, are fewer and they are now collected at the end of the book. There seems little advantage in this. Many of them have suffered less reduction than in the first edition, and their reproduction is correspondingly clearer. The book will prove of great value and interest to all students of neoplastic disease.

Problems of Aging

Transactions of the Fourteenth Conference. Sept. 7-8, 1951. Editor: NATHAN W. SHOCK, M.D., chief, section on gerontology, National Heart Institute, New York. Josiah Macy, Jr., Foundation. New York: 1952. Pp. 138. $3.

THIS verbatim report of a two-day conference between American, British, Danish, and Swiss representatives shows how indivisible are the problems of ageing. The care of the aged is so intimately bound up with the causes of ageing and with the prevention of the disabilities of the aged that any serious discussion of the subject must range over medicine, biology, and sociology.

The colloquial form makes the report difficult to read, and the significance of some of the physiological experiments in the biological section may escape the general reader. The discussion section on sociology, psychology, and education produced no concrete suggestions, apart from a vague wish to arrive at a "longitudinal study of ageing." But the facts given by the representatives of the different countries in the sections on economics, welfare, and employment, and on medical services show what can be done to ensure that the life of the old can be useful to the world and pleasant to themselves.

The conference were in favour of the elderly continuing at work in some employment suitable to their age. The drawback to this policy is that many, if not most, elderly people have an overwhelming desire to retire at about the age of 65. But delegates remained convinced of the importance of retaining the aged as normal members of the community. The growing appreciation of this fact is one of the justifications for a conference such as this.

A Method of Anatomy (5th ed. London: *Baillière,* Tindall, & Cox. 1952. Pp. 870. 54*s*.).—Here, from Toronto, is the new edition of Prof. J. C. Boileau Grant's delightful textbook, where the text dangles fly-papers in the track of wayward memory, and the diagrams all but speak. It has been revised, clarified, rearranged, and shortened in some places, amplified in others; and it has acquired 78 new illustrations. Thus it remains the same good friend, only better. We still have to regret that Professor Grant has not included the central nervous system.

Surgical Instruments and Appliances used in Operations (14th ed. London: Faber & Faber. 1952. Pp. 160. 8*s*. 6*d*.).—In 1905, Mr. Harold Burrows produced the first edition of this useful little book. Mr. Ronald Raven, his collaborator, points out in the preface to this new edition that the text has been radically revised in order to bring in the many important advances since the publication of the 13th edition three years ago. The book is intended to help house-surgeons, theatre sisters, and surgical nurses; and it is fully qualified to do so.

The Science and Practice of Surgery (9th ed. London: J. & A. Churchill. 1952. Vol. I. Pp. 872. 32*s*. Vol. 2. Pp. 1019. 36*s*.).—Mr. W. H. C. Romanis and the late Mr. Philip Mitchiner, with the help of collaborators on many special subjects, present again this well-tried textbook. Principles in surgery, as they point out in their preface, have altered little in the quarter of a century of this book's life; but the increased scope of the science of surgery has led to extensive specialisation. Students, however, need principles; and this book, despite its title, aims as ever at teaching them the roots and trunk of principles rather than the twigs and efflorescence of science and practice. New material has been included only when it has been thoroughly established, and when the authors have convinced themselves it has real value. The result is perhaps more sober and trustworthy than lively and stimulating, an impression which is fortified by some rather elderly illustrations. The authors note that several of the older ones have been replaced, and some new ones have been included; but we hope to see the process carried further.

THE LANCET

LONDON: SATURDAY, NOV. 22, 1952

The Extracorporeal Heart

With their new-found power, cardiac surgeons look ambitiously to the day when they can work in a dry field while the circulation is sustained through a by-pass by means of a pump and oxygenator. Circulatory pumps of the Dale-Schuster and other types have long been used in physiological laboratories, and much basic work has been done on oxygenators. Kolff,[1] working with the artificial kidney in Holland in the dark days of enemy occupation, showed that it was feasible to make blood circulate outside the body, "wash" it clear of uræmic constituents, and return it to a vein; but only a small rate of blood-flow was necessary in this extra circulation.

For cardiac surgery in adults the pumps will have to handle 5 litres per minute, and Dodrill and his associates[2] have found that this is mechanically possible. The machines themselves present a difficult problem in sterilisation. Autoclaving or formalin sterilisation seems to be best, but these methods are not easily applied to a complex system of tubing, connections, and moving parts. Furthermore, small traces of blood residues from previous use may be a troublesome source of toxic material. The next difficulty is to prevent clotting. Heparinising the patient may lead to oozing unless dosage is very carefully gauged; at the end of the pumping period the action of heparin has to be terminated by giving a large dose of protamine sulphate, which induces severe hypotension.[3] Another problem connected with heparin is that of small fibrin threads which have to be filtered out in the machine. Renal infarcts and other embolic troubles have been noted in dogs after use of the extracorporeal heart.[3] The Scylla of clotting and the Charybdis of bleeding caused Mustard and Chute[4] to abandon artificial oxygenators in favour of an animal lung, but even then only 10 of 45 dogs survived circulatory by-pass experiments. Suction-cannulæ can be placed in the atrium, from which blood is drawn for oxygenation and later returned to the aorta, perhaps by a cannula up the femoral artery. If the atrium is opened before the pump is emptying the heart completely, hæmorrhage will occur; alternatively air may be sucked into the pump with rapidly fatal consequences. In devices where blood is oxygenated under high pressure and is then forced into the arterial system under the high pressure necessary when plastic catheters are used, dissolved gases may reappear as bubbles in the circulation unless this danger is guarded against. The biological problems are no less troublesome. Emptying of the right auricle is apparently accompanied by severe reflex hypotension and bradycardia[2]; and leucocytes may be trapped in the extracorporeal circuit with consequent leucopenia. Fischer and his associates,[5] who used dog lungs as the oxygenator for experiments in dogs, plaintively remark: "It hardly seems possible that so many pitfalls could present themselves in the performance of these seemingly simple experiments."

Mustard and Chute[4] used a monkey lung as the oxygenator in dealing with blue babies; they were kept alive for as long as three hours,[6] but the conditions operated on by the surgeon proved intractable, and there was thus no opportunity to observe any subsequent complications from this device. Dodrill and his co-workers[7] by-passed the left ventricle in a case of mitral valve disease, taking blood from the left auricle to the aorta via a cannula inserted up the left subclavian artery. By this means they avoided oxygenator troubles and also hypotensive reflexes from the empty right heart.[2] The patient recovered after fifty minutes of circulatory substitution at a rate of $4^1/_2$ litres of blood per minute. In Cincinnati a machine has been used to assist oxygenation in a patient with severe pulmonary fibrosis and cor pulmonale.[8] Blood was drawn from the inferior vena cava by a long catheter threaded up from the saphenous vein on one side. After oxygenation blood was returned via the opposite saphenous vein. As much as 1280 ml. per minute was passed through the machine; arterial oxygen saturation improved from 43 to 58–65%, and respiration became quieter. In this instance no leucopenia developed. There was, however, no sustained improvement and the patient died two weeks later. Necropsy showed no untoward effects from the extracorporeal circuit.

We still seem to be some way from the useful application of all this work. The problems are still formidable, and until some of these are solved its practical value will remain doubtful. Gross and his associates[9] have shown that atrial septal defects can be tackled by another means. When the patient is laid on the left side and a rubber bag or well is attached to the auricular wall, hardly any blood spills from the open auricle, since the pressure is low, and the hole can be repaired at the bottom of the pool of blood.

Latter-day Pilgrims

Few problems so tantalise man as human behaviour. Addressing the New York Academy of Medicine last month, Prof. Franz Alexander suggested that this was governed by two impulses: one was to seek security, and the other to embark on creative venture. These were essential and complementary aspects of life, but the second became manifest only if mankind had at its disposal a surplus of energy after ensuring self-preservation.

In the past, American civilisation had been characterised by a spirit of self-confidence and adventure, but a trend towards seeking security above all things

was becoming evident in the young generation. Dr. ALEXANDER cited an inquiry in 1948 which disclosed that half the young men in a representative sample preferred a safe job, even if it were relatively poorly paid. A similar opinion poll conducted by *Fortune* Magazine[1] in 1949 showed that only 2% of college students intended to go into business on their own: most of the students wanted to work for large firms, which they thought would be more "depression-proof" than small concerns. Much of this quest for security was, no doubt, the aftermath of two world wars and the depression of the '30s; but, as in all mass social phenomena, there had been a considerable over-reaction. Probably, Dr. ALEXANDER continued, many people in the Western world lived nowadays in a state akin to panic, owing not only to the catastrophes that had befallen them but to their feeling that the complex and rapidly changing social and economic conditions of the modern world were beyond the individual's comprehension or control. When the mass of people felt that their world was frighteningly chaotic, they yearned for strong, authoritative leadership; and security became the boon which they craved above all else. Prof. ARNOLD TOYNBEE's[2] conclusion that civilisations made their greatest progress in an unfavourable environment should correct extreme pessimism: within limits, unfavourable conditions stimulated men not only to make the effort necessary for survival but to go beyond this and excel in cultural creativeness. Nevertheless it was obvious that impossibly difficult conditions could have a paralysing effect, with all available energy spent in the struggle to survive: at present half of America's resources were being devoted to rearmament. There was a danger that an emotional reaction, due to continued frustration, might explode in the Western community, as in an individual goaded to rage. Perhaps, too, Western civilisation was entering a period of decline; in TOYNBEE's view this began with the tendency towards centralised and solidified government. This development had led earlier civilisations to eventual disintegration, for two reasons: first, the governed fell more and more out of sympathy with their rulers, who necessarily became more harsh and impersonal as their sphere of authority extended; and secondly, they became more liable to military defeat, since rigidly centralised régimes were apt to cling to obsolete, traditional weapons in warfare. In this respect, said Dr. ALEXANDER, the Western world might have an advantage. The problem before us was to organise our society for a reasonable measure of security, so that creative energies might once more be set free.

In this country the series of Reith lectures now being broadcast by the B.B.C. will perhaps enable us to see ourselves as others see us; for in this series Professor TOYNBEE is discussing the impact of the West on other civilisations. Conceivably Western man's quest for security, though it may lead to a period of stagnation and decline, reflects a deeply unconscious need for a breathing-space from his fiercely competitive, extraverted society, so that he may become acquainted with himself.

Oral Contraception

IN his presidential address this year to the British Association, Prof. A. V. HILL, F.R.S., spoke of the ethical dilemma for preventive medicine in the prospect that "the pressure of increasing population, uncontrolled by disease, would lead not only to widespread exhaustion of the soil and of other capital resources but also to continuing and increasing international tension and disorder, making it hard for civilisation to survive." A reliable contraceptive that could be taken by mouth would have revolutionary implications; it would hold out the hope that men and women might exercise that control over the numbers of their children which, in the words of the Royal Commission on Population, "is one of the first conditions of their own and the community's welfare." It is precisely this discovery that is claimed by SIEVE[1] in a preliminary report on a trial of phosphorylated hesperidin. This substance is said to act by inhibiting hyaluronidase, the enzyme that may assist the spermatozoa to penetrate the gel surrounding the unfertilised ovum.

There has been much previous work in this field. In 1929 DURAN-REYNALS[2] described a factor in aqueous extracts of mammalian testicle that enhanced the lesions of vaccinia in the skin. McCLEAN[3] reported that this action was due to a dramatic increase in the permeability of the dermis, and that the factor was associated with the spermatozoa. He found that the immediate diffusion of injected material containing the factor "is so striking that it can be compared to the different behaviour of a drop of water when placed upon glazed and upon blotting paper." This action on the tissues was confirmed by HOFFMAN and DURAN-REYNALS.[4] The enhancing action of this factor was studied in other viral and bacterial infections, and factors with similar diffusing properties were obtained from the most diverse sources—for example, from culture-filtrates and extracts of many species of invasive bacteria,[5] from snake and spider venoms,[6] and from leeches.[7] Meanwhile other workers[8] in the U.S.A. were studying the nature of the viscous polysaccharides in such mesodermal tissues as vitreous humour, synovial fluid, and umbilical cord; and they reported that these polysaccharides were hydrolysed, and their viscosity was destroyed, by a group of enzymes produced by such invasive organisms as pneumococci and *Clostridium welchii*. It remained for CHAIN and DUTHIE,[9] working in Oxford, to make the observation that elucidated the nature of spreading factors and which, at the same time, suggested the possible significance in infection of the enzymes that had been studied by the American workers. CHAIN and DUTHIE reported a remarkable mucolytic activity of spreading factors derived both from testis and from other sources; this activity was associated with a rapid fall in the viscosity of synovial fluid and the liberation of reducing substances; and they showed that there was a significant correlation between "spreading" and "mucolytic" activity. In 1933 McCLEAN and MORGAN[10] had reported that the addition of purified testicular extract to diphtheria antitoxin injected subcutaneously approximately

oubled its rate of absorption; subsequent work[11] showed hat this action was due to hyaluronidase, which has ince been used clinically.

The work of Long,[12] Yamane,[13] and Pincus and nzmann[14] had demonstrated that a substance present n semen dissolved the viscous gel cementing the cumulus ells around freshly ovulated rat ova. In 1942 McClean nd Rowlands[15] showed that hyaluronidase from any ource—testicular, bacterial, or from snake venom—ould disintegrate the cumulus cell mass of rat ova, nd that this was due to the specific activity of the nzyme since the rate of dispersal was directly proportional to the concentration of hyaluronidase in the arious preparations. They suggested that for fertilisation large numbers of sperms had to be in the vicinity f the ovum so as to produce a high enough concentration f enzyme to liquefy the gel and allow penetration by he single effective sperm. Fekete and Duran-Reynals[16] confirmed this with mouse ova. Later, Rowlands[17] observed an increase in the fertilising apacity of dilute rabbit-sperm suspensions on the ddition of hyaluronidase. The hyaluronidase content of semen and its release from spermatozoa was studied by Swyer,[18] who concluded that in men, rabbits, bulls, and boars there is a close correlation between concentration of sperm and enzyme; the spermatozoa do not actively produce hyaluronidase—they liberate the preformed enzyme at a rate which depends on its concentration in the plasma. This explains the release of sufficient enzyme in the fallopian tubes to bring about disintegration of the cumulus surrounding freshly ovulated ova. In 1948 Pincus et al.[19] reported that various substances which inhibited the viscosity-reducing activity of hyaluronidase in vitro also inhibited the follicle-cell-dispersing activity of semen-hyaluronidase in vitro, and that when the inhibitors were added to sperm suspensions artificially inseminated in rabbits, the number of ova fertilised was significantly reduced. These substances were also contraceptive when introduced in sufficient concentration into the vagina of naturally mated females. Martin and Beiler,[20] having found that phosphorylated hesperidin is a powerful non-toxic inhibitor of hyaluronidase, administered this substance either intraperitoneally or orally to groups of rats with suitable control groups and observed the results of mating. They claimed approximately 80% reduction of conception in the treated rats, which, moreover, mated successfully after hesperidin was discontinued. The action appeared to be specifically on the female, although the œstrus cycle remained normal during treatment. Meyer[21] had shown that hesperidin preserves the coronal cell layer round the ovum in the presence of spermatozoa.

In his preliminary report Sieve[1] records the trial of a hesperidin derivative in 300 married couples. Each had had at least one normal child, and 41% had a period of fertility control followed by a normal pregnancy and repeated therapy for a second period of control. There was no evidence that this drug impaired fertility after treatment was stopped. The period of fertility control varied from three to thirty months, but 61 couples (20%) were controlled continuously for thirty months; an undertaking was obtained that during the period of control no other contraceptive device would be employed. Phosphorylated hesperidin was given by mouth to both the male and female partners in divided doses on the basis of 5 mg. per kg. body-weight per day, plus about 20% to allow for missed doses. Thus people of normal weight took about 500 mg. per day in five tablets at meal-times. Sieve emphasises the importance of maintaining the blood-saturation level, but it is not clear why the males were treated as well as the females, since preliminary animal experiments had not indicated that this influenced the results significantly. Continuous treatment for ten days is believed necessary before fertility is controlled, but a lapse of forty-eight hours restores fertility. This hesperidin derivative caused no toxic signs or symptoms, and 15 couples were given twenty-five times the normal dose for up to fifty days without any apparent ill effects. Only further experience, however, can demonstrate whether this substance is really free from danger. The report shows only 2 failures in the whole series of 300 couples, and these 2 couples admitted to having failed to take the tablets. 280 couples followed the instructions precisely, and the other 18 missed only occasional doses.

These results are so astonishingly good compared with those in most biological experiments that scepticism is natural. If, however, the claims were to be confirmed, they would be of vast importance. As we recalled last week, Pirie[22] has pleaded in our columns for intensive research into "the metabolism of gametes and zygote with special regard to methods of interfering with it." As he said: "Until we know as much about the biochemistry of human gametes as we do about rabbit liver there is little chance of discovering those biochemical anomalies on which differential inhibition—i.e., rationally based contraception—must depend." Sieve's work on phospho-hesperidin may at least provide the stimulus needed to fulfil Pirie's hope.

Annotations

LESSONS FROM HISTORY

The creation of the Emergency Medical Service was one of the most interesting events of the late war. It was something new; it was an attempt at a comprehensive organisation; and it was the foundation on which the National Health Service was later built. The *Medical History of the War* is rightly giving two volumes to this valuable by-product of the conflict. The first, which has just appeared,[23] describes the origin, as far back as 1923, of what grew into the E.M.S. and how it was run when the emergency came. This volume deals only with England and Wales; the arrangements in Scotland and Northern Ireland will be described in the first parts of the next volume.

The story of the air-raids has also been reserved for the next volume, which for the general reader may be the more exciting of the two: but the doctor, consciously living in contemporary history, will find in this volume the subjects of the greatest interest. Colonel Dunn has fortunately made it eminently readable. It is not an orthodox official document: adverse comments on what happened have not been by any means omitted. But what will immediately strike any reader is the vastness and complexity of the organisation, and the success with which it was both built up and administered. Critics

of the Civil Service—and there are plenty of them among doctors—will agree that Government departments on the whole did a good piece of work. Such lapses as there were, both recorded and unrecorded (for example building X-ray departments which could only be reached through operating-theatres, without showing the plans to the radiologists or surgeons), were due to that ubiquitous infirmity of the administrative mind, the tendency to save trouble by making decisions without consulting the expert. On the other hand some of the most brilliant successes were due to handing over control to those who understood. For instance real power was entrusted to the sector officers, who were all men who had been familiar with hospital practice all their lives. Is that not an example of the wisdom of giving day-to-day control to the expert and reserving policy-making for laymen? And is there not another lesson to learn here? Of course, a sector officer was an officer and not a committee, and democracy is not a prime necessity in war-time. But it is becoming evident, in the National Health Service, that public control and public auditing and democratic theory can become objectives on their own account, fetishes divorced from necessity. To balance efficiency and liberty is a proper aim, but is the sacrifice of efficiency and liberty to ideology as desirable?

The relation under the E.M.S. of the social and positive health services to the service for the treatment of disease, inevitably raises the question of the possibility of greater unification in the future. What might have been the result, if, as might easily have happened, we had set up a national medical service, including the medical branches of the three fighting Services, responsible for the treatment of both Service and civilian casualties and for the general medical care of the population? Such a combined service would have been a relatively small step further than the E.M.S. It would have made transfers of man-power and equipment simpler, and it would have prevented overlap, duplication, and waste. What would have been the history of the National Health Service if this had been done? The service would already have been there, in military guise. Would a conversion to a civilian form have been made easier by pre-existence, or would the reaction against discipline, combined with the shortcomings of a rapidly evolved scheme, have turned the profession against it?

IMMUNOLOGICAL PROCEDURES

UNFORTUNATELY many students pass their final examinations knowing more of the biochemical activities of *Salmonella typhi* than of the steps to immunise against infection with this organism. H. J. Parish's admirable book,[1] published in 1948, is well designed to fill this gap; a well-known work published by the American Public Health Association[2] is more inclusive since it is intended for use the world over, but it lacks the details of procedure which are so useful to the novice. A third book,[3] just published, is intended to provide administrative and professional guidance to medical officers in the Army; but it will be equally valuable to their colleagues in civil life. It is hard to praise this work too highly.

The recruit, unless he raises strong objections, is immunised against smallpox, diphtheria, tetanus, and the enteric fevers. If he goes to tropical Africa vaccination against yellow fever will be added to the list; and on occasion it may be thought wise to protect him against typhus, cholera, plague, and rabies. The older soldier must have his immunity maintained, and his wife and children may or must share his protection. B.C.G. vaccination against tuberculosis is available for members of the R.A.M.C. and Q.A.R.A.N.C. To detailed and lucid guidance on all these procedures the book adds instructions on the techniques of inoculation, single and in mass, and on the sterilisation of syringes. We know of no better examination of the pros and cons and caveats attached to the different methods of sterilisation, and we are glad to see the hot-oil method for needles given its due. It is odd, however, that an Army which standardises its ordnance and its boot-brushes cannot do the same with needles, syringes, and sterilisers.

We feel that this book might have placed more emphasis on the value of passive immunisation for controlling epidemic diphtheria in a closed community. On the other hand, the account of serum reactions is clear and accurate; and the exhaustive directions for the storing of serological products in temperate and tropical climates will undoubtedly help to reduce the proportion of condemned stores and unsuccessful vaccinations. At the price of two shillings this work is as good a bargain as we have met in years.

THE DELINQUENT'S BACKGROUND

> "The seriousness of the situation is plainly seen from the figures. . . . There is need for energetic action by all who may be in a position to help."

THIS statement, from the Memorandum on Juvenile Delinquents issued jointly by the Home Office and Ministry of Education in 1949, is quoted by Dr. Edelston[1] as a justification for "yet another book" on delinquency. Professor Ferguson[2] also apologises "for yet another book"; but they both rightly emphasise that there is still much to be said and much to be found out, which is supported by the fact that their two books hardly overlap at all. Dr. Edelston writes as a clinician, and is particularly concerned with the psychological make-up of the child. "In the [illegible] only thing that can account for the [illegible] is his own personality" and each one is unique. He gives 30 case-histories, in 25 of which stealing was a prominent feature; and he says that no two were alike and that even the stealing had a different significance in each case. Professor Ferguson takes the complementary approach. Making use of material already collected on a group of ordinary boys, a group of physically handicapped boys, and a group of mentally handicapped boys, he now studies the prevalence of delinquency among them and examines the circumstances in the home, school, and social environment which appear to induce it.

Professor Ferguson has collected a great deal of valuable material and sets it forth in a way that makes it readily assimilable; it has already been much quoted and it is bound to carry great weight. Nevertheless his selection of data and his interpretation of them are sometimes open to statistical question. Thus he says that "in broken homes delinquency rates were worse when family disruption was due to a cause other than death"—a statement based on the finding that when disruption was due to death, the delinquency-rate was 12·5%, whereas when disruption was due to other causes the rate was 15%. But the numbers at risk were respectively 192 and 179, and the statistician would say that these percentages are not significantly different. There are other cases where the difference shown may have been due to chance, but this cannot be discovered from the figures given, without additional work. Anyone who as attempted this sort of survey will know that an normous amount of arithmetic has already been done o produce the figures Professor Ferguson offers; but hose who will make most use of his book would have een glad of even more.

[1] The Earliest Stages of Delinquency. By A. Edelston, M.B., D.P.M., psychiatrist and director, Bradford Child Guidance Clinic. Edinburgh and London: E. & S. Livingstone. 1952. Pp. 200. 10s. 6d.
[2] The Young Delinquent in his Social Setting. By T. Ferguson, professor of public health and social medicine, University of Glasgow. London: published for the Nuffield Foundation by the Oxford University Press. 1952. Pp. 155. 16s. 6d.

His most important observation is, perhaps, the extent o which dullness of intelligence is associated with elinquency. It seems that the lowest 10% on the ntelligence scale contribute at least half as many delinuents as the remaining 90% of the juvenile population. Moreover, there is a tendency for adverse factors to luster: the dull boy tends to come from a bad and vercrowded home, and to have other delinquents in his amily; he tends to take a blind-alley job and keep it or a short time only; and he is likely to be rated by his eachers as of poor personality, lacking in reliability, nitiative, and perseverance. This last proposition is of nterest because it is contrary to accepted psychological heory, which holds that "intellectual" and "personality" factors are independent. Could it be that the ssessment is at fault? Teachers are not objective scientific observers; they cannot easily dissociate the child from the setting in which they see him. A boy trying to cope with tasks at or above the limit of his capacity will be likely to reveal such defects as his personality may have; whereas the brighter child, who achieves the same task without effort, may be just as deficient in the sterling virtues but able to conceal this from his teachers.

PROCAINE AMIDE

THE precise status of procaine amide as a substitute for quinidine in the treatment of cardiac arrhythmias is still a matter of controversy among cardiologists. Last year[1] we suggested that procaine amide was the drug of choice in the treatment of paroxysmal ventricular tachycardia, and that it was of value in abolishing troublesome ventricular extrasystoles, but that there was no evidence that it was of value in the treatment of auricular arrhythmias. Some reports which have been published since then suggest that side-effects may be commoner than was originally appreciated. In dogs, for instance, Harris et al.[2] found procaine amide to be "very effective" in reducing the frequency of severe ectopic ventricular tachycardia associated with myocardial infarction, but, in view of 3 fatalities, they recommend that "in all cases of severe ectopic ventricular tachycardia only that amount of drug which is required to reduce the ectopic rate to a safely low range and to maintain it at a low level should be administered." They also advise that in such cases the drug should be given under simultaneous electrocardiographic control. Charlier[3] came to the same conclusion from his experience with the drug in anæsthetised dogs in which ventricular arrhythmia had been induced by aconite nitrate.

Although there is still some uncertainty as to whether or not procaine amide is of value in the treatment of auricular arrhythmias, the balance of opinion favours the view that it is not. On the basis of his findings in 2 patients with ventricular arrhythmia and one with auricular arrhythmia, Schaffer[4] does not believe that it has "a preferential effectiveness on ventricular as compared to auricular arrhythmias," while Miller and his colleagues[5] report restoration of normal rhythm following its use in each of 7 cases of paroxysmal auricular fibrillation, in 6 of 13 cases of chronic auricular fibrillation, and in 2 of 3 cases of auricular flutter. They emphasise that such patients should be digitalised before procaine amide is given. On the other hand, Zapata-Diaz et al.[6] conclude from their clinical and experimental work that in auricular flutter the use of procaine amide is "dangerous because it can lead to a 1 : 1 atrioventricular response," and that, while it may restore sinus rhythm in paroxysmal auricular fibrillation, "it does not seem to be devoid of danger." Bellet et al.[7] found that auricular fibrillation did not respond to procaine amide in the 11 patients they treated with it; and Schreiner and Kelley[8] describe the onset of ventricular tachycardia following the use of procaine amide in a patient with auricular fibrillation. Schack et al.[9] found that auricular fibrillation and flutter of over three years' standing were unaffected, though some auricular arrhythmias that had resisted quinidine responded to the drug by mouth. However, reports of its efficacy in controlling ventricular arrhythmias continue to appear.[10–12] Another use suggested for procaine amide is to give it before cardiac catheterisation, as a means of preventing induced arrhythmias,[13] but Lucas and Short[12] could not confirm its value for this purpose.

The toxic effects which have been reported may be divided into those involving the heart and those of non-cardiac origin. The latter include a case of agranulocytosis,[14] a generalised reaction,[15] and an allergic reaction involving the skin.[16] In all 3 cases the procaine amide was given by mouth, and all 3 patients recovered. Among the cardiac side-effects are ventricular fibrillation[17 18] and ventricular tachycardia,[19] and here the drug was given intravenously. This question of how to give procaine amide is one of the major difficulties in its use. Oral administration is unreliable in its effect, except for maintenance doses, and it is liable to produce nausea and vomiting. The intravenous route is potentially dangerous unless the drug is given by what almost amounts to a drip technique and under electrocardiographic cover; it can therefore be considered only in emergencies. Fortunately, evidence is now accumulating that the intramuscular route may prove relatively safe and effective. Bellet and his colleagues[7] have shown that an intramuscular injection of 1 g. of procaine amide raises the blood-level of the drug in five minutes; a peak is reached in fifteen minutes to one hour, and significant levels are still present after six hours. In spite of the relatively large volume of the injections given—up to 15 ml.—no irritation or swelling appeared at the site of injection. It may well be, therefore, that the safest and most effective method of using procaine amide is by the intramuscular route, reserving the intravenous route for cases of real urgency. The exact position about oral treatment is still in doubt, but it should probably be reserved for maintenance doses and, to a lesser extent, for initial trial in patients whose condition is not urgent. In a certain number of these patients it will be effective, and so remove the need for intramuscular injection. But, however it may be used, procaine amide must only be given under strict supervision and, certainly in the early stages of treatment, this means in hospital.

ACCIDENTAL POISONING IN CHILDREN

ALTHOUGH poisoning is relatively uncommon among children, some recent reports [1-3] suggest that it is on the increase. This increase is probably due to the large number of medicines and other potential poisons which are now brought into the home, and to overcrowded living conditions which increase the risk of these substances being left where children can get at them.

The child may be brought to the doctor with a story of having taken a known or, more commonly, an unknown quantity of some known substance; or he may have been found with a bottle or container whose contents are unknown; or he may have symptoms which the parents do not suspect to be the result of poisoning. Such symptoms may be vomiting, diarrhœa, cyanosis, drowsiness, loss of consciousness, convulsions, or collapse—any of which should suggest to the doctor the possibility of poisoning. The diagnosis may be made in some cases by smelling a volatile substance in the child's breath, or by recognising a characteristic set of symptoms and signs; but it may be necessary to analyse the vomit, urine, or blood to identify the poison.

If the nature and quantity of the poison are unknown, it is hard to decide how energetically to treat an apparently well child, but the fatal cases reported by Dr. Slade [4] indicate that it is always wise to assume that a dangerous amount has been taken. First-aid treatment with a salt or mustard and water emetic may safely be advised over the telephone, except when the poison is a corrosive or a volatile hydrocarbon. The parents should also be instructed to save any material vomited or urine passed.

Gastric lavage has long been considered a more effective method of removing poisons from the stomach than emesis, but there are certain objections to its use in children. Passing a stomach-tube can be a harmful business both physically and psychologically, and it may provoke a fatal convulsion. Moreover, solid objects, such as berries and tablets, may not be returned through the tube. The procedure is often ineffective in other ways,[5] and the introduction of fluid into the stomach may cause the pylorus to open and actually hasten the absorption of a poison. It is probably better to rely on emetics in children, and of these the best for the doctor's use is apomorphine, which should be given by subcutaneous injection. This drug has the advantages of diminishing intestinal motility and acting as a sedative, but it is, of course, contra-indicated in poisoning by opium alkaloids, or when the child is semi-comatose from any other cause. Another line of treatment which has long been followed, but whose value is doubtful, is the administration of purgatives: so far from promoting excretion of the poison, purgatives may hasten absorption by increasing intestinal motility, and syrup of figs was thought to have done so in one of Slade's cases. There is, however, no such objection to the use of daily enemata. In the case of poisons affecting the central nervous system, further elimination may be achieved by lumbar puncture.

When all possible steps have been taken to remove the poison from the body, an appropriate antidote can be given or, if the poison is unidentified, a universal antidote of charcoal, tannic acid, and magnesium oxide. Too much should not be expected from such treatment, however, and it should not be relied upon while action against the systemic effects of the poison is neglected.[2] Such action consists in counteracting loss of fluid and electrolytes, treating circulatory and respiratory failure, and giving physiological antidotes to neutralise the effect of the poison *after* it has been absorbed—e.g., methylene blue in toxic methæmoglobinæmia,[6] and dimercaprol (BAL) in poisoning by arsenic and certain metals. When the nature of the poison is known, the appropriate substance should be given before the onset of symptoms. The danger of convulsions in young children is very great, and it is advisable to give a barbiturate sedative in all cases of poisoning not caused by hypnotics.

Of course, the best treatment of all is preventive, and the old lessons must be put before parents (and others) as often and as forcibly as possible, especially when highly coloured or sugar-coated preparations are being prescribed. Nevertheless, dangerous drugs will continue to come by accident or oversight into the hands of children, and there seems little justification for continuing to manufacture potentially lethal substances in such an attractive form.

PHOTOSENSITISING SUBSTANCES

PHOTOSENSITISATION of the animal skin is exactly analogous to the action of the dye added to a panchromatic plate to extend its sensitivity-spectrum: it occurs when the tissues contain a substance converting light into chemical energy, which in turn produces local cell damage. In man the only well-known form of photosensitisation is that in congenital porphyria, where the photosensitising agent is probably uroporphyrin. In animals, however, several agents in addition to porphyrins may give rise to similar syndromes. These veterinary conditions have been reviewed by Clare [7] in a little book which might well be read by medical biologists.

Veterinary diseases giving rise to photosensitivity fall into three groups: (1) those in which the sensitising substance comes from an error of metabolism, as in cattle porphyria; (2) those in which it is ingested directly in the diet; and (3) those in which the primary disorder is a blocking of liver metabolism which prevents the destruction of chlorophyll derivatives. The most important substances in the second group are hypericin, a complex polyhydroxy-polycyclic compound from many species of St. John's wort, and fagopyrin from buckwheat. Of greater interest to human medicine is the photosensitisation due to phenothiazine used as a vermifuge. In man drug photosensitivity is uncommon; but it might lead to unpleasant side-effects in a first test, under tropical conditions, of material which had passed toxicity tests on clothed volunteers in a temperate climate.

In hepatogenous photosensitivity the sensitiser is phylloerythrin. This pigment is normally detectable in the bile and fæces of herbivores, though it may appear in other animals given large amounts of chlorophyll. In liver derangement due to various plant poisons the blood-phylloerythrin rises to a photosensitising level, and necrotic skin lesions appear. In some strains of sheep the inability to deal with this pigment appears to be congenital. Phylloerythrin has never been demonstrated, it appears, in human plasma; but possibly the chlorophyll fad, combined with a hot summer and a hobnailed liver, may yet yield an unsought demonstration of its presence.

In addition to the possible action of drugs or plant poisons, the study of photosensitivity in animals has a further bearing on porphyria in man. The episodic type of porphyria has at least some of the characters of a hepatogenous photosensitivity, in which an inborn metabolic error gives rise to the sensitising substance, a high concentration of which appears in the blood during a hepatic crisis. Photosensitivity is now increasingly recognised in some of these episodic porphyrias as well

as in the congenital form. There is also the striking observation of de Mello[8] that photosensitivity can itself induce porphyria. Rabbits sensitised with rose bengal and irradiated with ultraviolet light were found to have a grossly increased coproporphyrin output. This observation cannot yet be fitted into the general pattern of our knowledge of porphyrin metabolism, though it may prove important. Coproporphyrin itself has never been convicted as a sensitising material—probably the mechanism of its excretion is too efficient.

The whole subject of photosensitivity in its toxic, congenital, and hepatogenous forms is one where veterinary and human medicine could usefully converse occasionally—the knowledge obtained from animals might explain some of the obscure dermatological conditions, especially in the tropics.

SOCIETY FOR SPASTICS

THE National Spastics Society has been set up by the parents of children suffering from cerebral palsy, and its membership is entirely confined to them. The aim of this society,[9] under the presidency of Prof. J. M. Mackintosh, is to spread information and encouragement about spastic children to parents and others. In order to do this it must try to discover more parents of spastic children and adult spastics and bring them into the association. It must also try constantly to increase the number of local associations so as to cover the whole country and ensure a widespread interest in meeting this difficult problem. There are now parents' associations in nearly fifty towns in England and Wales; but all who are interested need to do much more work in starting new centres, in collecting funds for development, and in approaching local authorities for their help in providing education and medical care. The child with cerebral palsy is an outstanding example of the need for effective coöperation between voluntary effort and the State.

The total number of spastic children in this country is not known, but investigations have shown that the total cannot be far short of 30,000. Of these some 10% are of high average or superior intelligence, and a further 50% are educable. Of the remainder a substantial proportion may greatly benefit from new methods of training; wherever schools have been established for spastic children a surprisingly large number have clearly been helped by education combined with therapy. There is great need for various types of provision for such children; and experiment and assessment are necessary in order to find the right combination of services. The traditional view was that a spastic child could not develop mentally beyond the limits of his motor experience, because he had to translate his ideas into muscular activity in order to grasp anything. Thus the first object in treating a spastic was to educate his muscles until some control was secured. Until this goal was reached, academic instruction was deferred, and it might be neglected for ever. Only lately has it been realised that mental growth brought about through academic education promotes physical control as well as skill in circumventing a physical difficulty. As Carlson has said: "The spastic is ordinarily a badly spoiled child, completely lacking in self-discipline and the power of concentration. Yet it is only through the acquisition of these qualities that he can overcome his handicap. As a school is obviously the best way to develop his powers, it is also the best means of taking the child's mind off his own difficulties and thus increasing the benefits of physiotherapy, which cannot stand by itself as a form of treatment."

The diagnosis of cerebral palsy in a small child is by no means easy, but this is not the most serious difficulty. In the past the trouble has been rather that a hasty diagnosis was made by someone strange to the child, who, after comparatively superficial assessment, was assumed to be mentally defective and was relegated to the tragic ranks of the ineducable. It is now quite clear that no child should be regarded as ineducable until his condition has been thoroughly assessed; and the investigation should include an expert examination of sight and hearing and careful estimation of intelligence against the background of age and physical capacity.

The primary service to a spastic child is educational, and the special needs are as follows:

Day-nursery clinics where children may be brought for observation, proper assessment of their handicaps, treatment, and the all-important social contacts with other children: where parents can learn what treatment to carry on at home and understand better how to adjust themselves to having a handicapped child.

Day special schools or cerebral-palsy units in existing schools for physically handicapped children aged 5–16 years, in large cities; and special provision for children of lower mental grade, who tend to be ignored because of the great difficulty of finding the right type of occupational care.

Residential special schools which will provide for spastic children from the smaller towns and rural areas.

A residential special secondary school to take children of above-average intelligence whose handicap is such that they are unlikely to get jobs needing physical dexterity and whose brains must therefore be their main asset.

Residential homes for the very badly handicapped who have little or no hope of being trained for a vocation. There is seldom a vacancy for these children in other homes or institutions.

Training centres where adolescents and adults may receive treatment, be trained for a job, and get equipment that will make the job easier to do.

TREATMENT OF BENIGN TERTIAN MALARIA

BENIGN tertian malaria is not usually dangerous in itself, but it is an intractable and highly incapacitating nuisance, unworthy of the term "benign"; it would better be known as *Plasmodium vivax* malaria. In one way it is not intractable, for individual attacks respond readily enough to all the recognised drugs—quinine, mepacrine, proguanil, or chloroquine—but none of these can be relied on to prevent relapse. In the tropics *P. vivax* malaria has a short incubation period, and the primary attack takes place soon after the infective mosquito bite; the tissue phase persists and relapses are common. The archetype of *P. vivax* causing this form is the Chesson strain, which originated in the South-west Pacific area. But in temperate climates in Europe and America, and now notably in Korea, there exist strains of *P. vivax* which behave quite differently: there is either a long incubation period lasting several months or, after a primary attack at the end of a short incubation period, a latent period of six to nine months after which relapses tend to occur. The archetype of this form of *P. vivax* is the St. Elizabeth strain, which originated in the United States. Late relapses have been noted in American troops after returning from Korea, even though they had taken chloroquine regularly in the transmission season and, in many cases, had not had any primary attack in Korea. Chloroquine did not prevent infection and relapse; it did suppress the clinical manifestations of infection so long as it was taken regularly, but when it was discontinued the blood forms developed unhindered from the tissue phase, which had evidently persisted unharmed by the suppressive drug.

It has long been known that drugs of the 8-aminoquinoline series (pamaquin ['Plasmoquine'], pentaquine, isopentaquine) may prevent relapses if taken at the time of, or shortly after, the curative courses of quinine, mepacrine, or chloroquine; but drugs of this series may produce toxic effects in amounts not far removed from the minimum effective doses. The U.S. Council on Pharmacy and Chemistry reports work[1-4] done on a little known 8-aminoquinoline—primaquine (8-[4-amino-1-methylbutylamino]-6-methoxyquinoline)—which appears to be as effective as pamaquin but less toxic. Primaquine was synthesised at Columbia University during the great anti-malaria programme in the late war, and was tested on volunteers and in the field. It has now been used on a large scale in troops returning from Korea.

---

[8] de Mello, R. P. *Proc. Soc. exp. Biol., N.Y.* 1949, 72, 292.

[9] The society's headquarters are at 20, Pembroke Road London, W.8.

The first test[1] was made to find out if primaquine could safely be given to large numbers of men. The plan was to administer 15 mg. of primaquine base each day for two weeks, starting at the time of arrival at the military depot in Japan, and ending usually during the voyage home. During the malaria season in Korea the men had received chloroquine as a routine suppressive measure, but this was discontinued before primaquine was administered. In one combined test 2060 officers and men received 12–20 pills of primaquine (15 mg. of base), and 725 men received a placebo. This test showed that the drug could be handled effectively with large numbers of men, and was not toxic.

Garrison et al.[2] report that, of 232 men with first attacks of *P. vivax* malaria after a long latent period who were treated with chloroquine alone for three days, 27·6% had relapsed after four to eleven months; of 246 given chloroquine for three days and pamaquin (27 mg. of base daily) for fourteen days 0·4% relapsed; and of 231 given chloroquine and primaquine (15 mg. of base daily) none relapsed. Neither pamaquin nor primaquine, however, is effective against the erythrocyte stages of the parasite, and these drugs should therefore not be relied on for treating the acute attack; they should, according to Garrison et al., be given together with chloroquine. Pamaquin, and probably primaquine, should not be given at the same time as mepacrine.

Clayman et al.[3] describe toxicity studies in a large number of white volunteers. Primaquine was given in a daily dosage varying from 10 to 240 mg. of base, in single or divided doses, for five to fourteen days, alone or with other drugs, either for the treatment of clinical malaria or in the absence of clinical malaria. It was also given in a dosage of 30 mg. of base once or twice weekly for a year, together with chloroquine. It seems that at a daily dosage of 15 mg. of base, primaquine may safely be administered continuously for two weeks without special medical supervision, and adult white patients receiving as much as 30 mg. a day may remain up and about as outpatients. But at higher doses supervision in hospital is advisable; methæmoglobinæmia and abdominal symptoms, including vomiting, have been observed. Thus in white people the drug is fairly safe; but in Negroes this is not so, and Hockwald et al.[4] recall that the 8-aminoquinolines sometimes give rise to very severe hæmolytic crises resembling blackwater fever, and that these are especially common in Negroes. Primaquine in a daily dose of 30 mg. (base) gave rise to anæmia in 17 of 105 Negroes; and in 5 of these there was hæmolysis. With 30 mg. of pamaquin (base) these 5 men showed similar severe anæmia. They tolerated 15 mg. of primaquine daily, however, and Hockwald et al. conclude that 15 mg. of base can safely be given daily for two weeks to Negroes. It may be given with quinine or chloroquine, but never with mepacrine.

Primaquine is therefore a useful addition to the drugs we use for *P. vivax* malaria; it is, dose for dose, more effective and less toxic than pamaquin.

YESTERDAY IN TODAY

THE medical man is apt to think of history as a harmless hobby which collects the amusing superstitions and bric-a-brac of the past. Twentieth-century medicine is dizzy with the speed of its own advance. Scientific change is so rapid that the historic may be thought synonymous with the out of date, and to be out of date is to be guilty of the unforgivable sin. We sometimes forget that medicine is always a by-product of its times, not only in its scientific equipment but in its philosophy and objectives. In community medicine, as in other fields of policy, every situation is the result of historical developments, and only if these are understood can we plan properly for the present and future. We must know where we have come from to see where we should go next.

Dr. Henry Sigerist has done more than anyone in our time to teach medical men the importance of historical approach. He has brought immense learning to the study of the history of medicine; but to him historical study is not an end in itself, it is a lesson for today. It is not only a necessary instrument of policy, it is an important discipline in medical teaching.

In his Heath Clark lectures at the London School of Hygiene and Tropical Medicine, Dr. Sigerist ranges from Galen to the present time, using a cavalcade method to demonstrate medicine and medical policy as one aspect of the contemporary culture. Thus Galen's teaching on hygiene was an expression of the fact that for the Roman patricians to whom it was directed, the cult of the body was an end in itself. The Galenical philosophy on which the teaching was based lingered on in the Middle Ages, but its impact was quite different because Christianity had taught a different view of the body through whose suffering redemption might come. In the field of State medicine it is significant that the first major work comes from the eighteenth-century search for the philosophy of good government for the masses under benevolent despotism. Johann Peter Frank (*System einer vollständigen medicinischen Polizey*, 1779) in the period of the enlightened man had no less an ambition than the study of the health needs of man in his total environment, physical and social, and his policies were to be enforced by the enlightened despot.

The dominating events leading up to our own epoch were the rapid expansion of industry and the breakdown of the traditional supports of the static agricultural society. Established methods of dealing with the sick and infirm could not cope with the fast-growing new communities of wage-earners precariously poised on the edge of destitution and pestilence. The survival of the new society depended on certain public-health measures against epidemic disease. Slowly these measures of environmental control were put into effect. But the problem of providing medical care to the sick individual was still unsolved. Tsarist Russia sought a solution through a public State medical service, and this was taken over and developed by the Soviets. In Germany Bismarck tried another way: his intention partly paternalistic, partly to dish the rising Socialist party, he evolved the insurance method of social security provision which became a model for other Western countries. In our own day medicine is hoist with its own scientific and technical advance. The immense costliness of medical care today puts it beyond the means of the great majority to afford for themselves or for private charity to provide. Sigerist is doubtful whether the insurance method can solve the problem and he sees in our National Health Service, for all its imperfections, a great step forward, and an experiment watched by the rest of the world.

Special Articles

INITIAL PRACTICE ALLOWANCES

ARRANGEMENTS for paying initial practice allowances, in accordance with the recommendations of the Working Party on the distribution of remuneration among general practitioners, are announced this week by the Ministry of Health.[1]

These allowances will become payable from April 1, 1953, to certain doctors in areas classified as " designated" by the Medical Practices Committee. From the same date fixed annual payments will cease to be paid; but doctors receiving fixed annual payments immediately before April 1 will be entitled to a special payment for a temporary period in whatever type of area they are practising, subject to certain conditions.

In designated areas the following will be eligible to apply for an initial practice allowance:

1. Doctors who are genuinely setting up a new single-handed practice in a practice area new to them.
2. Doctors filling vacancies in small single-handed practices.

To qualify for the allowance a doctor must have been in general practice for not less than two years, whether as a principal or otherwise, or have been fully registered as a medical practitioner for not less than four years. The allowance will be payable for a maximum of three years at the rate of £600 in the first year, £450 in the second year, and £200 in the third year, subject to certain conditions in the second and third years.

NEW SINGLE-HANDED PRACTICES

First Year

Doctors should consult the appropriate executive council before making any final decision on whether to start a practice in an area which they believe to be classified as designated. If the doctor fulfils the necessary conditions payment of the allowance will begin from the date on which the practice is started following his admission to the medical list.

It may be necessary for the Medical Practices Committee to change the classification of some designated areas as soon as one or two additional doctors are admitted to the list. In such cases not all applicants may qualify for allowances. Doctors who apply for admission to the medical list in borderline designated areas would be well advised not to enter into any binding arrangements for acquiring practice premises before being informed that they have been granted an allowance, if their entry into practice in the area depends on this.

A doctor may apply for an initial practice allowance (and for admission to the medical list) before he has secured practice premises, provided that he indicates the district in which he proposes to secure surgery premises. He will then be admitted to the medical list provisionally. He may not, however, be provisionally included in the list for more than one area at any one time. Payment of the initial practice allowance and full admission to the list will be subject to his starting his practice within one month after provisional admission to the list; but this period will be renewable month by month up to a further two months at the discretion of the executive council.

If, after a payment has been started, the executive council considers that the doctor is not genuinely setting up in single-handed practice it will give the doctor three months' notice of intention to terminate payment.

Second and Third Years

The allowance for the second year will be conditional on the doctor obtaining 150 patients at the end of the first year, and will be the amount by which his gross professional earnings due for the first year, excluding the initial practice allowance in respect of that year, fell short of £1100, subject to a maximum payment of £450.

The allowance for the third year will be conditional on the doctor obtaining 500 patients at the end of the second year, and the amount will be that by which his gross professional earnings for the second year, excluding the initial practice allowance in respect of that year, fell short of £1000, subject to a maximum payment of £200.

If a doctor fails by a slight margin to reach the minimum numbers on his list to qualify for a continued payment the council may at their discretion, and in consultation with the local medical committee, regard the conditions as having been fulfilled. The minimum numbers to be reached may also be modified on other reasonable grounds—e.g., if the doctor has been ill or for other good reasons has been unable to carry on his practice duties for some part of the year.

If a doctor fails to qualify for a payment in his second year, either because his list does not reach the required size at the end of the first year or because his earnings exceed the limit, this will not debar him from a maximum payment of £200 in the third year if his list reaches 500 at the end of the second year and his earnings for that year are below the limit.

A doctor may not receive an initial practice allowance for more than three years even though he starts a practice in one area and then moves to start another practice in another designated area.

VACANCIES IN SMALL SINGLE-HANDED PRACTICES

Doctors filling vacancies in small single-handed practices in designated areas will be eligible for an initial practice allowance for three years. The allowance in the first year will be the sum required to raise the income calculated on the size of the list when taken over to a gross total of £1000, subject to a maximum payment of £600. Income for this purpose will be regarded as capitation fees and, where payable, additional " loadings " and mileage and dispensing payments. On this basis doctors taking over lists of up to 800–900 will be eligible to apply. A doctor filling a vacancy in a small practice who has previously received an initial practice allowance in respect of an effort to start a new practice elsewhere will not be eligible for payment for more than three years in all.

DOCTORS PREVIOUSLY RECEIVING FIXED ANNUAL PAYMENTS

Doctors in all areas who, when the scheme begins on April 1, 1953, have been in receipt of a fixed annual payment for less than three years, and whose applications for payment are received before Nov. 24, 1952, will receive a special payment at the appropriate initial practice allowance rate for the balance of the three-year period or for one year, whichever is the longer. The payment will be subject to the appropriate maxima on professional earnings during the preceding year (excluding the fixed annual payment and the percentage increase in respect of it paid as a result of the Danckwerts award). If payment is due for more than one year, its continuance will also be subject to the standard conditions relating to the size of the list to be secured at the end of each year.

A doctor who, when the scheme begins, is in receipt of a fixed annual payment which has continued for three years or more will receive a special payment for one year. The payment will be the amount by which his gross professional earnings due for the preceding year (excluding the fixed annual payment and percentage increase) fell short of £1100, subject to a maximum of £200.

Doctors receiving a fixed annual payment in areas other than designated and whose applications for payment are received by the executive council on or after Nov. 24, 1952, will receive a special payment for one year from April 1, 1953. The payment will not be continued in such cases after March 31, 1954.

No special payment will be made to a doctor in respect of his existing practice if he has never had a fixed annual payment in respect of that practice, or has had one and is no longer receiving it.

CHANGE IN CLASSIFICATION OF AN AREA

Doctors who after Oct. 18, 1952, and before April 1, 1953, have started a practice in an area which at the time of their starting the practice was classified as designated by the Medical Practices Committee will be eligible to apply for the initial practice allowance from April 1, 1953.

A doctor who after April 1, 1953, is receiving an initial practice allowance in an area whose classification is subsequently changed from designated will continue to be eligible for the payment for the remainder of the three years, subject to his satisfying the normal conditions. A doctor who is practising in an area which is not classified as designated will not be entitled to an initial practice allowance in respect of his existing practice if the classification of the area is subsequently changed to designated.

APPEALS TO THE MINISTER

Where the executive council has refused to grant or continue an initial practice allowance or special payment, or where the amount of payment is in dispute, the doctor will have a right of appeal to the Minister of Health.

RESPIRATORY AIR CURRENTS

The Semon Lecture

THE more violent respiratory air currents emerge as the coughs and sneezes that are of such popular epidemiological significance; but the gentler currents in the upper respiratory tract can also be important, as Dr. A. W. PROETZ, of St. Louis, showed in the 1952 Semon lecture of the University of London, given at the Royal Society of Medicine on Nov. 6. Dr. PROETZ described some of the physical properties of air currents in general. If smoke from a cigarette is blown through a straight glass tube of uniform bore, no particles are deposited on the tube; but if the tube is bent or constricted, there is a turbulence in the smoke and a deposit is rapidly formed just beyond the bend or constriction. A homely example of this may be found in the smoker who has an obstruction in one side of his nose. If he blows the smoke out through his nose there is a deposit of particles beyond the constriction, and the vibrissæ (or long hairs) just inside the nostrils become stained brown.

If the nose is healthy, the air currents pass into the nasopharynx without obstruction. The nasal airway in man is normally only about 1 mm. in width, and the nose gets its capacity through height rather than width. The air currents in the nose are affected by three things: the size and direction of the external nares; the general shape of the nose; and the difference in size between the anterior and posterior nares, the latter being larger than the former. Normally the nares are directed downwards so that, on inspiration, the air first of all passes straight upwards; it then passes through the upper part of the nose in a gentle curve; and it leaves the nose through the posterior nares to enter the nasopharynx. This inspired air does not come into contact with the ostia of the sinuses in the middle or the superior meatus. As the air passes downwards from the nasopharynx to the larynx, there are turbulent areas at the back of the mouth, under the palate, and round the epiglottis; and it is interesting to note that these are the very situations where aggregations of lymphoid tissue are found. During expiration there are in the normal nose eddies of air under the middle turbinates, and the ostia of the sinuses are, therefore, reached by this air alone, after it has been moistened. There is very little air exchange in the sinuses themselves.

Abnormal air currents may be caused by various lesions—by deviations of the nasal septum, by polypi, by swelling of the turbinates, by enlarged plicæ septi, or by adenoids. The air currents in the nose normally pass through its upper, and not its lower, part, and a swelling high in the nose, such as may occur in a common cold, will leave only a small passage for the air through the lower part of the nose. Air then passes straight back and impinges against the nasopharynx, where the adenoids are situated. This produces the dry spot at the back of the throat in the early stages of a cold. A deviation of the septum may often have to be corrected by surgery, but not always. Sometimes the turbinates will enlarge on the unobstructed side, and so adapt themselves to the abnormal condition of the septum. If a submucous resection is performed in such a case, there will be too much room on the unobstructed side when the septum comes to lie in the midline; and there will be a constriction on the other side where the straightened septum lies against the enlarged turbinate. In such a case, a dry area will develop, with subsequent stasis and liability to infection. The remedy is, therefore, not always surgical. When there is only a low spur on the septum, this is streamlined and air can pass above and below it. There is therefore no interference with the air currents and no harm is done. However, should the patient with a low spur catch a cold there will also be swelling in the upper part of the nose with considerable obstruction. Polypi in the superior meatus of the nose will interfere with the air currents, but polypi in the middle meatus, although they will have to be removed for other reasons, have an almost negligible effect on the air currents. If the middle turbinate is removed, there is practically no change in the air stream; but if both middle and inferior turbinates are removed, what is tantamount to atrophic rhinitis develops, and true atrophic rhinitis soon follows. Although there is then a much wider air space than normal, the patient complains of nasal obstruction, because there is eddying of air in the nose on inspiration, with deflection of the normal currents.

Dr. Proetz illustrated his remarks with two excellent films, which demonstrated the behaviour of smoke in various kinds of tubes; the mucus blanket being moved by the cilia; red cells being tumbled along at a great pace; the stasis that follows drying; and the normal air currents and their variation under different conditions.

Medicine and the Law

Doctor, Hospital, and Patient

IN the case of Payne *v.* St. Helier Group Hospital Management Committee and Another, reported in the *Times* (Nov. 12), the court placed upon a professional man the full responsibility for his professional actions. The casualty officer at the hospital was held to have been negligent; the management committee, as his employers, thus became liable also, since he was acting as their servant in the course of his duty as such. In awarding damages to the plaintiff, however, the judge made an order indemnifying the committee against the doctor in respect of the whole sum awarded as damages and in respect of two-thirds of the committee's costs.

The plaintiff, Mrs. Payne, was the widow of a horse-keeper employed by United Dairies. Early in the morning of July 10, 1950, the deceased was kicked in the abdomen by a horse. He consulted his doctor, who sent him to the hospital for examination. At the hospital the casualty officer examined him some nine and a half hours after the accident; this practitioner had been professionally qualified for two years. He observed an abdominal bruise, but, concluding that there was no internal injury, sent the patient home and told him to go to bed and to call in his own doctor if pain was felt. By July 28 the patient was very ill; he was readmitted to hospital where two operations were performed—first a lumbar incision, and secondly a laparotomy which showed general peritonitis. On Aug. 30 the patient died.

His widow alleged negligence as follows: the hospital system, she said, must be wrong if a patient, sent in by a general practitioner, was examined by a casualty officer only and not by a surgeon of consultant rank; the casualty officer must have been negligent in failing to heed that the bruising indicated a very severe blow, in failing to appreciate that a general practitioner's action in sending the patient for examination meant that a more experienced opinion was required, and in failing to keep the patient in hospital for observation or to have him examined by a consultant surgeon. For the defendant doctor (the casualty officer) it was contended that Mrs. Payne had not established that her husband's death from general peritonitis on Aug. 30, so long after the injury, was due to the negligence (if any) of the defendant on July 10, and that, even if the patient had been kept in hospital and examined by a consultant, there was nothing to show that his life would have been saved.

Mr. Justice Donovan found in favour of the widow. The clinical tests made by the defendant doctor were admittedly correct; but he must have, or ought to have liscovered that the patient was suffering from pain, hock, and rigidity of the abdomen; if these conditions vere present in addition to the bruising, then the diagnosis nd treatment represented less than the exercise of easonable care. It was wholly unjustifiable to send the nan home and not to detain him for examination by consultant. These findings amounted to a verdict of egligence; had the proper course been taken, his Lordship considered that the deceased would in all robability have survived. He awarded £2640 damages, lacing the liability substantially upon the defendant loctor in the terms already stated.

Parliament

Education of Blind Children

IN the House of Commons on Nov. 12, Mr. EDWARD SHORT called attention to the need for more facilities for the education of blind children. The National Institute for the Blind, with Government assistance, provided education for over 1100 young people, but owing to improved medical services the number of premature babies who survived was increasing. The prevalence of blindness was greater among premature babies than among normal babies. An increase in the incidence of blindness among children was therefore to be feared. Yet the only additional provision to be made this year for blind children seemed to be a share of 150 extra places to be provided in special schools for physically handicapped children. That, he thought, was inadequate to meet the probable increase in the present waiting-list of 150.

Mr. KENNETH PICKTHORN, parliamentary secretary to the Ministry of Education, claimed that the blind had got rather more than their share of accommodation compared with other handicapped children. He agreed that of the 1300 blind children who were the responsibility of the Ministry of Education about 170 were on a waiting-list to go to school. Most of these wanted to go to Sunshine Homes and not to the schools which had vacancies. Again many of them were under five years of age and their parents did not want to be parted from them. A considerable number had additional handicaps and were not eligible for the ordinary Sunshine Homes. Two Sunshine Homes did accept blind children with another defect. Deducting these two classes, he was left with the real waiting-list, and he did not believe they would have long to wait.

In the next ten years, he thought, about 200 additional places would be needed. But if the increase in the number of premature births surviving continued, then more than 200 places might be needed. A subcommittee of the Medical Research Council was inquiring into the problem of premature babies who are blind, especially into the geographical incidence of the condition which was oddly uneven. They could not say what further effect this particular kind of blindness—a new condition not earlier recognised or understood—might have.[1]

There were about 1800 partially sighted children, and according to the best opinion it was in their interests as well as those of the blind children to separate them in different schools. That was being done. He thought it was pessimistic to suppose that there was anything like a scandalous shortage of accommodation for partially sighted children.

QUESTION TIME

Lung Cancer among Gas-workers

Mr. S. T. SWINGLER asked the parliamentary secretary to the Ministry of Works, as representing the Lord President of the Council, on what lines it was intended to pursue research into the special causes of lung cancer in gas-workers, through the agency of the Medical Research Council.—Mr. A. H. E. MOLSON replied: The Medical Research Council has arranged for one of its expert committees to examine the possibilities. Until this committee has had time to consider the problem in detail, I shall not be able to indicate which lines of research are likely to be the most promising.

Mr. SWINGLER: Will the Minister consult the Minister of Fuel and Power, because one of the troubles is that two-thirds of the gas boards do not employ full-time medical staffs? Mr. MOLSON: The whole matter is under careful consideration. Investigations have already been made and the matter is still being followed up.

Medical Service in the Gas Industry

In reply to Mr. SWINGLER, Mr. GEOFFREY LLOYD, Minister of Fuel and Power, said he did not think it was necessary to establish in each area of the gas industry a full-time industrial medical staff as part of a comprehensive health service for the industry. He was in favour of developing a proper industrial health service, but for some boards with small and scattered installations it would not perhaps be the best plan to have a full-time medical officer; it might be better to rely on local medical practitioners. If they were to rely on a full-time medical officer, there was a danger that far too much of his time would be spent in travelling to the different installations over the whole area.

Hospital Expenditure

In answer to a question Mr. IAIN MACLEOD gave the following figures for the expenditure per head of population which it is estimated will be incurred by each regional hospital board in the current year:

Estimated hospital expenditure in 1952–53 per head of population

Regional hospital board	*Amount per head* £	s.	d.
Newcastle	4	6	3
Leeds	4	16	0
Sheffield	3	19	0
East Anglian	4	0	8
North West Metropolitan	5	5	4
North East Metropolitan	6	0	10
South East Metropolitan	5	17	5
South West Metropolitan	6	6	10
Oxford	4	17	10
South Western	5	10	0
Birmingham	4	5	2
Manchester	4	6	11
Liverpool	5	0	6
Wales	4	14	10

Incidence of Tuberculosis in the Regions

In answer to a question Mr. MACLEOD gave the following figures showing the percentages of the population suffering from tuberculosis in each region:

Regional hospital area	Number of notified cases on chest clinic registers at Dec. 31, 1951	% of population
Newcastle	19,706	0·68
Leeds	14,745	0·48
Sheffield	25,986	0·63
East Anglian	7449	0·51
N.W. Metropolitan	29,616	0·73
N.E. Metropolitan	21,750	0·72
S.E. Metropolitan	27,601	0·86
S.W. Metropolitan	30,471	0·67
Oxford	6474	0·45
South Western	16,839	0·61
Wales	21,831	0·84
Birmingham	26,013	0·58
Manchester	25,297	0·58
Liverpool	15,294	0·73

Special Grants during Preregistration Year

Sir GEOFFREY HUTCHINSON asked the Minister whether he would consider making special grants to doctors required to give one year's service as house-surgeons on qualification where doctors had served in H.M. Forces and for that reason were in a higher age-group than was normally the case, and where such doctors have family responsibilities.—Mr. MACLEOD replied: Such a house-officer may be eligible for a special grant from the Minister of Education, in addition to his salary.

School Dentistry in Scotland

Replying to a question Commander T. D. GALBRAITH stated that in Scotland the number of dentists in general practice taking part in the National Health Service had fallen from 1254 at the end of 1951 to 1210 at the end of last month. In the same period the number of dentists in the school service had increased from 104 to 131. There was no formal establishment of dentists in the school service, but he was advised that the present number, which was equal to the highest number ever before, was still far short of the total that could usefully be employed. The reason for the increase in the number of dentists now going into the school dental service was first of all the improved salary scales and also the reduction in the numbers attending the general dental service.

---

[1] See *Lancet*, 1951, ii, 1173; Oct. 25, 1952, p. 818.

South-West Metropolitan Regional Hospital Board

Dr. REGINALD BENNETT asked the Minister of Health what had been the result of his consideration of the suggestion that a separate region and regional hospital board should be created for the western area of this region.—Mr. MACLEOD replied: After consulting all the parties concerned in this matter, and having carefully considered all the views expressed, I have reached the conclusion that no substantial advantage would be gained by the creation of a separate region and regional board for this area. It seemed to me that the criticisms made by those who wanted a new region could probably be met more economically, and without the loss of the advantages at present deriving from the existence of a single region, by delegation of powers more freely to the western area committee rather than by creating a new region and a new board. I therefore asked the regional board to consider how this wider measure of delegation might be achieved, and sought their views on a number of suggestions which appeared to me to be practicable. These suggestions were discussed by representatives of the board and the western area committee with officers of the Ministry and I understand that the committee are preparing detailed proposals indicating how, in their view, the suggestions might be implemented and they will submit their proposals for the board's consideration in due course. I now await the board's considered views.

Prescription Charge for Nurses

Mr. M. TURNER-SAMUELS asked the Minister if he was aware that it is a tradition that hospitals should care for the health of their staff, especially of nurses whose occupation was of the nature of a vocation and who were expected to put the care of patients before the strict interpretation of terms of service; and if he would therefore withdraw the instruction of his department contained in Circular H.M.C. (52)52 that nursing staff of hospitals, whether resident or not, shall be charged the fee of 1*s.* for prescriptions made up in the hospital pharmacy unless they were inpatients of the hospital.—Mr. MACLEOD replied: While I certainly do not wish to discourage the proper care of the health of nursing staffs, I am not satisfied that the payment of this charge, which is payable by all other members of the community in similar circumstances, has this effect, or that it would be justifiable to make an exception in their case.

Hospital Staffs

Mr. ARTHUR BLENKINSOP asked the Minister what fresh instructions he had issued limiting hospital medical staffs and proposing reductions in hospital domestic staff.—Mr. MACLEOD replied: None, Sir; though I have opened discussions with the boards of governors about the medical staff establishments of the teaching hospitals.

Corporal Punishment

Replying to a question Sir DAVID MAXWELL-FYFE, the Home Secretary, said that before corporal punishment was abolished as a judicial penalty in September, 1948, the only important offences for which it could be imposed on male adults by the courts were offences of armed robbery and robbery with violence contrary to section 23 (1) of the Larceny Act, 1916. In 1946 and 1947 there were, respectively, 804 and 842 offences of this nature known to the police in England and Wales; the corresponding figures for 1950 and 1951 were 812 and 633. The provisional figure for the first six months of 1952 was 359.

Most other crimes of violence against the person had increased in recent years. In 1948, 646 cases of felonious wounding were known to the police in England and Wales, whereas the figure for 1951 was 1078. For malicious wounding the figures for 1948 and 1951 were 3547 and 4445, respectively; for rape 252 and 335; and for indecent assault on females 5659 and 7287. Corporal punishment could not, however, be imposed as a judicial penalty for any of these offences before 1948.

In England Now

A Running Commentary by Peripatetic Correspondents

SNOW has fallen in the Pennines. The wireless forecasts cold or rather cold weather throughout the country, and already I have been called out to see a man who tells me that his black eye and broken nose are due to a fall on the ice, not to a family misunderstanding. These signs of winter depress me, especially as I am continually hearing how healthy cold weather is. Patients affirm it as they display their rheumaticky limbs and chilblained fingers. They insist upon it as they cough in my face. Between sneezes they murmur in husky voices that the cold destroys germs. Plenty of fresh air, though it kills you, seems to be the motto for today. But, come to think of it, those who live in hermetically sealed rooms, those who believe that cold water is dangerous, and those who hold that too much water of any temperature is best avoided in winter—they are the ones who live to be eighty or ninety and seldom bother the doctor. My old chap down the road, who will be a hundred next month, knows better than to send for me when he gets a cold on the chest. He merely puts on yet another layer of winter woollies, stuffs another sock in the crack under his bedroom door, and gets better.

* * *

The conflict between the art of medicine and the science of medicine schools recalls a lesser but equally intense conflict between the art of wine-making and the science of wine-making groups. The art of wine-making is described in many cookery books; but many otherwise reliable textbooks of bacteriology lack a chapter on the science of wine-making. Yet good wine of high alcohol content can be readily prepared from the simplest ingredients—fruit, sugar, and yeast—provided ordinary bacteriological techniques are applied.

It is best to use a culture of *Saccharomyces ellipsoideus*, which has been repeatedly shown to attain a higher alcohol content (up to 15%) than any other yeast. A suspension is prepared by growing in a large volume of glucose-broth, centrifuging, and depositing the yeast in a small volume of saline. The fruit and sugar mixture should be sterilised in its container by heating in the oven for one hour at regulo no. 5. After cooling, the yeast suspension is added and a gas trap inserted. Fermentation should be carried out in a warm room (70°-75°F) and preferably at an even temperature. When fermentation has ceased the wine is filtered through a clean handkerchief and bottled without screwing the corks home tightly. In place of the traditional wooden cask, a pinch of tannic acid will often improve matters. Finally, and most difficult of all, don't drink the wine until it has matured for at least six months and preferably a year.

Inquiries about Château Medresco should not be addressed to Old Queen Street but to our filiale at Mont Moulin.

* * *

District midwifery in Lahore is often complicated by the fact that very few of our mothers seem to know where they live and seldom give us their correct address. We often wonder how they find their own way home. It would be less confusing if they told us to turn right at the third buffalo, and then follow the white horse with the lame leg to the fourth water tap by the Pipul tree. Perhaps W.H.O. should only recruit public-health nurses with second sight.

Kaneez, with ten pregnancies to her credit and two children who managed to survive infancy, was perhaps our prize problem mother. Sweetly vague, with her hair hanging in wisps from under her burka, she attended our antenatal clinic from the earliest months, but unfortunately rarely on the right morning. She would send for UNICEF milk, but always an hour too late so that the poor health visitor had to dirty her pots and pans again and make some more. She was always demanding little dabs of gentian-violet and 'Vaseline' at the most inconvenient moments. Then suddenly she would desert us for weeks, and it would take hours of home visiting and offers of soap (bribery) to persuade her to come to the clinic again for examination. She was a lady of uncertain temper. Some days when we visited her she would not speak, but went on with the cooking, slapping the chappati angrily while giving us fierce looks. At other times she would be sweet and docile and do everything we asked, except of course prepare her things for delivery.

As her time drew near it became routine to ask the midwife who had been on night call: "Has Kaneez delivered yet?" Eventually, at five o'clock one morning she sent her booking card, and we rushed like mad, pinning up our hair as we drove through the gate. We arrived there just in time: the baby was born, of course, but the cord was not cut. Kaneez was lying on the bed looking faintly surprised, and the baby, which she had forgotten to pick up, was lying squalling naked in a puddle on the mud floor. An obliging neighbour, string and vegetable knife in hand, was about to cut the cord. No-one was at all pleased when we demanded water to boil the ligatures and instruments, but we quietly got on with it, and then bathed the mother and baby. Kaneez did not like the idea of feeding her baby at the breast; it was not her custom for the first three days, but we eventually persuaded her. We put the infant in her arms, and when it was sucking well turned our backs for a minute to strap up the delivery bags. When we looked again the same helpful neighbour had taken the baby and was giving it a drink of nice sweet tea, hot and strong, throwing it expertly into its mouth with her grubby fingers while our Kaneez looked on approvingly.

* * *

The staff table at lunch was discussing the Motor Show, and the Senior Anæsthetist put forward the view that cars had deteriorated each year since the war. Challenged to prove this, he suggested that as the Ophthalmic Surgeon was present the company should consider visibility as a sample of modern trends.

His theory received instantaneous support. The Orthopædic Surgeon and the Obstetrician vied with one another in deploring the common practice of curving the wind-screen, which caused distortion particularly at the sides where the curve was greatest. Night-driving, the Physician declared, was made more difficult by the secondary images of bright lights, and by the head-lamps of following cars, for rear-blinds are now usually omitted. The Pathologist pointed out that continual renewal of wiper-blades was necessary if the curved rubber was to clear the whole area wiped. He added that, to cut prices, most windscreen-wipers now had no auxiliary hand-control, and if the electric motor packed up, the driver had had it, particularly as the screen itself now seldom opens—a fatal fault in thick fog. The substitution of toughened for laminated safety glass meant that the whole screen instantaneously became opaque if struck by a flying stone, a shattering experience that had happened to the Surgical Registrar and the Otologist. The Psychiatrist gave a moving description of the frustration he had experienced while touring abroad, particularly in mountainous countries, now that sunshine roofs had virtually disappeared.

The Surgeon summed up as he rose to go to his theatre: "I think we have got to admit that Old Stuffy is right, but this is the first time I have agreed with him for twenty years."

* * *

The National Health Service had not concerned him. A bachelor, he lived alone quietly, worked industriously, and had no occasion to consult his doctor until this week. An appointment was offered him as an outpatient at a time to suit his work, but he did not arrive. Later he was found, obviously lost, wandering through the nurses' quarters. He might have known better and probably wondered at the changes that had taken place in the last few years; but his only concern was to be examined by a specialist, and he faithfully followed the many signposts apparently placed to guide him on his way about the spreading hospital grounds. He did not know that the hospital was an examination centre for the nurses of this area and that the signs "To State Examinations" were not for him. We hope they never will be.

* * *

Father (murmuring over his advertisements at breakfast): "Urolucosil."

Peter (aged 3, indignantly): "No, I'm not."

Letters to the Editor

REVIEW OF MEDICAL ESTABLISHMENTS

SIR,—A letter from the Ministry of Health to boards of governors of teaching hospitals on medical establishments has come to the notice of the Joint Consultants Committee. This letter recommends in many cases reductions in the establishment of consultants, S.H.M.O.s, and registrars, though in some instances additional consultant posts are proposed. Although the committee knew of the inspections upon which these letters have been based, it had no opportunity of discussing with the Ministry the very important implications of the actions proposed.

These include the security of tenure of consultants threatened with displacement, the obligation upon boards to find them alternative work imposed by paragraph 16 of the Terms and Conditions of Service, and the effects of these measures upon the registrar problem.

A typical letter includes the following sentence: "When the Board's proposals have been examined and the establishment approved by the Ministry, the Board will be expected to take action to achieve any necessary reduction as soon as practicable so far as such action has not already been taken; it will be permissible for the Board to increase the number of medical establishments in any grade in any specialty only with the Minister's consent in each case." It is unquestionable that some control must be exercised over the total consultant establishment, but many will doubt whether this is best achieved by referring the decision in every individual case to Savile Row.

The Ministry's letter provides yet further evidence that the Health Service can be steered safely between the Scylla of planlessness and the Charybdis of excessive central control only by utilising the guidance of appropriate medical advisory committees at all levels, from the hospital management group up to the Ministry itself. I hope that boards of governors and their medical committees when considering these matters will bear in mind that the Joint Consultants Committee has still to discuss them with the Ministry.

W. RUSSELL BRAIN

Royal College of Physicians,
London, S.W.1.

Chairman,
Joint Consultants Committee.

FIBROCYSTIC DISEASE OF THE PANCREAS

SIR,—We are very pleased that Dr. J. C. W. MacFarlane (Aug. 16, p. 311) has been able to confirm the potential value of the antithrombin test in the condition of fibrocystic disease of the pancreas. It is gratifying that he has found it possible to simplify the test and the method of obtaining blood specimens. We are particularly impressed with the large series of cystic fibrosis cases studied and the number and selection of controls.

We agree that the most valuable information is obtained from the fifteen-minute and twenty-minute samples and that the shorter-time samples may be unnecessary. Expressing results as percentage of the mean of the normals tested on the same day certainly makes more accurate any comparisons of cases tested at different times.

The variance between Dr. MacFarlane's findings of uniformly lowered antithrombin titre in 60 of 67 cases, with near normal levels in 7 cases, and our determination of low titre in 1, elevated titre in 3, and normal titre in 9 cases seems to require further study or some reasonable explanation.

In our view the assumption that serum-antithrombin titre and plasma-antithrombin titre are so identical is *not fully established*, although our experience of many thousands of antithrombin determinations indicates that the curve resulting from plotting antithrombin action against time of incubation in the case of serum antithrombin is low and relatively flat, whereas that from antithrombin in defibrinated plasma rises in relation to the time of incubation of the mixture. Thus it is difficult for us to reconcile the finding of low antithrombin titres obtained from serum with unequivocal diagnosis of cystic fibrosis of the pancreas regardless of the extent of involvement.

In our data only *extreme* cases of cystic fibrosis of the pancreas, with minimal or absent external pancreatic secretions, show very low antithrombin titres. Further, in our experience there is no constant relation between absent pancreatic secretions in the duodenum and the antithrombin level in the blood.

Since it is apparent that serum-antithrombin determinations result in low flat curves, the stage of pancreatitis characterised by markedly increased antithrombin and trypsin levels in the blood would necessarily be missed in serum determinations.

It would indeed be most helpful in clarifying the differences in results obtained if plasma-antithrombin determinations could be made on the 67 cases so well presented and discussed by Dr. MacFarlane.

CONGENITAL DEFECTS FROM MATERNAL RUBELLA

SIR,—As an otologist and a member of the committee of the Deaf Children's Society, I have been very perturbed to learn that some general practitioners are questioning the diagnosis of rubella in the first three months of pregnancy when associated with fœtal abnormalities. In 1940 and subsequently, Gregg, Swan, and others in Australia pointed out the very definite danger of rubella early in pregnancy leading to congenital deafness, blindness, and sometimes a cardiac lesion. It is thought by some that the infection was not true rubella and that other cases have not occurred since.

This is a very dangerous, as well as an erroneous, supposition. There is no doubt whatever that children are still being seen with these tragic defects as the result of infection in their mothers by a "simple" illness indistinguishable from typical rubella; often this has been very mild. Pregnant women should still be extremely careful to avoid contact with rubella: in fact there seems every justification to recommend that all girls should be exposed to rubella before leaving school.

London, W.1. IAN G. ROBIN.

DENTAL TREATMENT FOR CHILDREN

SIR,—Your leading article of Oct. 25 contains the following statement concerning children's dentistry: "The work is mainly routine and holds little interest for the highly trained dental surgeon." May I encroach on your space to challenge as briefly as possible the correctness of this statement.

The public dental officer in treating the priority classes performs the same range of operations as is performed in the general dental service. In the case of school-children, who form the bulk of his patients, he must perform these same operations in a much smaller oral cavity and on a patient who is emotionally less stable than an adult, requiring from the operator a greater skill and more tact and patience than is necessary in other spheres of dentistry. As the school dentist is dealing with patients in their developmental stage, his knowledge and understanding of developmental irregularities, and their prevention and treatment, must be of a high order. By contrast the treatment of mature mouths, subject only to the processes of decay, is flat and insipid. The more frequent use of general anæsthetics, with increased difficulties of administration, is a further feature of children's dentistry.

I trust that this letter will go some way towards removing your implied slur on those dental surgeons who for vocational reasons remained faithful to the children, and resisted the financial attractions of the easier, though less satisfying, work of general service.

T. H. LIPTROT
Hon. Secretary, Public Dental Officers' Group,
British Dental Association.

THE CORRECT SPELLING OF MEDICAL TERMS

SIR,—Dr. L. E. Napier (Nov. 1) is fighting a battle for many of us in defence of etymologically correct spelling. Nowadays, editors refuse to accept *empyemata* and one journal recently removed *sinus* into the second declension.

Camberwell, London, S.E.5. KENNETH MARSH.

SKIING ACCIDENTS

SIR,—In 1950 a committee was set up by the Ski Club of Great Britain to inquire into ways of reducing the number of skiing accidents. A simple safety device was introduced consisting of a strap passing from the heel-spring of the ski binding to a ring attached to the ski 2 in. behind the heel. The object of this device was to cause the foot to come adrift from the ski in the event of a severe forward fall. Other and more elaborate safety bindings prevent rotation strains, but they have not yet been widely used in the Alps.

In order to obtain information on (*a*) the incidence of skiing injuries, and (*b*) the effectiveness of this simple safety device, a card was circulated in 1951 to 12,750 members of the Ski Club of Great Britain, asking for the following information:

Age; sex; number of seasons' experience; safety device used, if any; description of injury from any accident in previous season; causes of accident (fall, collision, snow conditions); days on ski before accident; feet downhill per day (average).

254 replies were received; the results of analysis were as follows:

	Accident	*No accident*	*Total*
S.C.G.B. safety device	20	95	115
No safety device	38	101	139
Total	58	196	254

$X^2 = 3{\cdot}80 \quad P < 0{\cdot}05$

Incidence of accidents:

Over-all	22·9%
With safety device	17·4%
Without safety device	27·3%

The injuries were as follows: *sprains* 46 (ankle 22, knee 20, shoulder 4); *fractures* 7 (ankle 3, patella 1, thumb 1, ribs 2); *muscle lesions* 2 (calf 1, thigh 1); *lacerations* 2 (thigh 1, wrist 1); *unspecified* 1.

Under causes of the accident the replies were as follows: *snow conditions* 40 (powder snow 15; wet soft snow 9; ice 7; icy ruts 5; breakable crust 4); *obstructions* 4 (tree, rock, or ice block); *collisions* nil. Snow conditions were not reported in 3 cases; 11 accidents happened *in good snow conditions* on the piste.

There are obvious statistical objections to this type of inquiry. The findings would not necessarily be the same in a random sample of the members of the Ski Club of Great Britain; they may apply only to the type of person who takes the trouble to reply, and people who have had accidents may be more likely to reply than those who have not. On the other hand, those who have worn a safety device and escaped injury may be more likely to reply than those who have had no injury and worn no safety device.

Despite these objections, the results confirm the impression gained from empirical observation that injuries to skiers are extremely common, though most of them are not serious. The evidence also suggests that the Ski Club of Great Britain safety device significantly reduces the incidence of accidents. This device clearly cannot influence the incidence of injuries to parts of the body other than the lower limbs. The number of such ther injuries is, however, distributed evenly between he two groups and does not affect the statistical result.

It is of interest that of 58 accidents only 11 happened n the piste in good snow conditions. Soft snow and icy onditions were important predisposing factors.

The replies indicated that 10–21 days is the usual uration of the post-war winter-sports holiday. There vas no evidence that the amount of downhill running ach day has increased since the war, despite the greater umber of ski lifts and funiculars.

Detailed analysis of the influence of factors such as ge, sex, experience, &c., will be deferred until more naterial has been collected.

MALE-TOAD TEST FOR PREGNANCY

SIR,—In connection with the letter last week from aptain Farrant and myself, my attention has been called o a letter from Dr. Jayewardene,[1] of the Medical Research nstitute, Colombo, which I had unfortunately missed eeing. I am very glad to see that our findings are in greement, and that *Bufo melanostictus* has served us oth so well.

Porton, near Salisbury,
Wiltshire.
F. E. BUCKLAND.

CAUSE AND TREATMENT OF LEG ULCERS

SIR,—Dr. Anning's excellent article (Oct. 25) leads me o record views gained from personal observation:

1. The application of compression-bandages must be arefully supervised. Attention to details of bandage tension, ize of pressure-pads, adequate stirrup-pieces, &c., makes the lifference between success and failure in gaining the patient's oöperation. Dr. Anning must have seen patients initially ntagonistic to the method because of bad technique in other places. There are even practitioners who expect satisfactory elf-application by the patient. I have used an 'Ichthopaste' bandage between the skin and adhesive-plaster layer, to protect from and minimise irritation. Reversal of the adhesive surface further helps. Application of pressure-pads over ichthopaste, and not directly to the skin surface, also lessens damage to the skin surface.

2. I agree that ulcer bacteriology counts for little except for the "foul, putrescent type." Of three recent cases one grew proteus and hæmolytic streptococci, and compression-bandaging had to be abandoned. Of the other two, one grew proteus and *Staphylococcus albus*, and the other hæmolytic streptococci, *Staph. albus*, and *Bacterium coli*. The ulcers healed with continuation of compression-bandaging and the application of 'Vioform' cream to the ulcer at the same time.

3. The most difficult type of ulcer seems to be associated with the hidebound, thinned leg and a long history of ulceration. General compression-bandaging of the leg seems of little value since there is nothing to compress. The ulcer is no less indolent and painful than the arteriosclerotic type.

A large pressure-pad supported by an ichthopaste bandage is helpful; but I have often found the local application of vioform cream more useful. Cream is put on the ulcer only—usually twice daily—and the leg supported by a crêpe bandage. The patient remains up, and the ulcer is not cleaned during treatment. Healing is slow, but pain is relieved at an early stage. Granulation tends to be profuse and heaped above the skin surface. A tenacious membrane forms over the ulcer surface and this seems peculiar to the mode of healing. The stimulus to granulation and epithelial growth is pronounced and apparently quite distinct from any bactericidal effect. The effect is greater than that of scarlet-red ointment or the balsam of peru preparation of the Mayo Clinic.

4. Unless the tissues have become excessively indurated and fibrosed, the long-standing ulcer is not necessarily the most difficult to heal. One can quite easily confirm Heller's observation that the larger the ulcer the more rapid the initial rate of healing. The most dramatic response to compression-bandaging may be seen in the large ulcer of long duration.

FULL-TIME AND PART-TIME CONSULTANTS

SIR,—We note in the Supplement of the *British Medical Journal* of Nov. 8 that the Staff Side of Whitley Committee "B" accepted the new mileage rates under protest as these benefited part-time consultants at the expense of their full-time colleagues. Why, in these circumstances, was the matter not submitted to arbitration?

A considerable time ago we were informed that the Central Consultants and Specialists Committee was negotiating on behalf of full-time consultants for the implementation of the terms proposed in the Spens report (which was accepted by the Government of the day), and the only result so far is that full-time consultants are now worse off than they were before. The Central Consultants and Specialists Committee has refused to allow consultants holding full-time contracts with regional boards any representation on the Staff Side of Whitley "B" Medical Council, and has also refused to sponsor negotiations for the payment of full-time consultants for domiciliary visits.

If this partisan attitude continues unchecked it will provide an absolutely unanswerable case for any Minister of Health seeking to introduce a whole-time salaried National Health Service.

PREMATURITY AND THE OBSTETRICIAN

SIR,—I was interested in the leading article on this subject in your issue of Nov. 8. You cite the successful prevention of eclampsia at the Women's Hospital, Sydney, and say that "This success has been achieved by an elaborate check of all antenatal patients to ensure regular attendance."

I feel that in this country it is most important that there should be a similar elaborate check. In reviewing maternal deaths due to toxæmia of pregnancy I have been struck by the lack of personal responsibility on the part of the patient to keep her antenatal appointments. I do not believe that, in the National Health Service, this should be the patient's responsibility. I feel that if the general practitioner and midwife are working on the case together, it should be the midwife's responsibility to see that the patient keeps her appointments at the antenatal clinic. If she does not, the midwife should visit her and communicate the reason for non-attendance to the patient's doctor. Only if the two of them work together shall we prevent the unpleasant results from patients' failure to attend. In rural areas the doctor is in daily contact with his district nurse and midwife, but in cities this is not so.

Close coöperation between midwife and doctor would reduce, not only maternal mortality from toxæmia of pregnancy, but also premature labours at home and the incidence of prematurity. The best "flying squad" container for the premature baby is the mother's uterus. The mother in premature labour, therefore, should be admitted to hospital.

---

[2] Schönberg, A., Sina, A. *Nature, Lond.* 1948, 161, 481; *J. Amer. chem. Soc.* 1950, 72, 4826.

There is also an urgent need for doctors and midwives to regard toxæmia of pregnancy as an obstetrical emergency and to refer such cases to hospital, not when the condition has become well established, but when the early signs, particularly a rise in blood-pressure, have become evident. An intense campaign to this end will undoubtedly pay dividends.

CONFUSIONAL PSYCHOSIS FOLLOWING ISONIAZID THERAPY

SIR,—I was greatly interested in Dr. Hunter's paper last week on confusional psychosis following isoniazid therapy, leading ultimately to an organic cerebral impairment of the Korsakow type.

The description of symptoms and signs is reminiscent of the encephalopathic syndrome first described in 1939 by Jolliffe[1] and by Sydenstricker's group.[2] They observed the condition by itself, and also in association with the dermatological and mucous membrane lesions of pellagra; nicotinic acid quickly reversed the confusional state. Whilst pellagrous, dermatological signs were apparently not noticed by Dr. Hunter, his patient's "mouth was very dry and she developed sores at the corners." Considering the many reports on the relation of confusional states to vitamin deficiencies,[3] it might be worth giving suitable vitamin treatment in further cases of this sort, in the hope of preventing organic cerebral impairment.

London, W.1. Z. A. LEITNER.

CERTIFICATION OF INSANITY

SIR,—There are two articles in your issue last week which, though they seem to have nothing in common, are connected in a very significant manner.

Dr. W. Rees Thomas ended his Maudsley lecture on the Unwilling Patient with an account of the increased use of voluntary admission to mental hospitals under the Act of 1930, and, according to your annotation, "looked forward to the time when admissions for mental illness will be regarded no differently from those for other causes." He expressed the hope "that certification will fall altogether into disuse."

I am sure that all (or nearly all) psychiatrists would agree, and look forward with him to the day when this can come to pass. But present progress in this direction, though all to the good, has brought about some strange repercussions in unexpected quarters. I would refer to the account in your "Medicine and the Law" section of a case in which a voluntary patient who became a "chronic" inmate of a mental hospital has given the Law Lords cause for much legal argument in settling divorce proceedings.

The difficulty was made painfully clear to me in a recent case in which I was consulted.

The patient, now a middle-aged man, has been in a mental hospital many years. He passed through the acute stages of his illness (in the hospital) without certification, though he was clearly certifiable at the time. Presumably it had been possible to get him to hospital and to keep him there as a voluntary patient, and so the need for certification had not arisen. But after the acute phase he steadily deteriorated, and when I saw him there was nothing to distinguish him from the ordinary run of incurable chronic cases in mental hospitals. Now that his wife wants a divorce, the "mental" clauses of the Herbert Act are inapplicable as he is not and never has been under certificate. On the other hand his mental incapacity, with lack of initiative, &c., is such that a petition for divorce on the grounds of desertion is pretty certain to fail on account of the absence of *animus deserendi* on his part. Yet were he to leave the hospital and return home it is generally agreed that he would break down again. (Of course he could then be certified; but apart from the objectionable nature of the procedure, there would be another wait of several years.)

A situation like this clearly defeats the object of the "mental" clauses of the Matrimonial Causes Act, and it is one that must become more common as more and more patients are treated in mental hospitals on a voluntary basis. The failure in the above case is, of course, due to the absence of certification—a purely sociolegal procedure which had hitherto been found unnecessary. Now, the introduction of a petition for divorce or desertion has introduced a new sociolegal factor, calling for certification before the required sociolegal remedy can be applied.

The danger is that, with examples like this in mind, there may be an understandable, but none the less regressive, tendency to hold on to certification *just in* case, or even to put a patient under certificate where there is a premonition of chronicity. (I believe this has happened already.) It is a matter that the legal experts would do well to look into; one day they may have to find some other and more appropriate way of defining "incurable insanity."

Leeds. H. EDELSTON.

A NEW ANTISEPTIC

SIR,—Your annotation of Nov. 15 states that the quaternary ammonium salts have no appreciable effect on the pseudomonas group. Although this is true for cetrimide, it is not a valid criticism of all quaternary ammonium salts. At least one of them, 'Roccal,' has appreciable activity against *Pseudomonas pyocyanea*. Furthermore, it should be appreciated that this criticism is one that can be levelled at all disinfectants.

Although the effectiveness of quaternary ammonium compounds against *Ps. pyocyanea* is very much less than it is against streptococci and staphylococci, *nevertheless* it is better than that of many disinfectants widely used in hospital practice. For instance, the killing power of roccal (containing 1% benzalkonium chloride) against *Ps. pyocyanea* is about three times greater than solution of chloroxylenol *B.P.* (containing 5% of active ingredient). Similarly, the same quaternary ammonium salt is about thirty times more potent than phenoxyethanol ('Phenoxetol') which was specifically developed as a disinfectant against gram-negative organisms.

As yet there is no disinfectant available which has a high killing power against the pseudomonas group. In the meantime, this should not prevent the use of those quaternary ammonium salts which are as effective against this group as most other disinfectants, and which have other advantages which are *leading to* their more widespread adoption.

London, W.4. L. M. SPALTON.

TUBERCULIN SENSITIVITY

SIR,—In his paper on tuberculin sensitivity of children (Nov. 8) Dr. Coles gave as the criterion of a positive Mantoux test the appearance of an area of erythema or erythematous infiltration at the injection site. It is, however, surely agreed that in the Mantoux test an area of erythema by itself, without infiltration, should be disregarded.

In the Prophit survey the standard laid down for a positive interpretation was œdema *with* surrounding erythema (the italics are mine); and in the World Health Organisation report on tuberculin testing[1] Ustvedt says that redness alone does not constitute a positive reaction.

---

[1] Jolliffe, N. *Ass. Res. nerv. ment. Dis. Proc.* 1939, 19, 111.

[2] Cleckley, H. M., Sydenstricker, V. P., Geeslin, L. E. *J. Amer. med. Ass.* 1939, 112, 2107.

[3] Hardwick, S. W. *Recent Progr. in Psychiat.* 1950, 2, 111.

[1] *Bull. World Hlth Org.* 1950, 2, 359.

Dr. Coles's comparison of the two jelly tests with the Mantoux test is of great interest, for it shows that when the modified jelly test is the only preliminary test in selecting candidates for B.C.G. vaccination a considerable number may wrongly be rejected as reactors. In a recent paper a comparison of the patch and 10 and 100 tuberculin unit Mantoux tests led the authors to conclude that the patch and the 100 tuberculin unit tests may give between 8 and 10% false positive reactions, and that the 10-unit test is the most specific.

H. G. CALWELL
Medical Director,
B.C.G. Vaccination Service,
Belfast. Northern Ireland Tuberculosis Authority.

FIFTY YEARS OF MIDWIFERY

SIR,—In referring (Nov. 1) to the recent golden jubilee celebration at the Royal College of Midwives of the passing of the Midwives Act, 1902, you have given a timely reminder of the many improvements in the training and status of midwives in the past half-century, and you have rightly emphasised the important place the midwife now holds in the health team. When, however, you relate these changes as closely as you do to the decline in maternal mortality your ground is less sure, and your statement that the midwives "may fairly take *much* (my italics) credit for the fall" may give a wrong impression to some of your readers. Most of the credit for this belongs to the medical profession, as the evidence clearly shows.

At the turn of the century, and for a few years after, the maternal mortality-rate was showing a downward trend. But this did not continue, and during the quarter-century 1910–35 the rate remained more or less constant at about 4 per 1000 total births. This was most disquieting, and in 1928 and subsequent years various committees were formed to examine this subject. Their reports, together with the confidential reports on the causes of maternal death by the chief medical officer to the Ministry of Health, brought many matters to light. Most important, perhaps, was the clear demonstration that maternal mortality was closely related to the availability and quality of antenatal and intrapartum treatment. About the same time, as a result of much research,[1] it became clear that in puerperal sepsis the responsible organism had often been introduced from the nose and throat of an attendant at the labour. This most important advance in knowledge led to much prevention and a better control of puerperal sepsis, which at that time was the first cause of maternal death. The throat-swabbing of those about to work in labour wards, the use of efficient face masks, and the isolation of septic cases were the main new methods introduced as a result of these observations. Also, there was the discovery, isolation, and testing of the new alkaloid of ergot, ergometrine.[2] Not long after came the sulphonamides, and later penicillin and the other antibiotics. The obstetrical flying squads in the charge of doctors and equipped to transfuse and give other emergency treatment to the woman too ill to move to hospital, were also started. The demonstration of the rhesus antigen and rhesus antibodies in human blood and the developments following the introduction of a National Blood Transfusion Service also led to a measurable lowering of the maternal-mortality rate.

The reduction in maternal mortality from a rate of about 4 per 1000 total births to the low figure of 0·65 per 1000 total births in 1951 has been the result of new discoveries and improved techniques. The midwife's main contribution has been her careful and conscientious attention to the normal case, her timely recognition of the abnormal pregnancy or labour, and her wil ness to act as a maternity nurse when a docto present.

Department of Obstetrics and Gynæcology,
University of Sheffield. C. S. RUSSEL

EFFECTS OF HEXAMETHONIUM

SIR,—We were most interested in the report Professor McMichael and his co-workers (Nov. 8) on effect of hexamethonium on the pulmonary circulat as these experimental observations provide a theore basis for our clinical experience with this drug emphysema.

We were first prompted to use hexamethonium in a wo aged 66, who had hypertension and emphysema, cyanosis and dyspnœa at rest which had failed to imp with the usual treatment. There was no evidence of ventricular failure and no response to mersalyl and dig She improved distinctly after 30 mg. of hexamethonium cutaneously; since being discharged 2 months ago she continued to take 30 mg. thrice daily, and has rema well.

We were not satisfied that this improvement due to relief of left ventricular failure and decide try the drug in further cases of emphysema and hy tension and of emphysema alone. The improven was equally good in both groups.

A man, aged 57, had been under our care for 4 years bronchitis and very gross emphysema. He had faile respond to breathing exercises, Christie's abdominal bin pneumoperitoneum, antispasmodics, and repeated course antibiotics. His heart was small, and blood-pressure aver 145/90 mm. Hg; and his cyanosis and dyspnœa rest could only be attributed to pulmonary disease. condition was immediately relieved after 20 mg. h methonium subcutaneously, and 30 mg. thrice daily conti to control his symptoms.

So far we have tried this treatment in too few ca of pulmonary disease to judge the likelihood of resp and of complications. We have found, however, t smaller doses are effective than those usually requ by hypertensives.

It seems probable that the improvement in t cases of emphysema is due to increased pulmonary bl volume, allowing a more efficient respiratory intercha of gases. If this is so, hexamethonium should ben many other types of pulmonary disease.

St. Richard's Hospital,
Chichester, Sussex.
J. D. WHITESID
M. H. COIGLEY.

SIR,—In their important paper Dr. Gilmore his colleagues interpret the increase in circulati time on tilting after administration of hexamethoni to the effect of gravity on pulmonary vessels to wl vasoconstrictor impulses have been reduced. But d this accord with the anatomy of the lung-vessels? pulmonary arteries and veins radiate in all directions, radiograms of these vessels after opacification sug that in some adults their total volume may be gre above than below their cardiac orifices, and roug equal on the dorsal and ventral sides of their orifices. this is so the centre of gravity of the whole mass of bl in the two lungs is within the heart, and tilting the b would alter the effect of gravity on the pulmonary bl no more than rotating it about its centre of gravit that is, not at all.

The figures given for cardiopulmonary blood volu indicate that in the tilted position after hexamethoni it may be double that in the horizontal position be hexamethonium. If so radiograms should show difference in pulmonary vascularity under the conditions. Lastly it would be interesting to know if change in respiration was noted when the

Public Health

Unification of the Health Services

Dr. Hugh Paul, medical officer of health for Smethwick, suggests, in his annual report for 1951, that "the splitting of the health and medical services of this country into three sections is almost universally admitted to have been a mistake, and most observers would agree that unification is the most pressing medical problem before us at the present time."

Dr. Paul considers how such a unified service might be operated. A corporation of the B.B.C. type would, he says, be too vast and too impersonal; while a board such as the Midland Electricity Board would be unsuitable because its efficiency could not be measured at the end of each year in pounds, shillings, and pence. The new body, says Dr. Paul, must be elected; and he suggests a two-tier system of control.

The country, he proposes, should be divided into 40 "counties," each with an average population of just over a million, though in more sparsely populated parts the total would be smaller and around the conurbations it would be about two million. (London, with its special problems, is not included in this scheme.) Each of the "counties" would be divided into four or five "county boroughs." The county council would consist of all the councillors of each of the county-borough councils; and to secure liaison between the county boroughs, each might appoint one member to serve on the other three or four in the county. The county council would be the supreme health authority in its area; and the special interests of the various professions would be cared for by coöption at county and county-borough level.

The health authorities "would have constantly before them the knowledge that their foremost function was to reduce the number of beds in hospitals by reducing the need for their occupation." The medical officer of health should be closely associated with the hospitals as well as with the district. All professional workers in the hospital should spend only part of their time there and the remainder on the district: "The hospital consultant would be expected to spend more time in the homes of the people and in the workshops and factories." The health visitor should go round the hospital with the consultant, study the home problems of patients, and visit them on the district. She should be able to bring to the physician or surgeon in charge, when the patient first goes to hospital, a picture of the background of his disability; and when he is discharged she should be in a position to arrange for him to have such assistance as would help to prevent recurrence of his illness.

"The service in this country can never be completely satisfactory until the controlling body, whatever its name, views its duties and responsibilities as a whole."

Housing in Sheffield

In his report on the year 1951, Dr. Llywelyn Roberts, medical officer of health for Sheffield, remarks that in the late war the flow of new houses was completely stopped. In the city houses condemned but still occupied total 10,597, made up as follows: houses included in clearance areas confirmed by the Minister of Health and tenants not yet rehoused, 4506; houses for which demolition orders have been made and tenants are awaiting rehousing, 57; houses where schemes have been accepted under section 11 of the Housing Act, 1936, and tenants are still awaiting rehousing, 28; houses where public inquiries have been held by the Minister of Health in regard to clearance areas but no decision has yet been reached, 1529; houses in clearance areas represented by the medical officer of health but no public inquiries have been held, 4477. In addition, 138 houses have no piped water-supply from the corporation mains, and 277 houses have no access to a water-closet.

There is still, says Dr. Roberts, a great deal of overcrowding, and he cites the following instances:

A tenant and three subtenant families (total of 13 people, all related) live and sleep in a three-room house of poor type; two of the families (8 people) sleep in one room.

A tenant and four families related by marriage (total of 20 people) live in a four-bedroom-type house.

A man, his wife, and 4 children of both sexes and of ages ranging from 11 to 18 years, are sleeping in one bedroom.

Dr. Roberts observes that the provision of new houses by itself will not cure the many ills associated with poor accommodation: "A policy of education in responsibility *and in the proper enjoyment and improvement* of amenities must be part of housing policy."

Domestic Help at Night

At a meeting last Tuesday, London County Council approved a proposal by its health committee that a night service of domestic help should be provided for the chronic sick in their homes. Such a service, the committee suggested, "would give relief to the relatives and friends by enabling them to obtain some undisturbed sleep each week." This extension of the home-help service will have to be approved by the Ministry of Health.

Poliomyelitis in England and Wales

In England and Wales uncorrected notifications of poliomyelitis in the week ended Nov. 8 were as follows: paralytic 81 (65), non-paralytic 36 (21); total 117 (86). This is an increase of 31 on the previous week, the figures for which are shown in parentheses.

Appointments

Fletcher, G. C., M.B. Manc.: appointed factory doctor, Middleton district, Lancashire.
Frankland, A. W., M.A., B.M. Oxfd: M.O. to the allergy clinics, St. Mary's Hospital, London.
Grainger, C. N., M.D. Lond., D.C.H.: appointed factory doctor, Totnes district, Devon.
Greer, James, L.R.C.P.I.: asst. school M.O., Sheffield.
[illegible], M.B.: house-physician, The Hospital for [illegible] at Ormond Street, London.
[illegible] B. Aberd., F.R.C.S.E.: part-time registrar, [illegible] ment, The Hospital for Sick Children, Great [illegible] ondon.
[illegible] M.B. Lond., M.R.C.P.: asst. physician (con- [illegible] Garrett Anderson Hospital, London.
[illegible] Lond., D.P.H.: deputy M.O.H., Tottenham.

Colonial Service:

Boardman, H. M. S., L.R.C.P.E.: senior M.O., Sierra Leone.
Bruvels, N. R., M.D. Latvia: M.O., Federation of Malaya.
Eckhart, G., M.D., D.T.M. & H.: M.O., Tanganyika.
Leitch, Neil, B.M. Oxfd, D.P.H., D.T.M. & H.: senior M.O., Nigeria.
McCreery, W. C. C., M.B. Dubl.: M.O., Federation of Malaya.
MacFarlane, A. L., M.B. Lond., F.R.C.S.E.: senior M.O., Kingston Public Hospital, Jamaica.
O'Brien, J. J., M.B. Belf.: M.O., Federation of Malaya.
Purcell, Bridget, L.R.C.P.E.: M.O., Federation of Malaya.
Richardson, Alison, M.B. Camb.: M.O., Federation of Malaya.
Wells, A. V., M.B. Edin., D.T.M. & H.: M.O., St. Lucia, Windward Islands.

South Western Regional Hospital Board:

Bussell, L. J., B.A., D.M. Oxfd, M.R.C.P., D.C.H.: senior medical registrar, Plymouth clinical area.
McGwinn, P. L., M.B. N.U.I., D.A.: anæsthetic registrar, Frenchay Hospital, Bristol.
Ray, R. L., M.B. Lond.: asst. chest physician, West Cornwall clinical area.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

Births, Marriages, and Deaths

BIRTHS

Hill.—On Nov. 9, at Southmead Hospital, Bristol, to Mary (*née* Bladon), wife of Dr. Pascoe Hill—a son.

Lennox.—On Nov. 11, at Hammersmith Hospital, London, to Mary (née Smith), wife of Dr. Bernard Lennox—a daughter.

Ogilvie.—On Nov. 15, at the Middlesex Hospital, London, W.1, to Lavender (*née* Challinor), wife of Dr. B. M. Ogilvie—a daughter.

Williams.—On Nov. 12, to Anne (*née* Boddington), wife of Dr. Ivor Williams, of 59, Gainsborough Road, Ipswich—a son.

MARRIAGES

Cummins—Heneker.—On Nov. 15, Arthur Dillon Croker Cummins, M.R.C.P.I., surgeon-commander, R.N. retd, of Worthing, Sussex, to Dorothy Alice Heneker, formerly of Montreal, Canada.

*Rutherfoord—Tomlinson.—On Oct. 18, at Chiswick, Geoffrey Temple Rutherfoord, M.B., to Teresa Elizabeth Tomlinson.

DEATHS

Dickson.—On Nov. 8, at Inverleith Place, Edinburgh, Robert Milne Dickson, O.B.E., M.D. St. And., D.O.M.S., colonel Army Medical Services, retd.

Shepherd.—On Nov. 15, at Guildford, Charlotte Dorothy Shepherd, M.B. Edin., of Bramshott Court, Liphook, Hampshire.

Stacey.—On Nov. 9, at Critters, Curbar, near Sheffield, John Eric Stacey, M.D. Sheff., F.R.C.S.E., F.R.C.O.G.

*Amended Notice.

Obituary

DAVID MUNRO

K.C.B., C.I.E., M.A., LL.D. St. And., M.B. Edin., F.R.C.S.E.

Air Vice-Marshal Sir David Munro was an expert in occupational health, and as director of the R.A.F. Medical Service, as secretary to the Industrial Health Research Board, and as chief medical officer to the Ministry of Supply he had gathered his experience among Servicemen and civilians, and in war and peace. He died at Halton on Nov. 8.

The twelfth child of his parents, he was born in 1878 at Boreham Wood, near Elstree, where his father owned a not too successful preparatory school. Consequently he had somewhat of a financial struggle to get educated, first at St. Andrews University, which he entered at the age of 14, and later at Edinburgh, where he was able to study medicine only because he was awarded a scholarship by the Skinners' Company.

Elliott & Fry

He qualified in 1901, towards the end of the South African War. His imagination had been stirred by Kipling, and he at once decided to try for the Indian Medical Service, at that time at the zenith of its fame. Entrance to the service was then by competitive examination and he passed in 5th. At Netley he studied under Almroth Wright and Leishman.

In India he served two years on the military side, mainly on the Waziristan front, and from then till 1914 in Bengal on the civil side. He took the F.R.C.S.E. in 1911.

At the outbreak of the first world war he was recalled to military service, first with the Indian troops in France, and later in Mesopotamia where he was appointed C.I.E. for distinguished service at Basra. It was there he met Colonel Matthew Fell, a meeting which was completely to alter his later life. In 1918 he was transferred from Mesopotamia to Egypt, at his own request, as surgical specialist to the 23rd Indian General Hospital which was stationed at Masaid near El Arish on the borders of Palestine. There had been trouble in France in March, 1918: the war was not going well, and twenty-four British battalions had been withdrawn from Palestine, sent to the Western front, and replaced by Indian troops. This created problems of hospital administration to which the British medical officers in Palestine were unaccustomed—problems of religion and race, food, sanitation, touchable and untouchable. In consequence Munro was pulled out of his post as surgeon at Masaid, rather against his will, and appointed D.A.D.M.S. Indian troops under Lieut.-Colonel J. Johnston Abraham, who was A.D.M.S., Lines of Communication. He held this appointment until the end of the war.

Back in England in 1919, he again met Colonel Fell, who had been given the task of creating the medical service of the Royal Air Force. Fell offered him the post of first principal medical officer in India, and after considerable difficulty he was able to transfer from the I.M.S. to the new service. Two years later, when Sir Matthew Fell became director-general of Army Medical Services, Munro succeeded him in the R.A.F. Nine years of fine administrative work followed during which he built well on the foundations laid by Fell. He retired in 1930 from the R.A.F. with a K.C.B. at the age of 52, only to take up another job. The same year he became secretary of the Industrial Health Research Board of the Medical Research Council, a post which he held for twelve years. The students of St. Andrews University elected him rector in 1938. During the late war he was chief medical officer of the Ministry of Supply from 1940 to 1943. One of his greatest moments was in 1942 when he was elected master of the Skinners' Company, to which he owed his chance to become a doctor. Two years later he was elected vice-chairman of the board of management of the London School of Hygiene and Tropical Medicine.

A friend writes: "David was a good mixer. He played an excellent game of golf. He learnt to fly. He played polo for the R.A.F. He rode to hounds. He picked the right men for his service, and when he put them into posts he let them prove themselves. He was in fact a great success as an administrator. It was uphill work fighting for his service, but he held his own against the Treasury with a disarming grin that got him just where he wanted. He had charm. He loved music, pictures, good literature, good food. He used to contribute occasionally to *Blackwoods*, traditionally the Indian officer's magazine, and in 1941 he published his charming nostalgic autobiography. In *It Passed Too Quickly*, with characteristic sly humour, he described life in his beloved St. Andrews, the final years of the British Raj in India, life in the Air Force, and the last years in Buckinghamshire."

Recalling the early days of the R.A.F. Medical Service, T. C. M. says: "When Munro succeeded Fell as Director-General he promptly entered the arena to serve as a member of the Cabinet committee to decide whether there should be a separate R.A.F. medical branch, or whether it should be taken over by either the Army or Navy medical services. Subordination no, coördination certainly. The battle was soon over, for David Munro was a 'bonny fechter' with a silver tongue. 'If I had one ideal for my new medical service,' he later wrote, 'it was that the officers should be doctors first and not become too military, and I believe it was attained.' This was what he strove for during his nine years as Director-General and in this he was strongly supported by Lord Trenchard, and so the R.A.F. Medical Branch came into being and the camaraderie between the flying and medical branch was cemented for all time.

"David Munro, the man himself, was one who warmed both hands before the fire of life. Fear was a stranger to him; blessed with excellent hands and a good eye, all games came easily to him: a scratch golfer, he represented the R.A.F. on many occasions. A keen rider to hounds with the Old Berkeley and Whaddon Chase, an enthusiastic polo player, he believed that the best view of the world was between the ears of a horse. At 55 he rode his first of many point-to-points, but if the truth be told, with many falls, for he was a thruster. He preached the dogma and who will gainsay him that 'guts count as high as brains,' and he was the fortunate possessor of both in ample measure. At 75, as commanding officer of the local A.T.C., he plunged with enthusiasm into the art of gliding, piloting his glider over the countryside in his beloved Bucks and gazing nostalgically from 300 feet over the scene of his past athletic triumphs."

R. H. S. writes: "Munro had a flair for negotiating, organising, and selecting the right man for a particular purpose. He saw clearly the importance which applied physiology would play in the medical care of flying personnel, and he encouraged Martin Flack from the London Hospital to lay the sound physiological foundations upon which the special medical examination in the Air Force is built. He once wrote, 'It seems to me that for those officers or airmen who for one reason or another leave the Royal Air Force whilst they are still vigorous, industrial medicine offers an outlet.' He certainly found an outlet for his own abilities and vigour in that field for on leaving the Royal Air Force, he became secretary of the Industrial Health Research Board, and later as chief medical officer of the Ministry of Supply he built up the large and efficient medical service for the munitions factories.

"At the age of 75 he learned to glide. Only a few months ago he applied for two medical posts and was somewhat hurt when told that his age was against him. He had also been told that he would not be allowed to glide solo, but he was hopeful of finding a way round this, and as throughout his life one of his outstanding characteristics was his ability to find a way round things, he was optimistic about succeeding.

Public Health

Unification of the Health Services

Dr. Hugh Paul, medical officer of health for Smethwick, suggests, in his annual report for 1951, that "the splitting of the health and medical services of this country into three sections is almost universally admitted to have been a mistake, and most observers would agree that unification is the most pressing medical problem before us at the present time."

Dr. Paul considers how such a unified service might be operated. A corporation of the B.B.C. type would, he says, be too vast and too impersonal; while a board such as the Midland Electricity Board would be unsuitable because its efficiency could not be measured at the end of each year in pounds, shillings, and pence. The new body, says Dr. Paul, must be elected; and he suggests a two-tier system of control.

The country, he proposes, should be divided into 40 "counties," each with an average population of just over a million, though in more sparsely populated parts the total would be smaller and around the conurbations it would be about two million. (London, with its special problems, is not included in this scheme.) Each of the "counties" would be divided into four or five "county boroughs." The county council would consist of all the councillors of each of the county-borough councils; and to secure liaison between the county boroughs, each might appoint one member to serve on the other three or four in the county. The county council would be the supreme health authority in its area; and the special interests of the various professions would be cared for by coöption at county and county-borough level.

The health authorities "would have constantly before them the knowledge that their foremost function was to reduce the number of beds in hospitals by reducing the need for their occupation." The medical officer of health should be closely associated with the hospitals as well as with the district. All professional workers in the hospital should spend only part of their time there and the remainder on the district: "The hospital consultant would be expected to spend more time in the homes of the people and in the workshops and factories." The health visitor should go round the hospital with the consultant, study the home problems of patients, and visit them on the district. She should be able to bring to the physician or surgeon in charge, when the patient first goes to hospital, a picture of the background of his disability; and when he is discharged she should be in a position to arrange for him to have such assistance as would help to prevent recurrence of his illness.

"The service in this country can never be completely satisfactory until the controlling body, whatever its name, views its duties and responsibilities as a whole."

Housing in Sheffield

In his report on the year 1951, Dr. Llywelyn Roberts, medical officer of health for Sheffield, remarks that in the late war the flow of new houses was completely stopped. In the city houses condemned but still occupied total 10,597, made up as follows: houses included in clearance areas confirmed by the Minister of Health and tenants not yet rehoused, 4506; houses for which demolition orders have been made and tenants are awaiting rehousing, 57; houses where schemes have been accepted under section 11 of the Housing Act, 1936, and tenants are still awaiting rehousing, 28; houses where public inquiries have been held by the Minister of Health in regard to clearance areas but no decision has yet been reached, 1529; houses in clearance areas represented by the medical officer of health but no public inquiries have been held, 4477. In addition, 138 houses have no piped water-supply from the corporation mains, and 277 houses have no access to a water-closet.

There is still, says Dr. Roberts, a great deal of overcrowding, and he cites the following instances:

A tenant and three subtenant families (total of 13 people, all related) live and sleep in a three-room house of poor type; two of the families (8 people) sleep in one room.

A tenant and four families related by marriage (total of 20 people) live in a four-bedroom-type house.

A man, his wife, and 4 children of both sexes and of ages ranging from 11 to 18 years, are sleeping in one bedroom.

Dr. Roberts observes that the provision of new houses by itself will not cure the many ills associated with poor accommodation: "A policy of education in responsibility and in the proper enjoyment and improvement of amenities must be part of housing policy."

Domestic Help at Night

At a meeting last Tuesday, London County Council approved a proposal by its health committee that a night service of domestic help should be provided for the chronic sick in their homes. Such a service, the committee suggested, "would give relief to the relatives and friends by enabling them to obtain some undisturbed sleep each week." This extension of the home-help service will have to be approved by the Ministry of Health.

Poliomyelitis in England and Wales

In England and Wales uncorrected notifications of poliomyelitis in the week ended Nov. 8 were as follows: paralytic 81 (65), non-paralytic 36 (21); total 117 (86). This is an increase of 31 on the previous week, the figures for which are shown in parentheses.

The same year he became secretary of the Industrial Health Research Board of the Medical Research Council, a post which he held for twelve years. The students of St. Andrews University elected him rector in 1938. During the late war he was chief medical officer of the Ministry of Supply from 1940 to 1943. One of his greatest moments was in 1942 when he was elected master of the Skinners' Company, to which he owed his chance to become a doctor. Two years later he was elected vice-chairman of the board of management of the London School of Hygiene and Tropical Medicine.

A friend writes: "David was a good mixer. He played an excellent game of golf. He learnt to fly. He played polo for the R.A.F. He rode to hounds. He picked the right men for his service, and when he put them into posts he let them prove themselves. He was in fact a great success as an administrator. It was uphill work fighting for his service, but he held his own against the Treasury with a disarming grin that got him just where he wanted. He had charm. He loved music, pictures, good literature, good food. He used to contribute occasionally to *Blackwoods*, traditionally the Indian officer's magazine, and in 1941 he published his charming nostalgic autobiography. In *It Passed Too Quickly*, with characteristic sly humour, he described life in his beloved St. Andrews, the final years of the British Raj in India, life in the Air Force, and the last years in Buckinghamshire."

Recalling the early days of the R.A.F. Medical Service, T. C. M. says: "When Munro succeeded Fell as Director-General he promptly entered the arena to serve as a member of the Cabinet committee to decide whether there should be a separate R.A.F. medical branch, or whether it should be taken over by either the Army or Navy medical services. Subordination no, coördination certainly. The battle was soon over, for David Munro was a 'bonny fechter' with a silver tongue. 'If I had one ideal for my new medical service,' he later wrote, 'it was that the officers should be doctors first and not become too military, and I believe it was attained.' This was what he strove for during his nine years as Director-General and in this he was strongly supported by Lord Trenchard, and so the R.A.F. Medical Branch came into being and the camaraderie between the flying and medical branch was cemented for all time.

"David Munro, the man himself, was one who warmed both hands before the fire of life. Fear was a stranger to him; blessed with excellent hands and a good eye, all games came easily to him; a scratch golfer, he represented the R.A.F. on many occasions. A keen rider to hounds with the Old Berkeley and Whaddon Chase, an enthusiastic polo player, he believed that the best view of the world was between the ears of a horse. At 58 he rode his first of many point-to-points, but if the truth be told, with many falls, for he was a thruster. He preached the dogma and who will gainsay him that 'guts count as high as brains,' and he was the fortunate possessor of both in ample measure. At 75, as commanding officer of the local A.T.C., he plunged with enthusiasm into the art of gliding, piloting his glider over the countryside in his beloved Bucks and gazing nostalgically from 300 feet over the scene of his past athletic triumphs."

R. H. S. writes: "Munro had a flair for negotiating, organising, and selecting the right man for a particular purpose. He saw clearly the importance which applied physiology would play in the medical care of flying personnel, and he encouraged Martin Flack from the London Hospital to lay the sound physiological foundations upon which the special medical examination in the Air Force is built. He once wrote, 'It seems to me that for those officers or airmen who for one reason or another leave the Royal Air Force whilst they are still vigorous, industrial medicine offers an outlet.' He certainly found an outlet for his own abilities and vigour in that field for on leaving the Royal Air Force, he became secretary of the Industrial Health Research Board, and later as chief medical officer of the Ministry of Supply he built up the large and efficient medical service for the munitions factories.

"At the age of 75 he learned to glide. Only a few months ago he applied for two medical posts and was somewhat hurt when told that his age was against him. He had also been told that he would not be allowed to glide solo, but he was hopeful of finding a way round this, and as throughout his life one of his outstanding characteristics was his ability to find a way round things, he was optimistic about succeeding.

"It is fitting that he should rest in the quiet churchyard of Wendover Church, near to his house high in the Chilterns; near to the Royal Air Force Hospital he had seen built; and in the county he loved so well and in which he had spent so many happy years."

Sir David Munro married in 1905 Isabel Cunningham, who had been a fellow student at St. Andrews. She survives him with a son and a daughter.

JOHN ERIC STACEY

M.D. Lond., M.B. Sheff., F.R.C.S.E., F.R.C.O.G.

THE death of John Eric Stacey, on Nov. 9, at Curbar, Derbyshire, has taken from Sheffield and the North of England one of its most distinguished obstetricians and gynæcologists.

He was born in Sheffield just over sixty years ago, and he entered the University of Sheffield from Christ's Hospital with an open medical scholarship in 1908. He had a brilliant undergraduate record, graduating M.B. at the age of twenty-one, and carrying off the gold medal in clinical medicine and surgery. The same year he became house-surgeon at the Jessop Hospital for Women, Sheffield, and his service to the hospital was only interrupted by his service abroad with the R.A.M.C. during the first world war as regimental medical officer with the Royal Berkshire Regiment. At the battle of Loos he sustained a severe wound in his back, which caused a complete paraplegia lasting for eight months. When signs of recovering function appeared, his determination to recover overrode all obstacles, and it was not long before he was playing his part again, operating at the 3rd Northern Hospital in Sheffield for long hours with the aid of surgical supports. His fortitude in circumstances that would have crushed a lesser spirit was a source of wonder to his friends and an inspiration to his patients.

At the end of the war he turned again to obstetrics and gynæcology as a career; he was appointed registrar to the Jessop Hospital in 1920. The same year he took the F.R.C.S.E., in 1921 the M.B. Lond., and the following year the M.D. Lond. in diseases of women. In 1924 he was elected assistant surgeon to the Jessop Hospital.

In his specialty he had wide contacts, and as a consultant he was popular with the general practitioners of South Yorkshire. He held appointments as surgeon to the Beckett Hospital, Barnsley, and Retford Cottage Hospital, and he was for many years lecturer in obstetrics and gynæcology to the University of Sheffield.

L. B. P. recalls his delight in teaching and the popularity of his lectures. "Mr. Stacey," he continues, "did not write much. His great energy was devoted to the practice of gynæcology—he was a deft and rapid operator—and his writings were based on his experience. A fair fighter, he was ever ready to champion those in trouble with authority, if he believed in their case. His opinions were forthright, and he did not hesitate to express them. He had many and varied interests and entered into social activities with zest. He was a lively and entertaining host, delighting his friends by his ability as a raconteur."

As a founder member Stacey took a great interest in the Royal College of Obstetricians and Gynæcologists. In 1937 he was elected F.R.C.O.G., and he served as a member of council for ten years, and as vice-president from 1949 to 1952. He acted as examiner for its membership for many years and last year visited Canada and the United States as its representative. He examined, too, for the Universities of Sheffield and London, for the Conjoint Board, and the Central Midwives Board. A week before his death, although he did not know it, he was elected an honorary fellow of the Royal College of Obstetricians and Gynæcologists of Athens.

C. G. P. writes: "Stacey was a man brimming over with vitality and cheerfulness. Whatever the problem that faced him, he tackled it with a single-minded sincerity and determination, coming to decisions rapidly, and acting upon them resolutely. He enjoyed opposition, but when he could be convinced that his views were wrong, he gave way with a charming grace. His manner could be at times aggressive, but this was born of his convictions, and he never bore ill will to his opponents. His surgical work was a reflection of his character; he was a neat, speedy, and intrepid operator and his kindness, skill, and impish good humour endeared him to his patients.

"As a teacher he spared no pains to explain any problems, drawing rather from his experience than the textbook to emphasise his points. His clinics were always crowded with students and every lesson was illustrated by shafts of wit. It is perhaps the long succession of residents, many coming from the Dominions, who have the greatest cause to be grateful to him as a teacher. He took great trouble to make them a credit to his hospital, encouraged them to take responsibility, and supported them wholeheartedly in all their actions.

"He made relatively few contributions to the literature of his specialty, but those he made were outstanding. His influence was felt perhaps more in his contributions to the North of England Obstetrical and Gynæcological Society, where his vast experience, shrewd judgment, and salty phrase always provided an expectant and never disappointed audience. It is hard to feel that John Eric, a man who seemed to be imbued with perennial youth, is no longer with us."

His wife, Dr. Margaret Stacey, herself a former resident at the Jessop Hospital, survives him with their son and daughter.

HENRY SORDS MEADE

M.Ch. N.U.I., F.R.C.S.I.

BY the death of Prof. Henry Meade, Ireland has lost one of her great surgical figures. He was one of the last of the general surgeons, who could turn their hands successfully to widely different tasks.

He qualified in 1909 from the Catholic University of Dublin, now part of the National University of Ireland, and he took the F.R.C.S.I. the following year. Soon afterwards he was appointed visiting surgeon to St. Vincent's Hospital, Dublin, and he shared in the work of this large teaching hospital for over forty years. In the first World War he served both in the R.A.M.C. and in the French Army, and in recognition of his work the French government conferred on him the decoration of chevalier in the Legion of Honour.

In 1928 he was appointed to the chair of systemic surgery at University College, Dublin. His many hospital appointments included that of surgeon to the National Maternity Hospital. In 1934 the National University of Ireland conferred on him the honorary degree of M.CH. He served a term of office as president of the Royal College of Surgeons in Ireland, and he also presided over the Association of Surgeons of Great Britain and Ireland when they met in Dublin in 1949. Most of his holidays abroad were spent searching for new techniques, and observing the work of the leaders of surgery in European centres, and he was a well-known figure at surgical conferences throughout Europe. He had a competent knowledge of many languages, and one of his greatest delights was riding around Paris beside a taxi-driver, discussing the affairs of the day. Besides these informal contacts he had many academic links with the Continent. He was a member of the council of the International Society of Surgery, and he represented Ireland in this society for many years. He was also a member of the French Association of Surgery, an associate of the French Académie de Chirurgie, a member of the Société Internationale d'Urologie, of the German Society of Surgery, and during his last illness he received notice of his election as an honorary member of the Belgian Society of Surgery.

"To his colleagues in St. Vincent's," writes T. C. J. O'C., "Harry Meade was more than a leader. He was, in the true sense, a colleague, and perhaps his greatest attribute was his lack of envy or jealousy at the success of his juniors or assistants. Many a time he appeared at clinical meetings in the Academy of Medicine and elsewhere in the rôle of an assistant to one of his juniors. He fostered amongst his colleagues the development of specialist lines in surgery and helped them in their work, but he himself remained a general surgeon to the end.

"In the university and at the bedside his teaching was essentially personal. His students will remember the wagging finger, the dogmatic pronouncements, and the practical nature of his instruction. One of his favourite questions to a candidate in the final medical examination was: 'What would you do with this patient on the side of a mountain, twenty miles from the nearest hospital, on a wet Saturday night?' He never neglected, however, also to impart the knowledge of recent advances in surgery, and he was a pioneer in Ireland of many modern techniques. He was one of the first in these islands to introduce, after the first world war, Böhler's treatment of fractures.

"Meade was a hard worker. He spent long hours in the operating-theatre and demanded from his assistants and house-surgeons a devotion to duty never less than exacting. His relaxations were stamp-collecting and the cultivation of flowers, in which he was expert. He was a staunch supporter of the university rugby football and athletic clubs. He never wore an overcoat, and his old students, scattered throughout Ireland and the British Commonwealth, will remember the familiar figure, with his hands in his trousers pockets, standing on the touch-line on a sleety afternoon watching an inter-hospital battle. His real hobby, however, was surgery, and often he would leave a social gathering to come to the hospital to operate upon a patient in his wards. He entertained in his home in the old style, and at his table, presided over by his beautiful and gracious wife, one met the leaders of the cultural life of the country."

He leaves his wife with a daughter and two sons.

JAMES THOMAS EDWARDS

D.Sc. Lond., M.R.C.V.S.

Dr. Edwards, whose death we announced last week, had had a distinguished career as a veterinary research-worker in this country and in India.

Soon after graduating in 1911, he came under the influence of Sir John McFadyean, who drew him into the research work which was being undertaken in the department of pathology at the Royal Veterinary College, London. Here Edwards was closely concerned with investigations covering such diverse subjects as joint-ill in foals, contagious abortion in cattle, and Johne's disease. He also shared in the teaching of the department. When war broke out in 1914 he at once joined the Royal Army Veterinary Corps, and he saw service in France, including the battle of Mons, but he was soon recalled to his research work at the Royal Veterinary College.

In the years immediately after the war, despite a heavy burden of teaching and research, he undertook the editorship not only of the *Tropical Veterinary Bulletin*, but also of the *Veterinary Record*, which, having passed through evil times, was being built up as the official organ of the National Veterinary Medical Association. He was singularly fitted for this task, for he combined a sound knowledge of scientific literature with a fine command of the English language. His literary ideals were high, and he strove, often far into the night, to bring out journals which would be a credit to the veterinary profession.

His talents did not go unmarked, and in 1923 he was appointed director of the Imperial Institute at Muktesar, India. Here he found ample scope for his genius for original research. He had always shown a great interest in, and a profound knowledge of, tropical diseases. He immediately plunged into extensive researches, the most important of which was the attempt to improve the methods of combating rinderpest. It is no exaggeration to say that the adaptation of rinderpest virus to the goat, an investigation which required great intuition coupled with painstaking and, at times, most discouraging experiments, revolutionised the whole problem of rinderpest control in all parts of the world, and laid the foundations of a progressive programme for the conservation of livestock, the full benefits of which have yet to be reaped.

On his return to England Edwards joined a group of workers who were investigating foot-and-mouth disease. He made the important observation that variations in diet could alter the susceptibility of experimental animals to infection. He also pointed out that not only is the hedgehog highly susceptible to this virus, but the agent persists in a latent form in the species during hibernation: in addition, the hedgehog is capable of disseminating infection from the lungs by the dispersal of air-borne particles. He was also engaged in various projects for improving vaccines for the control of the disease. His death has removed a scientist of outstanding ability.

ROBERT MILNE DICKSON

O.B.E., M.D. St. And., D.O.M.S.

Colonel Dickson, director of the Ross Foundation for the Study of the Prevention of Blindness, Edinburgh, died on Nov. 8.

After graduating M.B. from the University of St. Andrews in 1906 he joined the R.A.M.C. While he was on service in India with the King's Dragoon Guards the first world war broke out, and he was recalled to serve in France. He was mentioned in despatches for attending wounded under fire. During the retreat from the advancing Germans he was severely wounded at Hooge. He spent his convalescence preparing his M.D. thesis and in postgraduate studies of ophthalmology. He took the D.O.M.S. in 1921, and later was appointed ophthalmic specialist at the Queen Alexandra Hospital at Millbank. In London he had opportunities to work at Moorfields with Sir William Lister and Sir John Parsons, but he had to interrupt this work when he was transferred to Ceylon as senior medical officer. His power of administration made a permanent mark on Army medical organisation there.

On his retirement from the Army in 1937 Colonel Dickson was appointed the first director of the Ross Foundation for the Study of the Prevention of Blindness in Scotland. On the outbreak of the second world war he was recalled to the Army and he was appointed A.D.M.S. Edinburgh area. He filled this post with distinction until, for reasons of health, he had to retire in 1941, when he resumed his work at the Ross Foundation.

A colleague writes: "No better appointment as director of the Ross Foundation could have been made. Dickson's zeal and energy have already produced far-reaching results. He visited factories and mines to study conditions of work. He made contact with research-workers, coördinated their efforts, and in every way encouraged them by his recognition of the importance of their investigations. He had a happy knack of getting on with all kinds and conditions of men, and his humour and friendliness made him a most acceptable companion everywhere. Underneath it all was a basic seriousness that recognised that 'here we have no continuing city.'"

HELEN MARGARET WOOD

M.B., B.Sc. Birm., D.A.

Dr. Wood, who died at the Queen Elizabeth Hospital, Birmingham, on Nov. 8, was consultant anæsthetist to the Midland regional thoracic unit, to Yardley Green Sanatorium, and to the Birmingham Children's Hospital. By her skill she had contributed greatly to the successful development of thoracic surgery in the Midlands.

She was a student of Birmingham University and she graduated B.SC. there in 1931 and M.B. in 1936. After holding some general hospital appointments, she decided to become an anæsthetist, and she received her specialist training in the Birmingham United Hospitals and in the Nuffield Department of Anæsthetics at the Radcliffe Infirmary, Oxford. She obtained the D.A. in 1943.

F. B. writes: "Helen Wood was a fine happy healthy-looking young woman who seemed able to work hard, to play hard, and to enjoy life to the full. Indeed it was because she found that in her favourite game of golf she was not quite up to standard that she came to realise that something was amiss. She slipped quietly away to see what could be done—so quietly that weeks passed before many of her friends knew that she was seriously ill. Her placid temperament, her quiet humour, and her imperturbability made her peculiarly well suited for her work, and she quickly won a place in the first rank of her specialty."

Her father, Dr. J. Arthur Wood, of Ludlow, survives her.

Notes and News

APPROVED NAMES FOR DRUGS

THE British Pharmacopœia Commission has issued the following new supplementary list of approved names:

Approved name	*Other names*
Azamethonium Bromide	3-Methyl-3-azapentane-1:5-bis(ethyl-dimethyl-ammonium) dibromide. Pendiomide.
Benzylalkonium Chloride	Alkylbenzyldimethylammonium chloride. Zephiran Chloride.
Caramiphen	2-Diethylaminoethyl 1-phenyl*cyclo*pentane-1-carboxylic acid. Parpanit is the hydrochloride.
Chloropyrilene	*N*-5-Chloro-2-thienylmethyl-*N'N'*-dimethyl-*N*-2-pyridylethylenediamine.
Chloroquine	7-Chloro-4-(4-diethylamino-1-methylbutyl-amino)quinoline. Aralen.
Co-carboxylase	Pyrophosphoric ester of aneurine.
Dextran	
Dichlorophenarsine	3-Amino-4-hydroxyphenyldichloroarsine.
Disulfiram	Tetraethylthiuram disulphide. Antabuse.
Doxylamine	2-(α-2-Dimethylaminoethoxy-α methylbenzyl)-pyridine. *Decapryn.*
Eucatropine	4-Mandeloyloxy-1 : 2 : 2 : 6-tetramethylpiperidine. Euphthalmine.
Gentisic Acid	2 : 5-Dihydroxybenzoic acid.
Glutamic Acid	1-Aminopropane-1:3-dicarboxylic acid.
Hydralazine	1-Hydrazinophthalazine. Apresoline is the hydrochloride.
Hydroxamethocaine	[illegible]
Meralluride	[illegible] Mercuhydrin.
Mercaptomerin Sodium	Disodium salt of *N*-(3-carboxymethyl-thiomercuri-2-methoxypropyl)camphoramic acid. Thiomerin Sodium.
Mercurophylline Sodium	Mixture of the Sodium salt of *N*-(3-hydroxymercuri-2-methoxypropyl) camphoramic acid and Theophylline. Mercuzanthin.
Methanthelinium Bromide	2-Diethylaminoethyl xanthen-9-carboxylate methobromide. Banthine Bromide.
Methaphenilene	*N'N'*-Dimethyl-*N*-phenyl-*N*-(2-thienylmethyl)-ethylenediamine. Diatrin is the hydrochloride.
Methiodal Sodium	Sodium iodomethanesulphonate. Skiodan Sodium.
Methœstrol	*αβ-Diethyl-4 : 4'-dihydroxy-3 : 3'-di*methyl-stilbene.
Methylergometrine	(+)-1-Hydroxy-2-butylamide of (+)-lysergic acid. Methergine is the tartrate.
Neocinchophen	Ethyl 6-methyl-2-phenylquinoline-4-carboxylate.
Oxyphenonium Bromide	2-Diethylaminoethyl α-*cyclo*hexyl-α-phenyl-glycollate methobromide. Antrenyl.
Pentaquine	6-Methoxy-8-(5-*iso*propylaminoamyl-amino)-quinoline.
Phentolamine	2-*N*-*m*-Hydroxyphenyl-*p*-toluidinomethyliminazoline. Regitine is the hydrochloride.
Phenylbutazone	4-*n*-Butyl-1 : 2-diphenylpyrazolidine-3 : 5-dione. Butazolidine.
Piperocaine	3-(2-Methylpiperidino)propyl benzoate. Metycaine is the hydrochloride.
Polyvidone	Polyvinylpyrrolidone.
Pregnenolone	3-Hydroxy-5-pregnen-20-one.
Propyliodone	*n*-Propyl 3 : 5-di-iodo-4-pyridone-*N*-acetate.
Sodium Cyclamate	Sodium *cyclo*hexysulphamate. Sucaryl.
Sulphamethizole	2-*p*-Aminobenzenesulphonamido-5-methyl-1 : 3 : 4-thiadiazole. Urolucosil.
Suxamethonium Chloride	[illegible] succinate [illegible] Scoline.
Suxethonium Chloride	[illegible] succinate bisetho-chloride.
Thonzylamine	*N*-*p*-Methoxybenzyl-*N'N'*-dimethyl-*N*-2-pyrimidylethylenediamine. Neohetramine.
Vinbarbitone	5-Ethyl-5-(1-methylbut-1-enyl) barbituric acid. Delvinal.

The approved names amidone and isoamidone are withdrawn, and replaced as follows:

Approved name	*Other names*
Methadone	6-Dimethylamino-4 : 4-diphenylheptan-3-one. Amidone. Physeptone is the hydrochloride.
Isomethadone	6-Dimethylamino-5-methyl-4 : 4-diphenylhexan-3-one. Isoamidone.

THERAPEUTIC SUBSTANCES REGULATIONS, 1952

THESE regulations,[1] which have just been published, consolidate the various regulations issued between 1931 and 1950, and make certain new provisions. Streptomycin, in forms intended for parenteral injection, and dimercaprol (BAL) and its derivatives will be added to the Schedule to the *Therapeutic Substances Act, 1925*, as substances the purity or potency of which cannot be adequately assessed by chemical means. Detailed regulations are now made for the preparation, testing, and labelling of certain substances which already come within the schedule to the Act, but which are at present covered only by general provisions. These substances are B.C.G. vaccine, tuberculin P.P.D., oxophenarsine salts, globin insulin, and protamine zinc insulin. The regulations will take effect from Jan. 1, 1953.

MEDICAL LIBRARIES

ON Oct. 31 the medical section of the Library Association met at the Royal College of Surgeons of England, when Mr. W. R. Le Fanu, librarian of the college, described an American report on Scope and Coverage in Medical Libraries. The committee which drew up the report, as a guide to the future development of the Army Medical Library (or, as it is now called, the Armed Forces Medical Library) in Washington, took "scope" to mean the range of subjects considered pertinent to the main field of the library, and "coverage" the extent to which these subjects are covered by the literature in the library. They laid down four degrees of coverage—skeletal, reference, research, and exhaustive—into which they arranged the subjects included in the library. Thus, they suggested that purely medical subjects should be treated exhaustively—that is to say all relevant literature would be collected—whereas borderline scientific subjects should only be covered by a skeletal collection. Mr. Le Fanu believed that the report offered a new approach to book-selection.

The following officers and committee of the section were elected for 1953:

Chairman, Mr. W. A. Lee (Liverpool Medical Institution); hon. secretary, Mr. G. J. Hipkins (British [illegible]; exchange manager, Mr. F. N. L. Poynter [illegible] Medical Library); members of committee, [illegible] dcliffe Science Library), Mr. W. J. Bishop [illegible] Medical Library), Mr. W. R. Le Fanu (R[illegible] ons of England), Mr. F. A. Tubbs (St. Thom[illegible] chool), and Mr. G. Wilson (Manchester Univ[illegible]

ITALIAN HOSPITALS

IN May and June this year the International Hospital Federation made a study tour of Italy. Mr. John Dodd took part in this tour and has written an account of his impressions.[2]

THE PRIVATE LIFE OF A UNIVERSITY

EMBARRASSED by the need to explain the essential Oxford—to utter, in fact, to three American senators, and at short notice, the secret none can utter—members of a senior common room in one of the ancient colleges sat down to compose an Oxford guide-book. The result, as presented by J. C. Masterman,[3] is necessarily partial and incomplete (for who are dons to think they know their Oxford ?), providing very inadequate exponents of science and religion, showing an imperfect knowledge of contemporary undergraduate mood, and entirely omitting—as the senators when they arrive, are the first to point out—the women's colleges. But for one side of Oxford life—the masculine club-life of the colleges, in which many find the inspiration to do their best work—it is as disarming an apologia as could be written. Here are the beautiful surroundings, the matchless service, the long tradition, the courtesy, the gentle malice, the precise use of language, the loyalty to one college before all other colleges, and one university before its only peer, and the subtly flavoured stories of past dons—all those things which are enjoyed perennially by the few and remembered appreciatively by the many. Whether readers who catch the siren song of the place for the first time through these pages will feel impelled to jump in and swim for it is rather hard to say. Certainly Mr. Masterman's dons had in mind that one of the senators might think of sending his sons to Oxford, and so were at pains to deliver the air truly and keep good time; and considering their average age they made a very pretty concert of it. It is, as others have hinted, a difficult song to sing.

University of Cambridge

On Nov. 8 the degrees of M.B., B.CHIR. were conferred on Nora L. Blackwell.

Royal College of Surgeons of England

At a meeting of the council on Nov. 13, with Sir Cecil Wakeley, the president, in the chair, Mr. Hedley Atkins and Prof. Victor Dix were re-elected, and Mr. A. Dickson Wright was elected, members of the court of examiners. A Hunterian lectureship was awarded to Prof. Milroy Paul (Ceylon) for a lecture on the Surgery of the Congenital Anomalies of the Mid-line Ventral Abdominal Wall. Sir James Paterson Ross was appointed Bradshaw lecturer for 1952 in place of the late Mr. Mitchiner, and Sir Reginald Watson-Jones was appointed Bradshaw lecturer for 1953.

The John Tomes prize was presented to Prof. E. B. Manley (Birmingham); the James Berry prize to Mr. R. H. C. Robins (Newcastle and Exeter); the Hallett prize to Dr. J. K. Ross (Middlesex Hospital); the Begley prize to Mr. J. H. Breed (Westminster Hospital). Mr. R. Sprinz, F.D.S., was appointed assistant lecturer in the department of anatomy.

Diplomas of membership and diplomas in medical radiodiagnosis and medical radiotherapy were conferred on the candidates named in our report of the comitia of the Royal College of Physicians (*Lancet*, Nov. 8, 1952, p. 943). A diploma in child health was also conferred on K. M. Pearce, and diplomas in tropical medicine and hygiene on T. G. Behan, D. E. W. Knight, and M. J. J. T. Becker.

Royal College of Obstetricians and Gynæcologists

At a recent examination for the D.OBST. the following were successful:

J. F. Adam, Anne Alexander, Maryan G. Anderson, Eileen Atkinson, Margaret A. Austin, Pamela M. Bacon, G. F. Barnes, Edith M. Beecher-Bryant, J. D. Belt, J. S. G. Blair, W. W. Bowie, J. D. Brackenridge, Gladys V. Bradshaw, J. M. Brown, Janet C. Bryce, A. E. R. Buckle, M. G. Budden, D. W. Bull, Sheila G. Burnie, A. F. Bushby, Mary Campbell-Mackie, I. T. Carrie, Carmelo Cassar, D. J. Cawthorne, J. S. W. Chambers, Vera Choithramani, Sheila R. Clarke, P. W. Clements, June P. Cooper, K. V. Cooper, J. H. Cowie, Ann C. Coyle, O. J. Curl, J. W. B. Dalgleish, J. K. Davidson, H. F. Davies, Elizabeth Dennys, J. C. Dilley, Prabhavati Ravindranath Dixit, F. B. Dobbs, D. J. Dobson, Margaret K. Douglas, Diana F. J. Duncan, W. A. W. Dutton, G. F. E. Edmondson-Jones, Mary G. Eldridge, Wilfred Ellenbogen, J. M. Elliott, Luba Epsztejn, Jack Eyton-Jones, Margaret D. Findlay, G. R. C. Fisher, Mary L. Fraser, G. C. Galea, Barbara E. Gibbs, Alan Gillespie, D. L. Golightly, J. L. Goodger, Anne L. M. Graham, D. A. H. Grieve, Stanley Hacking, A. B. Haigh, Ethna J. Halpin, Ikbal Abd El-Walid Hamdy, Marion Hanson, H. A. Harding, Elizabeth M. Harpur, D. T. G. Harris, Helen J. Harthoorn, Robert Hewitt, J. M. Hiddleston, Margaret I. Hill, J. A. Holmes, J. L. Honig, J. M. Hood, R. A. St. C. Hoyte, Anne L. Hunter, Anne E. Jameson, M. H. Jameson, Helen Jessler, J. M. Jewitt, G. A. H. Jones, W. T. Joseph, Margaret Kassab, J. A. N. Keane, G. E. Kelly, Sybil V. Kinley, Frances E. W. Kinnaird, Frances E. Kirk, A. L. Kirkland, Chung Yue Lai, E. C. Lewis, Isabel J. Lim, M. D. W. Low, Helen M. M. McCallum, J. M. S. McCoy, Yvette McCoy, J. A. McCraith, Sarah C. McEwan, Anne M. McKechnie, J. G. McKenny, Edith M. McLean, Margaret E. Maclean, B. N. McQuade, D. H. McVie, A. R. Magarey, Maureen A. F. Malcolm, M. D. Manion, J. G. Markus, G. F. G. Marshall, G. G. M. Miles, J. L. Miller, R. C. Molk, Elisabeth Monkhouse, D. J. R. Morgan, June Morgan, K. D. Mullen, B. J. Murphy, Salvino Muscat, J. P. Norris, K. R. Norton, K. F. O'Callaghan, D. W. Orton, T. G. Osmond, R. B. Ottley, H. J. G. Palmer, [illegible] Perry, R. J. Pett, Mary P. Phelan, [illegible] S. J. S. Polwin, Joan M. Ponsford, [illegible] Hilary R. Pullon, D. W. Quantrill, D. J. H. Rogers, Annapurna Sabhesan, Prem Sarin, Rachel D. R. Sasieni, M. K. Sawday, G. C. W. Sharpe, R. W. Simpson, S. L. Skoll, Henry Stabile, A. J. H. Stephens, J. E. L. Sutcliffe, C. G. W. Sykes, P. K. Sylvester, Derek Tacchi, Aly Dawood El-Tannir, A. R. Taylor, Joseph Taylor, J. G. A. Troup, P. W. Tucker, J. B. Turtle, I. S. Waller, Daphne M. L. Walters, Paula M. Watkin, Joyce M. Watson, W. L. Whitehouse, Kathleen M. Whitham, L. M. Wolf, Elizabeth J. A. Yool.

Royal College of Surgeons of Edinburgh

On Nov. 5 Sir Cecil Wakeley, P.R.C.S., and Sir Reginald Watson-Jones were admitted to the honorary fellowship of the college. Prof. Walter Mercer, the president, said that it had been the custom of the college through many generations to grant the honorary fellowship to distinguished members of the medical profession and others who had deserved well of the nation. Mr. W. Quarry Wood, the vice-president, referred to Sir Cecil's achievements as surgeon, author, and as president of the Royal College of Surgeons of England; and Mr. R. I. Stirling spoke of Sir Reginald's appointments as extra orthopædic surgeon to the Queen and as president of the British Orthopædic Association.

Royal College of Physicians of Ireland

On Nov. 7 the following were admitted to the membership:

D. F. Cantwell, J. A. C. de Silva, J. C. McGoldrick, K. M. Hickey, R. J. Marshall, E. M. A. McElligott, G. E. Peters, A. L. Wells.

Chadwick Trust

Mr. J. Rawlinson, chief engineer of the London County Council, will deliver a Bossom lecture at 2.30 P.M. on Tuesday, Nov. 25, at the Royal Sanitary Institute, 90, Buckingham Palace Road, London, S.W.1. His subject will be the History of the Main Drainage of London.

Royal Society

A Royal medal of the society has been awarded to Sir Frederic Bartlett, F.R.S., for "his creation of an experimental school of psychology which has established under his leadership an outstanding position recognized internationally as without superior."

Institute of Psychiatry, London

Prof. J. Elkes will deliver a lecture at the Maudsley Hospital, Denmark Hill, S.E.5, on Thursday, Nov. 27, on Uses and Limitations of Pharmacological Method in Psychiatric Research. Dr. Graham Weddell will give a lecture on Thursday, Dec. 4, on the Mechanisms of Cutaneous Sensibility. Both lectures are at 3 P.M.

British Psycho-Analytical Society

Prof. Roger W. Russell, PH.D., will deliver the Ernest Jones lecture at a meeting of this society to be held at 1, Wimpole Street, London, W.1, on Monday, Dec. 1, at 8.15 P.M. The lecture is entitled Behaviour under Stress.

Institute of Laryngology and Otology, London

Dr. Ettore Bocca, of the otolaryngology clinic of the University of Milan, will deliver a lecture at the institute, 330, Gray's Inn Road, W.C.1, on Wednesday, Dec. 3, at 5.30 P.M. The title of the lecture, which will be illustrated by a cinematograph film, is Laryngectomy with Block Dissection of the Neck—Unilateral and Bilateral.

Helicopters for Evacuating Wounded

Helicopter ambulance units are to be formed as an integral part of the U.S. Army Medical Service. Helicopters have been used in the Korean war to rush severely injured soldiers to mobile army surgical hospitals and evacuation hospitals, but hitherto they have not been formally incorporated in field units. Each of the new units will include five two-rotor helicopters capable of carrying three stretcher or four walking patients, together with a medical attendant and a pilot.

Food and the Future

The nutrition panel of the food group of the Society of Chemical Industry is to hold four meetings on this subject. The first will take place on Wednesday, Dec. 10, at 6.15 P.M., in the rooms of the Chemical Society, Burlington House, London, W.1, when Mr. F. Le Gros Clark and Dr. E. W. Russell will speak on the Problem of Future World Food Supply. Other speakers in the series will include: Dr. G. A. C. Herklots and Prof. John Yudkin (Present Methods of Attack on the Problem); Mr. N. W. Pirie, F.R.S., and Dr. A. C. Thaysen (New Natural Sources of Foodstuffs); Dr. W. F. J. Cuthbertson, Mr. P. N. Williams, and Mr. Norman Wright, D.SC. (Synthetic Food Potentialities).

Volunteers for Common Cold Research Unit

About 600 volunteers between 18 and 45 years of age are wanted to take part in experiments next year at the Medical Research Unit at Harvard Hospital, Salisbury. They are needed to test experimental materials for the presence of cold germs. Since the unit began its work six years ago 2989 volunteers have taken part in the trials; 248 volunteers have paid two visits and 140 have taken part in three or more trials. The method of testing for the cold virus in experimental materials is by means of nasal drops given to volunteers after a preliminary period of observation to make sure that they are free from a "natural" cold. The procedure gives little or no discomfort at the time, and any colds that result are usually mild. Volunteers are isolated in pairs for periods of ten days, and full medical and nursing facilities are available at all times. Fares to and from Salisbury up to a maximum of £3 are paid, and volunteers are given 3*s*. a day pocket-money. Anyone who wishes to volunteer should write to the medical officer, Harvard Hospital, Salisbury.

British Medical Association

For 1953 the council of the association has chosen for the essay prizes for medical students the topic that a Good General Education is a Necessary Preliminary to a Medical Career. Further particulars may be had from the secretary of the association, B.M.A. House, Tavistock Square, London, W.C.1.

Competition for Medical Films

The *Presse Médicale* is again offering a prize of 100,000 francs and other awards for the best medical and surgical films submitted by amateurs. The films (16 mm.) may not be subsidised by a commercial laboratory or firm. Further particulars may be had from the secretariat of the journal, 120, Boulevard Saint-Germain, Paris. Films should reach the secretariat not later than March 10, 1953.

Manchester Mental Nursing Survey

The University of Manchester and the Manchester Regional Hospital Board have arranged for a survey of mental nursing to be made at Lancaster Moor Mental Hospital, the Royal Albert Mental Deficiency Hospital, Lancaster, and the Calderstones Mental Deficiency Hospital, Whalley. The investigation was suggested by the survey of nursing in general hospitals on which the Nuffield Provincial Hospitals Trust is shortly to report. Mr. H. A. Goddard, who directed the Nuffield survey and who is now an independent management consultant specialising in health service problems, is also to direct the Manchester survey, and he and his team of four graduates have already studied the routine nursing duties at one of the selected hospitals.

Society of Medical Officers of Health

The child health group of the Scottish branch of this society will meet at Ayrshire Central Hospital, Irvine, on Saturday, Nov. 29.

Medical Honour

Major James Stuart Hitsman, M.D. Queen's University, Ontario, R.C.A.M.C., has been appointed M.B.E. (military division) in recognition of gallant and distinguished services in Korea.

Plea for a New Hospital

In the report for 1951–52 of Charing Cross Hospital, London, Lord Inman, chairman of the board of governors, remarks on the continued delay in starting construction of the new hospital at Northwick Park. "No new hospital," he says, "has been erected in this country for over a decade. It would be a tremendous fillip throughout the entire health services of the country if a new hospital could be established incorporating the latest and most modern developments. It would draw as visitors to this land medical men and hospital administrators from all over the world and restore the country to its traditional place in the forefront of medical and surgical science."

EMERGENCY BED SERVICE.—In the week ended last Monday, acute cases numbered 1069. The proportion

Prof. B. S. Platt and Prof. A. A. Moncrieff are attending a conference on kwashiorkor, at Fajara in the Gambia, British West Africa. The conference, which opened last Wednesday, is being held under the auspices of the *Commission for Technical Coöperation in Africa, south of the Sahara.*

Diary of the Week

NOV. 23 TO 29

Monday, 24th

MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8.30 P.M. Prof. R. V. Christie, Dr. Neville Oswald: Bronchitis.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, S.E.1
5.30 P.M. Prof. Thomas Nicol: Applied Anatomy of the Orbit.

INSTITUTE OF CHILD HEALTH, The Hospital for Sick Children, Great Ormond Street, W.C.1
5.30 P.M. Prof. W. I. B. Beveridge, D.V.SC.: Resistance and Susceptibility to Viruses.

INSTITUTE OF PSYCHIATRY, Maudsley Hospital, Denmark Hill, S.E.5
4.30 P.M. Dr. E. Stengel: Lecture-demonstration.

MANCHESTER MEDICAL SOCIETY
9 P.M. (University of Manchester.) *Section of General Practice.* Dr. M. C. Tod: Carcinoma of the Cervix.

Tuesday, 25th

BRITISH POSTGRADUATE MEDICAL FEDERATION
5.30 P.M. (London School of Hygiene and Tropical Medicine) Prof. Adrien Albert, D.SC.: Selective Toxicity. (First of two lectures.)

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
8 P.M. *Section of Medicine.* Dr. Stanley Banks, Dr. J. C. Broom, Mr. J. V. Crawford: Treatment of Non-tuberculous Meningitis.

INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2
5.30 P.M. Prof. Henry Barcroft: Peripheral Circulation.

INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY
4.30 P.M. (Chelsea Hospital for Women, Dovehouse Street, S.W.3.) Sir Stanford Cade: Scope and Limitations of Surgery after Pelvic Irradiation.

WEST END HOSPITAL FOR NERVOUS DISEASES, 73, Welbeck Street, W.1
5.30 P.M. Dr. Douglas Gordon: Radiological Methods in Neurology.

PADDINGTON MEDICAL SOCIETY
8.45 P.M. (St. Mary's Hospital, Paddington, W.2.) Discussion on Recommendations of the Working Party.

Wednesday, 26th

ROYAL EYE HOSPITAL
5.30 P.M. Mr. A. J. Cameron, Miss Iris Kane, Mr. R. A. Burn: Methonium. (Symposium.)

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, W.1
3.30 P.M. Dr. A. Austin Eagger: Health in the Factory—Slough Industrial Health Service.

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. H. Haber: Benign Epithelial Tumours.

INSTITUTE OF UROLOGY, St. Paul's Hospital, Endell Street, W.C.2
5 P.M. Mr. H. P. Winsbury-White: Frequency and other Disturbances of Micturition.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW, 242, St. Vincent Street, Glasgow, C.2
5 P.M. Mr. T. Holmes Sellors: Cancer of the Lung. (Weild lecture.)

Thursday, 27th

BRITISH POSTGRADUATE MEDICAL FEDERATION
5.30 P.M. Professor Albert: Selective Toxicity. (Second of two lectures.)

ROYAL ARMY MEDICAL COLLEGE, Millbank, S.W.1
5 P.M. Major-General Sir Heneage Ogilvie: A Eulogy of the Yes-man.

ROYAL EYE HOSPITAL
5.30 P.M. Miss M. Savory: Newer Therapeutic Measures.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, S.W.1
5 P.M. Dr. Desmond Curran: Psychiatry lecture-demonstration.

INSTITUTE OF PSYCHIATRY
3 P.M. Prof. J. Elkes: Uses and Limitations of Pharmacological Method in Psychiatric Research.

UNIVERSITY OF OXFORD
8.30 P.M. (Wingfield-Morris Orthopædic Hospital.) Mr. R. G. Pulvertaft: Problems of the Injured Hand and its Repair.

MANCHESTER MEDICAL SOCIETY
8.15 P.M. *Section of Anæsthetics.* Dr. A. H. Galley: Kidney in Relation to Anæsthesia and Analgesia.

LIVERPOOL MEDICAL INSTITUTION, 114, Mount Pleasant, Liverpool, 3
8 P.M. Dr. Robert Hughes: Treatment of Coronary Thrombosis with Anti-coagulants. Dr. B. J. Bickford: Treatment of Angina Pectoris by Sympathectomy.

HONYMAN GILLESPIE LECTURE
5 P.M. (University New Buildings, Teviot Place, *Edinburgh.*) Dr. J. A. Fraser Roberts: Inheritance *of* Sex-linked Abnormalities in Man.

UNIVERSITY OF ST. ANDREWS
5 P.M. (Medical School, Small's Wynd, Dundee.) Prof. G. A. G. Mitchell: Innervation of the Thoracic Viscera.

Friday, 28th

ROYAL SOCIETY OF MEDICINE
5 P.M. *Section of Pædiatrics.* Mr. James Robertson: A Two-year old Goes to Hospital. (Film.)
8.15 P.M. *Section of Obstetrics and Gynæcology.* Mr. A. L. Gunn,
[illegible] and Recording of
Dr. Mic[illegible] Fœtal Distress in
Fœtal H[illegible] A. B. Clemetson:
Relation [illegible] Artery and Vein
Oxygen [illegible] o Cord Obstruction.
Blood at [illegible]

ROYAL EYE HOSPITAL
4.30 P.M. Mr. A. J. Cameron: Medical Ophthalmology.

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. P. F. Borrie: Vascular Disorders.

INSTITUTE OF LARYNGOLOGY AND OTOLOGY, 330, Gray's Inn Road, W.C.1
4.30 P.M. Mr. A. R. Dingley: Sulphonamides in Otitis Media.

MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 11, Chandos Street, W.1
7.30 P.M. Dr. A. N. Ashworth: Cortisone in Treatment of Syphilis of Eye.

Saturday, 29th

INSTITUTE OF OBSTETRICS AND GYNÆCOLOGY
11 A.M. (Hammersmith Hospital, Ducane Road, W.12.) Dr. C. L. Cope: Anæmia and Pregnancy.
NOON. Dr. Mary Barber: Investigation of Sepsis in a Maternity Ward.

THE SURGICAL TREATMENT OF ULCERATIVE COLITIS

P. BRIAN COUNSELL
F.R.C.S.
SENIOR SURGICAL REGISTRAR, GUY'S HOSPITAL, LONDON; FORMERLY SURGICAL REGISTRAR, ST. MARK'S HOSPITAL, LONDON

J. C. GOLIGHER
Ch.M. Edin., F.R.C.S.
ASSISTANT SURGEON, ST. MARY'S HOSPITAL, AND SURGEON, ST. MARK'S HOSPITAL, LONDON

THE modern radical surgical treatment of ulcerative colitis, which has been developed mainly as a result of the work of Bargen (1928), Bargen et al. (1932), Lahey (1949), Cattell (1939, 1948), Cave (1945), and McKittrick and Moore (1949) in America, consists of ileostomy, usually followed by colectomy and excision of the rectum. At first physicians were reluctant to advise such a drastic step as a permanent ileostomy to their patients before the issue had clearly become one of life or death, and as a consequence patients were only referred to the surgeon when they had become virtually moribund. This led to a very high operative mortality, which in turn confirmed the physician in his cautious approach to surgery. Recent improvements in the design of ileostomy appliances, however, have robbed ileostomy of several of its objectionable features; so these patients can now lead full and active lives with remarkably little inconvenience. As a result more patients with ulcerative colitis are now coming for surgical treatment and at an earlier stage, and surgery has a growing part to play in the management of this disabling and lethal disease.

At St. Mark's Hospital some 120 patients are seen each year with various forms of chronic non-specific proctocolitis, and about 15–20 of the more severe cases are operated on. We report here the collective experience of the hospital in the management of the first 90 cases of ulcerative colitis submitted to the modern surgical régime; 6 of these patients had already undergone ileostomy elsewhere and were referred for completion of their treatment.

INDICATIONS FOR SURGERY

Chronic Invalidism

This was by far the commonest indication and led to operation in 71 of the cases. Though these patients had usually been admitted to hospital many times before during exacerbations of their colitis and had eventually recovered from these, they were seldom restored to normal health. On discharge they still usually had troublesome diarrhœa confining them to the house, passed blood and mucus, were well below their normal weight, and were capable at best of only light duties. After a time with periodic aggravations of their condition they entered a chronic invalid state, becoming extremely emaciated and looking like the semi-cadaverous inmates of the notorious Belsen and Auschwitz concentration camps. The duration of the disease in about half the cases was more than four years, and retrospectively it seems that a decision in favour of surgical management could in many instances have been made earlier and the patients thus spared much unnecessary disability and suffering. However, we appreciate the point made by McKittrick and Moore (1949) that patients must have suffered severely from ulcerative colitis if they are to be convinced that an ileostomy had become essential for their recovery. Too early a resort to surgery might have led to the patients being less well adjusted psychologically to their ileostomies.

When these patients were admitted to St. Mark's Hospital they were usually in a phase of remission of symptoms, but in a few, where the disease seemed active, further medical treatment was adopted for a time to allow them to reach a quiescent period before resort was made to surgery. 4 patients, however, looked as if they were going to die unless something more than medical measures (transfusions, vitamin therapy, protein concentrates, and intestinal antiseptics) were adopted, and with considerable reluctance ileostomy was done while they were virtually in extremis, with 3 deaths.

Perforation

1 patient was operated on for perforation of the colon. At laparotomy the cæcum was found ruptured and, owing to the friable condition of its wall, was sutured with difficulty; an ileostomy was also done. The patient died sixteen hours after operation, apparently of shock. In a fitter patient we think it might have been better to have attempted exteriorisation of the perforated bowel instead of suture, or to have done an immediate subtotal colectomy and ileostomy.

Hæmorrhage

In 1 case severe hæmorrhage was the indication for operation. The bleeding took place a week or so after an ileostomy and was eventually stopped only by an emergency subtotal colectomy. In our view severe bleeding in ulcerative colitis is an indication not for ileostomy but for combined ileostomy and colectomy, as recommended by Ferguson and Stevens (1948) and by Lahey (1949), as soon as the patient's general condition can be sufficiently improved by massive blood-transfusion.

Abscesses and Fistulæ

In 12 patients anal fistulæ or perianal or ischiorectal abscesses were present and were the immediate indications for ileostomy. These were long-standing severe cases which would probably have come to surgery in any event. We know from experience that these complications of colitis never clear up unless an ileostomy is established to render the diseased colon and rectum inactive. Usually some local surgical treatment was necessary, the abscesses and fistulæ being laid open. Some of the patients later underwent colectomy with excision of the rectum.

Metastatic Complications

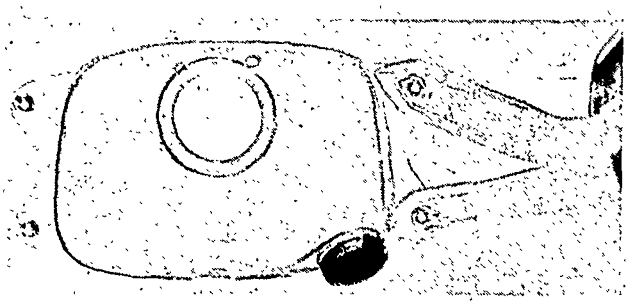
Arthritis developed in 4 cases. Of these 4 patients 1 already had an ileostomy when the arthritis first appeared, and in another it persisted after subtotal colectomy till the rectal stump was excised. These experiences indicate the necessity for complete removal of the colon and rectum in patients with a complicating arthritis, and this was done in all 4 cases in this group.

One patient with severe ulcerative colitis had *erythema multiforme*, which cleared up completely after ileostomy and excision of the colon and rectum.

PREOPERATIVE CARE

Most of the patients requiring surgical treatment were anæmic and had some hypoproteinæmia and vitamin deficiency. For nearly all of them blood-transfusion was necessary, and this was the most important single factor in restoring them to a reasonable condition. Usually several slow drip transfusions of one or two pints were given at intervals of twenty-four to forty-eight hours until the hæmoglobin level was raised to 70–80%. In addition a high-protein diet was prescribed and supplemented by the addition of the casein preparation 'Casilan,' 5 or 6 oz. daily. Vitamins were also given in suitable doses, vitamin-B complex and vitamin C being the most important. Intestinal antiseptics—e.g., phthalylsulphathiazole, succinylsulphathiazole, and oral streptomycin and other antibiotics—were not usually given in preparing patients for ileostomy. They were used, however, in the preparation for colectomy because,

Fig. 1—Original pattern of Donald Rose ileostomy appliances as seen from the front: (a) ileostomy box; (b) ileostomy bag with plastic upper part. Note raised edge showing as a ring surrounding opening in appliance which fits against ileostomy, and ventilating holes present on upper part of box or bag.



(a)

(b)

no matter how carefully this operation is done, occasionally the friable bowel is opened. An emulsion of phthalylsulphathiazole 5 g. and streptomycin 1 g. in 5 oz. of water was instilled daily for five or six days into the rectum and distal ileostomy opening, when present.

ILEOSTOMY APPLIANCES

In this country there are at present available two main types of ileostomy appliance:

(1) *The plastic box or rubber bag with plastic upper part* manufactured by Donald Rose Ltd. to the specification of Mr. R. S. Corbett of St. Bartholomew's Hospital (fig. 1). The essential feature of this appliance is the raised rim immediately round the opening, which when firmly pressed against the skin by a rubber belt ensures a fairly watertight apposition. A small ventilating hole is provided; obviously some sort of vent is essential in the box type at least because nothing can enter unless the contained air is displaced. Unfortunately during the night, if the patient is lying flat, the ileal contents gravitate into the upper part of the appliance and tend to leak through the ventilating aperture. Rose has recently modified his appliance by fitting it with a ventilating snout, and leakage is less common with it.

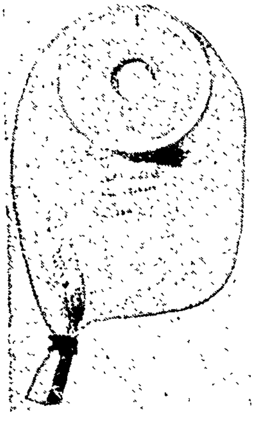


Fig. 2—Posterior aspect of Salt ileostomy bag. Note opening into which ileostomy fits and slightly convex disc of metal covered with rubber which surrounds this opening and which is cemented to skin of abdominal wall.

(2) *The stick-on type of bag.*—Unfortunately the original Koenig-Rutzen pattern of adhesive bag, which is manufactured in America, is not available to patients in this country unless they have dollars. Recently similar bags have been made by British firms:

(*a*) Salt & Son Ltd. make an appliance (fig. 2) which closely resembles the original Koenig-Rutzen apparatus. It consists of a rubber bag with a hole in the upper part of its posterior surface which fits over the ileostomy opening. Surrounding this hole is a slightly convex disc of metal covered with rubber, or a flat disc of firm rubber, with a central perforation corresponding to the aperture in the bag. This disc is stuck to the skin with special cement. As an additional precaution, an elastic belt is also worn to hold the appliance to the body. The bag is emptied through an opening at its lower end which is normally kept clipped off. The usual procedure is to empty the bag every four hours or so as required, usually every time the patient micturates. Complete removal of the appliance, by dissolving the cement with benzene, is necessary every twenty-four to forty-eight hours for washing and changing; otherwise the rubber is apt to smell.

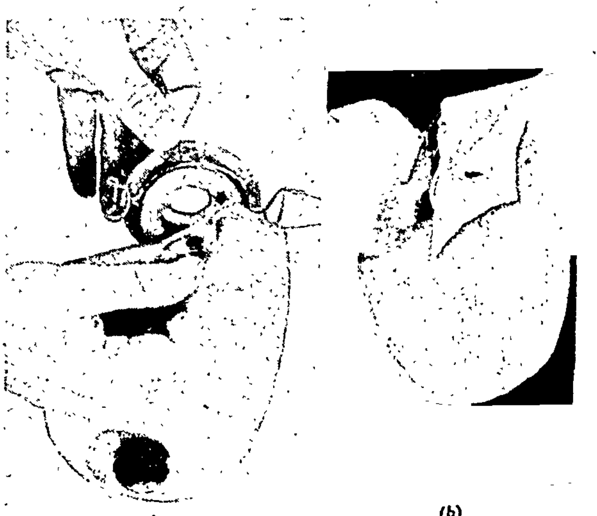
(*b*) Down Brothers also make a stick-on bag (fig. 3). It comprises a rubber disc with a projecting grooved neck to which a detachable rubber bag is fitted. Fixation to the skin is achieved with a square of double-sided adhesive plaster with a central perforation, one side of which sticks to the disc and the other to the skin. For washing, the bag may be detached from the rigid rubber upper part without having to unstick the adhesive disc, which may therefore be left undisturbed for five or six days at a time. A further modification of Down Brothers' appliance is the light rectangular bag made of plastic material. It has the advantage of being free from the smell associated with rubber bags. It is worn for two or three days, being emptied at its lower end as required, and is finally discarded.

In our experience, when they work, the adhesive types of bag are the more satisfactory, but some of our patients have had so much irritation of the skin from the adhesive cement or plaster that they have had to discontinue using this form of appliance. In several such cases it has been found convenient to prescribe both an adhesive bag and a Donald Rose appliance so that the patient may use them alternately according to the amount of skin irritation produced. We feel that there is still considerable scope for improvement in the design of stick-on bags as regards both the material and the cement.

SITE OF ILEOSTOMY

American writers usually recommend a site in the right iliac region, at or a little below McBurney's point, sufficiently far away from both the umbilicus and the anterior superior iliac spine to allow the easy application of the disc of an adhesive ileostomy bag to the intervening skin without overlapping either of these landmarks (fig. 4B).

Most of the ileostomies done at St. Mark's Hospital, however, have been placed at a higher level, in the wais



(a) (b)

Fig. 3—Down Brothers rubber ileostomy bag: (a) bag being fitted to rubber disc which is applied to ileostomy; (b) posterior view showing square of adhesive plaster with central perforation stuck to back of rubber disc (in actual practice the adhesive is first fixed to the skin, and the bag is then applied to the adhesive).

line about $1^1/_2$ in. to the right of the midline (fig. 4A). We believe that ileostomy appliances can be more firmly pressed against the abdominal wall if they are worn in the belt line rather than lower down, where a belt if tightened is liable to slip up, pulling the bag with it, and preferably near the midline, where the taut rectus muscle makes the abdominal wall more rigid. It must be borne in mind, moreover, that, though one may hope to prescribe a stick-on type of bag the patient's skin reaction to the adhesive may compel her to rely entirely on pressure to prevent leakage, and the ileostomy should therefore be sited so that this may be exerted most advantageously. More recently, as an alternative to a belt, we have been using a roll-on type of corset with a perforation (fig. 5), which holds either the Donald Rose or the adhesive bag much more securely than does any belt.

OPERATIVE TECHNIQUE

Loop Ileostomy

In 13 of the earlier cases the ileostomy established was of the loop variety, but the difficulty of fitting a satisfactory appliance and the increased tendency to prolapse led to the abandonment of this procedure in favour of a terminal ileostomy.

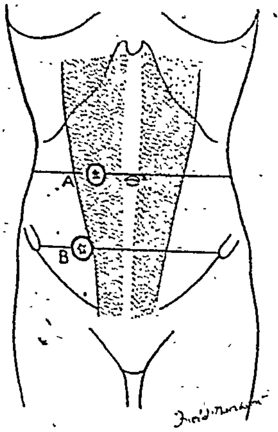


Fig. 4—Ileostomy sites : A, site generally used at St. Mark's Hospital ; B, site recommended by many American workers.

Terminal Ileostomy

In this operation the lowest loop of ileum and its mesentery are divided 6 in. or less from the ileocæcal junction, care being taken to ensure that the distal ileum itself is not involved in the disease, as it was in 3 of our cases, when a more proximal section was required. The proximal end is brought to the surface as the functioning ileostomy. The distal end can either be exteriorised 3 or 4 in. from the ileostomy (fig. 6) or closed like a duodenal stump in a gastrectomy and dropped back—Rankin's method (Bargen et al. 1932). Though the latter method is open to the theoretical objection that in these debilitated patients the blind ileal stump might rupture, nearly half the terminal ileostomies in this series were of the Rankin type, the ileum being divided within 1 in. of the ileocæcal valve (fig. 7), and in none of these cases was there leakage or other complication referable to this blind end.

In about half the operations a right rectus-splitting incision was used, the proximal ileum being brought out through this main incision on a level with the umbilicus, and the distal ileum, if exteriorised, drawn through a separate stab incision in the right iliac region. In the other half a gridiron incision centred on McBurney's point or slightly medial to it was chosen, and in these cases the proximal ileum was implanted in a separate stab wound $1^1/_2$ in. to the right of the umbilicus, and the distal ileum placed in the gridiron wound itself.

In securing the terminal ileum direct suture of the bowel to the parietes has been avoided because of the danger of producing subcutaneous ileal fistulæ at the site of the stitches. To hold the terminal $1^1/_2$–2 in. of ileum out of the abdomen reliance has been placed on the support given by several layers of wool to a Paul's tube tied into the end of the projecting bowel. In many instances also the cut edge of the ileal mesentery has been sutured to the anterior parietal peritoneum (fig. 6), as recommended originally by Cattell (1939). In some of the cases with a double ileal opening the lateral peritoneal space on the outer side of the distal ileal opening has been closed, as recommended by Hardy et al. (1949), to prevent small gut from passing through this lateral space and becoming obstructed. Technically it has not always been easy to do this, particularly in cases with only one ileal opening near the midline in which this space has been very large. The parietal incision was usually sutured with non-absorbable material, such as fine silk and stainless-steel wire, and the skin wound was finally sealed off round the projecting ileum with gauze soaked in Whitehead's varnish (Sumatra benzoin in coarse powder 100 g., prepared storax 75 g., balsam of tolu 50 g., iodoform 100 g., solvent ether to 1000 ml.). Finally a Paul's glass tube was tied into the extreme end of the proximal ileum and connected with a wide-bore thin rubber tube to a urinal in the bed alongside the patient. The inactive ileal end was left closed with a Zachary Cope's clamp.

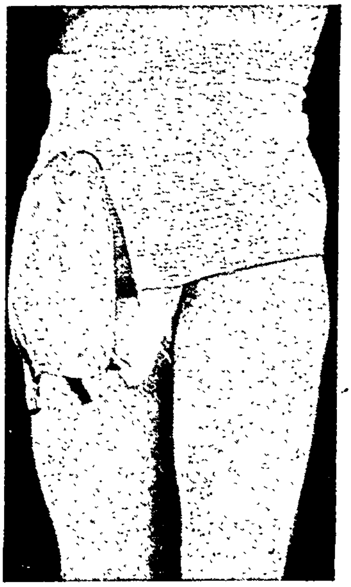

Fig. 5—Method of holding Koenig-Rutzen bag by roll-on corset with perforation which fits between bag and its metal flange.

The projecting ileum can be covered with skin to produce a penile type of ileostomy. This is done by applying Thiersch grafts, as recommended by Dragstedt et al. (1941), or pedicle grafts of abdominal skin, as proposed by Monroe and Olwin (1949). We used the former method on two occasions but found that, with the ordinary type of ileostomy bag, the skin covering the ileum, which protruded into the appliance, was liable

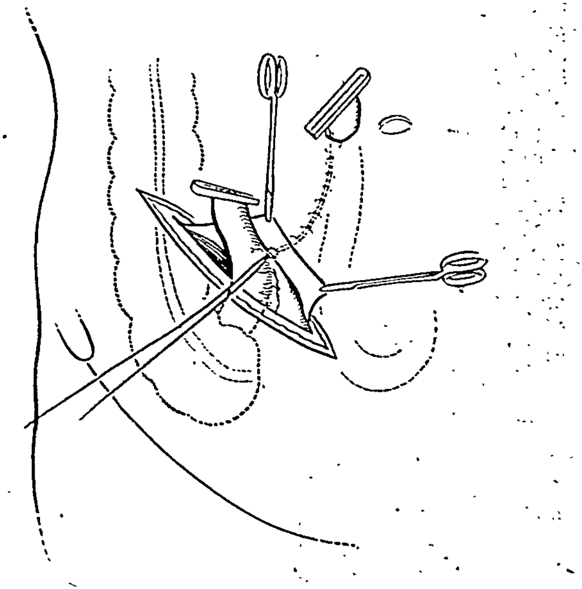

Fig. 6—Technique of ileostomy : proximal end of ileum has been drawn through separate stab incision traversing right rectus muscle at or just above level of umbilicus, and distal end has been implanted in the gridiron wound ; suture of cut in ileal mesentery to anterior parietal peritoneum has just been completed.

to become digested and sore, and we are not convinced that the method presents any real advantages.

POSTOPERATIVE CARE

Two special considerations dominate the postoperative management of ileostomy cases: the maintenance of fluid and electrolyte balance, and the care of the ileostomy opening.

Maintenance of Fluid and Electrolyte Balance

In the average case, though there may be some small ileostomy actions on the first day after operation, it is usually not until 24–48 hours after operation that the ileostomy starts to act properly, and then the discharge is often profuse and watery. This usually continues for several days, during which time it is very easy for the patient to become dehydrated and depleted of sodium and potassium. It is therefore especially important for the surgeon to bear in mind the severe losses of fluid and electrolytes that may be sustained in these circumstances and to allow for them in calculating the intake required.

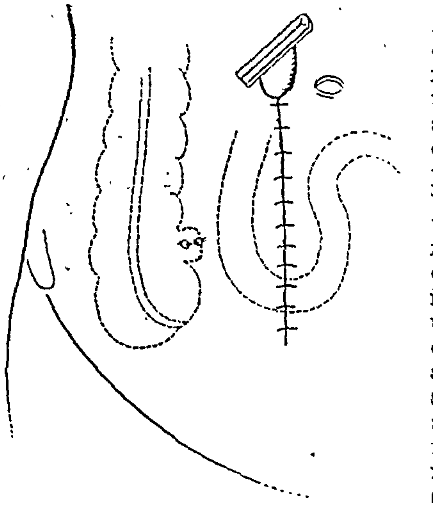

Fig. 7—Alternative ileostomy technique: suture of distal piece of ileum close to ileocæcal junction; ileostomy established at usual site to right of umbilicus at upper end of right paramedian wound used for this operation.

Many ileostomy patients do not require intravenous fluids as a routine but rely in the first instance on oral administration. Only if the fluid balance cannot be maintained in the face of profuse ileostomy actions, or of obstructive symptoms with perhaps vomiting, is an intravenous infusion instituted. In such patients prolonged intravenous administration may be required and may have to be supplemented by blood-transfusions and administration of vitamin and protein concentrates.

Management of Ileostomy Opening

(1) The patient returns to the ward with a Paul's tube tied in the active ileostomy opening. This provides a safe conduit for ileal contents to the receiving bottle in the bed for the first few days.

(2) After five to seven days the silk ligature holding the Paul's tube in situ cuts through, and the bowel contents are liable to soil the wound. We have relied at this stage on fitting a temporary or first-stage ileostomy bag of Donald Rose pattern, leakage being minimised by the application of soft-paraffin gauze immediately round the ileostomy. Occasionally, to guard against digestion of the abdominal skin if there is any leakage of ileal contents, we have painted it with "Baltimore paste" (powdered aluminium, zinc oxide cream, paraffin as required).

TABLE I—POSTOPERATIVE COMPLICATIONS IN 60 CASES TREATED BY ILEOSTOMY

Complication	No. of cases
Early:	
Intestinal obstructive episodes	26
Subphrenic abscess	2
Wound disruption	1
Severe wound sepsis	1
Subcutaneous fistula	1
Late:	
Ileostomy prolapse	9
„ retraction	3
„ stenosis	3

(3) By the end of three or four weeks the ileostomy has shrunk to its permanent size and shape, projecting about 1 in. above the skin surface and being covered on its outer surface with mucosa. The patient may now be fitted with the final ileostomy appliance.

POSTOPERATIVE COMPLICATIONS

The complications encountered in this series are listed in table I, from which it will be seen that the most important immediate trouble in these ileostomy cases was the occurrence of *obstructive episodes*, which were a feature in nearly half the cases. These usually began about a week after operation, the patient complaining of abdominal pains, distension, and vomiting, and the ileostomy ceasing to act. Their symptoms and signs suggested a mechanical obstruction rather than a paralytic ileus, but if treated conservatively with gastric suction and administration of fluids they often recovered satisfactorily, though such a régime may have had to be continued intermittently for more than two weeks. Five patients were submitted to laparotomy because the surgeon believed that a true mechanical obstruction must be present, but in none was a "surgical" obstructive lesion found. Usually the ileum was dilated right down to the ileostomy opening in the abdominal wall.

These experiences have convinced us that in the management of these obstructive episodes it is usually best to avoid re-exploration and to persist with conservative measures. An important part of these is the insertion of a soft rectal catheter for a distance of 6–12 in. into the terminal ileum. This is often followed by the escape of some 200–300 ml. of ileal contents apparently under pressure. This may require to be repeated two or three times a day for several days, or the catheter may be left in situ, especially during the night.

TABLE II—CAUSES OF HOSPITAL DEATHS IN 60 CASES TREATED BY ILEOSTOMY

Cause of death	No. of cases
Subacute intestinal obstruction	4
Toxæmia and electrolyte imbalance	4
Bronchopneumonia	1
Perforation of cæcum and peritonitis	1
Terminal ileitis, perforation, and peritonitis ..	1
No cause found at necropsy	2
Total	13

By far the most troublesome late complication of ileostomy has been *ileostomy prolapse*, which has already occurred in about a fifth of our cases and may, of course, yet develop in other patients in this series. The prolapse involves the full thickness of the ileal wall and may project as far as 5 or 6 in. We have discovered no certain means of avoiding this complication, and in particular have not found that the technique described by Cattell (1939) of stitching the cut edge of ileal mesentery to the anterior parietes is a reliable preventive. Once prolapse has developed, we have sometimes reoperated and tried to tighten the opening in the abdominal parietes and also stitched the ileum to the anterior parietal peritoneum, but this has only rarely been successful. We have also experimented with anti-prolapse discs which fit over the opening on the ileostomy box or bag, but it is difficult to strike the right size for the disc perforations which will at the same time allow easy escape of ileal contents but not permit the ileum to prolapse.

Ileostomy stenosis and retraction have been dealt with by the same sort of simple reconstruction operation used for these complications developing in connection with colostomies. To prevent the development of an ileostomy

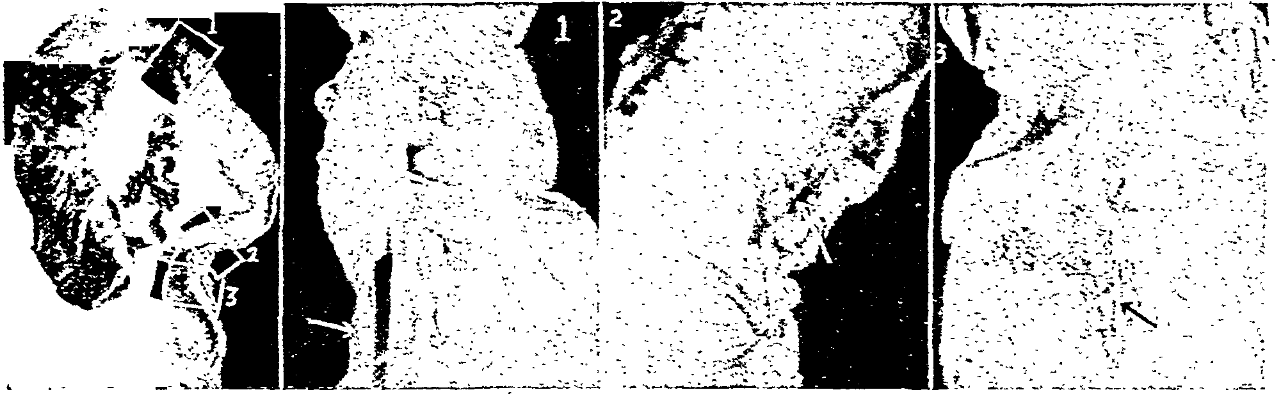

Fig. 8—Specimen of colon and rectum, removed by immediate ileostomy and panproctocolectomy from case of ulcerative colitis, with three separate carcinomata of plastic non-ulcerating type simulating simple fibrous thickenings of bowel wall ; histologically two of these (growths 1 and 2) were anaplastic colloid carcinomata.

stenosis the occasional passage of a finger into the opening may be useful.

OPERATIVE MORTALITY

Of the 60 patients submitted to ileostomy 13 died, giving an operative mortality of 21·6%. If, however, the 4 cases of emergency ileostomy and the 1 case of cæcal perforation, for which ileostomy and suture of the perforation were done, are excluded, the series is reduced to 55 patients with 9 deaths, a mortality of 16·4%. The causes of death are shown in table II, from which it will be seen that intestinal " obstruction " was often the lethal factor.

COLECTOMY AND EXCISION OF THE RECTUM

Indications

Recently our views at St. Mark's Hospital on the indications for colectomy in ulcerative colitis have undergone a sharp change. This has been brought about by the experience we have had in the last two years of observing carcinoma develop in some part of the diseased large bowel in no less than 11 of the 90 patients on whom this report is based. In 4 of the cases the growth arose in the rectum and was detected on clinical examination. In 1 other case an unsuspected rectal carcinoma was discovered at necropsy, and in 1 other case an apparently benign stricture of the splenic flexure was treated by colectomy and found on microscopy to be a carcinoma. In 4 cases, after routine colectomy and excision of the rectum, several carcinomata were discovered in the large bowel (fig. 8). In the 11th case an inoperable growth of the transverse colon was revealed at laparotomy done with a view to colectomy. As Dukes has emphasised a striking feature of these growths was that they were often multiple, often atypical in their gross appearance, in that they presented not as ulcerating lesions but as a slight " fibrous " thickening of the bowel wall, and on histological examination were usually found to be highly active and invasive (Counsell and Dukes 1952).

The precise incidence of neoplastic change in ulcerative colitis is difficult to estimate. Cattell (1948), reporting on the experience of the Lahey Clinic, states that no less than 1 in 3 of their cases of colitis of more than nine years' duration have developed carcinoma in the large bowel. In view of the fact that the symptoms and signs produced by a growth in these patients may easily be attributed to an exacerbation of the colitis and the presence of the neoplasm overlooked, we consider that the only safe course is prophylactic colectomy and removal of the rectum in all cases of ulcerative colitis sufficiently severe to require ileostomy. We do not know enough about the incidence of carcinoma in the milder forms of colitis, which would not usually be deemed severe enough to warrant surgical treatment, to say whether the danger of malignant degeneration justifies advising ileostomy and colectomy more often at this stage of the disease.

The policy in the earlier part of this series therefore was to advise colectomy and excision of the rectum only to patients who did not make a complete recovery in general health after ileostomy, or had complicating fistulæ, arthritis, or skin lesions. But now all cases are proceeding to this operation as a routine, and patients who have had ileostomy some years ago are being recalled for colectomy and excision of the rectum.

Interval between Ileostomy and Colectomy

Generally an interval of three to six months has been allowed to elapse after the ileostomy to give time for improvement in the general condition of the patient before proceeding to colectomy. More recently the tendency has been to shorten this interval and to do colectomy within three to six weeks of ileostomy, whilst latterly most of us have adopted as a routine the proposal of Miller et al. (1949) and of Bacon and Trimpi (1950) to do colectomy and ileostomy simultaneously. We hope that this will avoid the rare instances where the patient has not responded after ileostomy alone, and will also be associated with a more rapid restoration of general health than would occur after simple ileostomy. Colectomy may seem a serious addition to ileostomy in the sort of patient who presents for this operation, but it is not technically difficult ; and, if the distal end of the divided sigmoid colon is

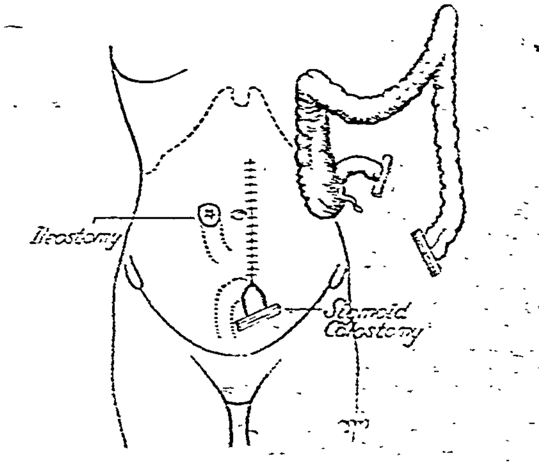

Fig. 9—Incision used for second-stage of subtotal colectomy, or for one-stage ileostomy and subtotal colectomy, and the amount of bowel removed at this operation. Note that distal sigmoid colon is brought to surface as colostomy at lower end of left paramedian incision.

brought out as a colostomy, no suture lines are created in the alimentary tract which might leak because of the patient's poor general condition. In fact the more gravely ill the patient the stronger is the argument for immediate colectomy, and the best results obtained to date in the treatment of acute fulminating ulcerative colitis, which is nearly always fatal if treated medically or by ileostomy alone, have been secured by immediate ileostomy and colectomy combined (Crile and Thomas 1951). We have treated 14 patients by simultaneous ileostomy and colectomy followed by excision of the rectum, and 4 by one-stage ileostomy and panproctocolectomy; all made speedy and successful recoveries.

Technique of Colectomy and Excision of Rectum

Some of the earlier colectomies were done as staged procedures, consisting of right hemicolectomy as the first stage, left hemicolectomy down to an iliac colostomy as the second, and excision of the rectum as the third, the intervals between stages being about three months. More recently, however, these have been reduced to two stages, the first comprising subtotal colectomy, and the second excision of the rectum. This is the technique described below.

First stage—subtotal colectomy.—A long left paramedian incision usually gives adequate access (fig. 9). If the distal ileum has been exteriorised, a circular incision is made round this and deepened into the peritoneal cavity. Through the main wound the peritoneum on the outer side of the cæcum and ascending colon is next divided as in a right hemicolectomy for cancer and the right colon mobilised, care being exercised at this stage to avoid damaging the ileostomy by too vigorous retraction. The greater omentum is next divided between forceps and the splenic flexure, and the descending and iliac colon fully mobilised. It merely remains now to tie and divide the ileocolic and right, middle, and left colic vessels and the medial leaves of peritoneum still attached to the colon. Finally the lower end of the iliac colon is brought out through the lower end of the main paramedian wound as an iliac colostomy. Since the sigmoid colon is thickened and friable, the usual type of crushing clamp, such as de Martel's or Parker-Kerr's, tends to cut right through the bowel and is therefore unsatisfactory. A very good clamp for this purpose is an enterotome fixed transversely across the bowel and tightened just sufficiently to grip the colon and to prevent it from falling back. We have preferred exteriorisation of the iliac colon in this way to the technique advocated by Brooke (1951) of dividing the bowel at a lower level and closing the rectal stump by intraperitoneal suture. We have been afraid that the unhealthy bowel wall would not lend itself well to suturing and might leak. We have not attempted to peritonealise the raw surface on the posterior-abdominal wall created by the excision of the colon. Of the 30 patients submitted to subtotal colectomy to date 2 have died, one of peritonitis and the other of paralytic ileus.

Second stage—excision of rectum.—28 cases have proceeded to excision of the rectum as a second stage. This has usually been done three to six months after subtotal colectomy but is perhaps better done rather sooner. The operation has followed the lines of a combined excision of the rectum, each surgeon using his normal technique for this procedure, either synchronous combined or perineo-abdominal excision. Owing to the perirectal fibrosis often present in these cases the excision has often been difficult. One patient died after removal of the rectum, death probably being due to a perforated peptic ulcer.

Colectomy with preservation of sphincter action.—This may take the form of a colectomy with ileosigmoid anastomosis, often done by the modification of the Mikulicz-Paul extraperitoneal colectomy technique described by Devine and Devine (1948), or may follow Ravitch's (1948) plan and consist of removal of all the colon and the proximal part of the rectum, "coring out" of the mucosa from the anorectal stump, and the establishment of a "pull-through" ileo-anal anastomosis. The former operation is really only suitable for cases in which the rectum and lower colon are unaffected by the disease, a state of affairs which, though apparently not uncommon in America (Cave 1945, Sloan et al 1950), is exceedingly rare in this country. In our experience the rectum is the part of the large bowel most consistently and usually most severely affected in ulcerative colitis; and, though the proximal extent of the disease may vary considerably from a point on the descending colon to as far as the cæcum or even the lower ileum, distally it practically invariably reaches to the mucocutaneous junction in the anal canal. Our opportunities for using this operation therefore have been limited, but in 4 cases, in which the rectum was only very mildly implicated, colectomy with ileosigmoid or ileorectal anastomosis was done. All 4 patients did well at first; owing to the loss of the greater part of the colon they had frequent motions but were perfectly continent. However, eventually one of the patients developed an anal abscess and fistula, and another, after remaining fairly fit for over a year, started to discharge a great deal of blood and mucus per rectum and suffered some loss of weight and failure of general health; both patients had their ileostomies re-established and the colorectal remnants removed. The other 2 patients are satisfied with their condition though they pass some mucus and blood with the motions and sigmoidoscopy shows that the rectal mucosa is still inflamed and therefore presumably liable to septic complications or to malignant degeneration. Having now accepted the possibility of carcinoma arising in the diseased large bowel as one of the dominating considerations in the management of ulcerative colitis we doubt if there can be much place for incomplete operations of this sort.

Proctocolectomy with ileo-anal anastomosis has the merit of removing all the diseased mucosa down to the mucocutaneous junction in the anal canal. Unfortunately this step also impairs rectal sensation with the result that the retained sphincters cannot act efficiently. We have only submitted 2 patients to this operation, but, as previously reported (Goligher 1951), they were both incontinent.

CONCLUSION

From this survey one fact emerges very clearly: ileostomy is but part of the surgical management of ulcerative colitis. Ileostomy alone often fails to secure the greatest improvement in general health or to prevent complications such as malignant degeneration, severe hæmorrhage, arthritis, and other metastatic manifestations of the disease. To achieve a complete cure the colon and rectum must be removed, and this should be the ultimate aim of the surgeon who undertakes to treat severe cases of ulcerative colitis. The present trend is towards earlier colectomy, which is perhaps best done simultaneously with the ileostomy.

We are greatly indebted to the surgeons of St. Mark's Hospital for permission to undertake this review of their cases; to Dr. Cuthbert Dukes and the Research Department, St. Mark's Hospital, for the photographs and pathological report on the case illustrated in fig. 8; and to Dr. P. N. Cardew and the photographic department, St. Mary's Hospital Medical School, for the photographs of ileostomy appliances in figs. 1, 2, 3, and 5.

EFFECT OF WEIGHT-REDUCTION ON NORMAL AND RAISED BLOOD-PRESSURES IN OBESITY

LAURENCE MARTIN
M.D. Camb., F.R.C.P.
PHYSICIAN TO ADDENBROOKE'S HOSPITAL, CAMBRIDGE

THERE is abundant evidence from life-assurance statistics and other sources (Hartman and Ghrist 1929, Levy et al. 1947, Boynton and Todd 1948, Green and Beckman 1948, Master et al. 1950) that people who are overweight have higher average blood-pressures than those whose weight is normal. Clinical experience also shows that obese hypertensive patients are subjectively improved by weight-reduction, which forms part of orthodox treatment. What is not so clear, however, is whether reduction in weight is likely to be followed by a significant fall in blood-pressure in cases of obesity with hypertension.

The relevant literature is by no means explicit on this matter, either because reports are founded on average figures for blood-pressure before and after weight-reduction in large series of cases, or because they only describe spectacular falls in blood-pressure in selected cases of obesity after treatment.

Master and Oppenheimer (1929) recorded their results in 99 obese patients of whom 65 had a systolic blood-pressure exceeding 150 mm. Hg. In 53 of the latter, whose average loss of weight was 25–30 lb., the average reduction of systolic pressure was 25–30 mm. Hg and of diastolic pressure 15–20 mm. Hg.

Terry (1923) observed in 24 obese hypertensive patients an average drop in blood-pressure from 196/103 mm. Hg before treatment to 170/95 afterwards, and in his patient with the greatest individual loss of weight (60 lb.) a fall in blood-pressure from 190/90 to 148/95.

Moreover it is not apparent in various similar reports that the common fallacies inherent in serial blood-pressure records have always been taken into account, and in general the clinician who wishes to know the likely effect of weight-reduction on the blood-pressure in any individual case will receive little help.

It therefore seemed worth investigating this question in obese patients with normal blood-pressures and in others with hypertension. By using a standard sphygmomanometric technique suitable for the clinic or the consulting-room, and by making proper allowances for variability in the expression of the results, it was hoped to reach conclusions of clinical value.

GENERAL CONSIDERATIONS

All blood-pressure readings obtained with a sphygmomanometer have inevitable and well-known sources of error which can be reduced or standardised to some extent by using a constant technique. In any investigation such as the present one, however, which entailed serial readings over several months, it was also desirable to allow for the well-known observation that the first reading is not uncommonly higher than any other (Diehl and Lees 1929). Neglect of this pitfall may clearly vitiate the results of a study involving the effect of any treatment on blood-pressure.

For example, if the widely cited paper of Rose (1922) be examined, in which presumably selected obese patients with hypertension were treated by diet and other measures, it is clear that in many cases very high initial readings had given a false impression of the efficacy of the treatment. Thus, in the first case the initial blood-pressure at a weight of 180·5 lb. was 204/110 mm. Hg, but seven days later, after only 2·5 lb. of weight had been lost, the blood-pressure was 178/100, and eleven months later still, when a further 20 lb. had been lost, 156/90.

Results of other series in which the effect of weight-reduction was measured solely by the first and last blood-pressure readings must be similarly suspect.

There is also the difficult problem of the circumference of the arm to which the sphygmomanometer cuff is applied. Ragan and Bordley (1941) made observations by arterial manometer and sphygmomanometer on 51 adult males (but avoiding "excessively obese individuals") and concluded that in those with an arm circumference of 30·0–42·5 cm. there was a positive error of 3 mm. Hg in the sphygmomanometric diastolic pressure for each 1 cm. increase in circumference. The same trend was followed by the systolic pressure, and an error of 30 mm. Hg might be attained. Wendkos and Rossman (1943), who estimated the blood-pressure in the thighs and arms of 500 people, found a higher average reading of 154·8/91·9 mm. Hg in the thighs compared with 118·3/70·6 in the arms. This they attributed to the greater thickness of the thighs, and it is reasonable to suppose that the greater the thickness of soft tissues surrounding an artery the greater will be the pressure needed in the sphygmomanometer cuff to secure compression. Nevertheless, when the arm readings of Wendkos and Rossman are examined, it is seen that they only rose by an average of 6·6 mm. Hg systolic, and 3·3 mm. diastolic through a range of body-weights of 100–220 lb. These differences are small and unlikely to be of clinical importance but, with the findings of Ragan and Bordley, they show that the matter should be borne in mind when establishing criteria for significant falls in blood-pressure after reduction of weight in the obese.

MATERIALS AND METHODS

The present series consisted of 37 obese patients of whom 18 had normal blood-pressures and 19 had hypertension. None had chronic nephritis, malignant hypertension, or valvular heart-disease. They were unselected apart from fulfilling the criteria of having kept to Marriott's (1949) reducing diet and thereby lost at least 14 lb. in weight during a period of observation of at least six months. The only other treatment given was 'Dexedrine' 5 mg. twice daily to 17 patients to assist them to keep to the diet. It was considered that such dosage would not influence the blood-pressure, because published reports do not show any constant effect of *d*-amphetamine in doses of less than 20 mg. by mouth. Thus Dyer (1939) reported a rise of systolic blood-pressure of 10 mm. Hg in only 2 of 10 people given amphetamine sulphate 10 mg. by mouth.

Patients were seen monthly, and one blood-pressure estimation was made on each occasion from the right arm with the patient recumbent after a few minutes' rest. All the readings were taken personally in the outpatient clinic or consulting-room with which the patients were familiar, the same sphygmomanometer being used with the technique recommended by the Cardiac Society of Great Britain and Ireland (1939). Readings were recorded to the nearest 5 mm. interval above the observed level unless coincidence with a 10 mm. marking was obtained.

To reduce the errors of day-to-day variation and the possibility that the first reading might be the highest of a series, the average of the first three monthly readings was taken as the initial level of each patient. On this average figure each patient was classified as normal or hypertensive, and the arbitrary level of 160/90 mm. Hg

TABLE I—LOSS OF WEIGHT

Blood-pressure	No. of cases	Male	Female	Average age (yr.)	Average initial weight (lb.)	Average loss of weight (lb.)
Normal	18	5	13	46·0	218·8	42·3 (*19%*)
Hypertensive	19	6	13	48·8	212·6	35·7 (*16%*)

TABLE II—EFFECT OF WEIGHT-REDUCTION ON BLOOD-PRESSURE OF 18 OBESE PATIENTS WITH NORMAL BLOOD-PRESSURE

Case no.	Age (yr.)	Sex	Height (in.)	Period of observation (mos.)	Initial weight (lb.)	Weight lost (lb.)	Average blood-pressure (mm. Hg)		Result
							Initial	Final	
1	57	M	64·5	19	303	83 (*27·3%*)	147/83	123/78	Systolic lower, diastolic unchanged

6	27	F	62·0	16	198	15 (*7·6%*)	132/70	128/73	Unchanged
7	15	M	69·0	7	215	53 (*24·6%*)	120/60	112/57	Unchanged
8	48	M	69·0	8	301	79 (*26·2%*)	137/72	117/60	Systolic lower, diastolic unchanged
9	65	F	62·0	6	168	23 (*13·6%*)	158/82	165/77	Unchanged
10	34	F	59·5	8	204	53 (*25·9%*)	148/77	132/77	Unchanged
11	49	F	65·0	6	194	37 (*18·5%*)	155/82	140/78	Unchanged
12	17	F	64·0	6	217	57 (*26·2%*)	125/62	117/68	Unchanged
13	47	F	68·0	6	285	75 (*26·3%*)	157/83	145/78	Unchanged
14	54	F	61·0	6	196	36 (*18·4%*)	138/87	133/83	Unchanged
15	65	M	67·0	8	198	24 (*12·1%*)	132/73	153/82	Systolic higher, diastolic unchanged
16	66	F	60·5	7	177	22 (*12·4%*)	142/83	143/83	Unchanged
17	61	F	60·5	7	234	21 (*8·9%*)	133/83	138/78	Unchanged
18	23	F	68·5	6	241	29 (*12·0%*)	139/80	114/60	Systolic lower, diastolic lower

was taken as the dividing line between normality and hypertension.

Similarly, an average of the last three monthly readings was taken as the final level of blood-pressure after treatment. Under these conditions it was considered that a significant fall of blood-pressure could be claimed if the final average systolic or diastolic pressure showed a fall of, or exceeding, 20 mm. Hg or 15 mm. Hg respectively, compared with the initial average level.

RESULTS

Table I shows average values for age, initial weight, and loss of weight which are similar for the patients with normal blood-pressure and the patients with hypertension.

The effect of weight-reduction on each group was:

Normal Blood-pressure (18 cases, table II).—Systolic and diastolic levels were unchanged in 13, both were lowered in 1, and systolic pressure alone was lowered in 3 and raised in 1.

Hypertension (19 cases, table III).—Systolic and diastolic levels were unchanged in 12, both were lowered in 2, and systolic pressure was lowered alone in 5.

Statistical Analysis

Examination of the protocols of each case led to the following conclusions:

(1) There was an over-all significant regression of systolic blood-pressure on weight having a value of + 0·35 ± 0·08, meaning that, on average, the blood-pressure was reduced by *3·5 mm. Hg for every 10 lb. of weight lost.* There were considerable individual variations, but it was clear that weight-reduction in the series as a whole did have some slight effect on blood-pressure.

(2) No significant differences were found between the two groups or between males and females, and there was no particular correlation with the patient's age or initial weight.

(3) More information might have been obtained from more extensive data, but on the present material there is no suggestion of any striking relation between weight-reduction and changes in systolic or diastolic blood-pressure.

DISCUSSION

Although statistical analysis has shown a significant regression of systolic blood-pressure amounting to about 3·5 mm. Hg for each 10 lb. of weight lost, this finding is insufficient to be of clinical importance. Admittedly there were individuals in the present series who did show clinically significant falls of blood-pressure in response to dieting. But unfortunately they did not provide any evidence or characteristics upon which such a response could be predicted in future cases. Thus it must be concluded from the present series, in accord with the opinion of Green and Beckman (1948), that the effect of weight-reduction on blood-pressure in obesity with hypertension is both inconstant and unpredictable. Nevertheless the chance of an occasional success, coupled with subjective improvement in the great majority of cases, appears to justify the continuation of weight-reduction as a routine measure in obese hypertensive patients. Moreover the loss of a substantial weight of fat must reduce the demands made on the heart during ordinary daily life, quite apart from strenuous exertion.

SUMMARY

37 obese patients, of whom 18 had normal blood-pressures and 19 hypertension, were treated by weight-reduction.

According to the criteria specified, a clinically significant fall in systolic blood-pressure, alone or with the

TABLE III—EFFECT OF WEIGHT-REDUCTION ON BLOOD-PRESSURE OF 19 OBESE PATIENTS WITH HYPERTENSION

17	51	F	63·5	9	172	32 (*18·5%*)	210/105	208/103	Unchanged
18	68	F	62·0	6	157	21 (*13·3%*)	180/97	190/110	Unchanged
19	58	F	65·0	7	199	44 (*22·1%*)	197/127	182/115	Unchanged

diastolic blood-pressure, was observed in 4 cases with normal blood-pressures, and in 7 cases of hypertension.

No clinical or statistical evidence could be adduced to distinguish the cases in which the blood-pressure fell with weight-reduction from those in which it did not.

Statistical analysis revealed that, on average, the systolic blood-pressure was reduced by 3·5 mm. Hg for every 10 lb. of weight lost.

I am indebted to Mr. Norman T. J. Bailey, statistician to the medical school in the University of Cambridge, for making and interpreting the statistical analysis of the data.

JEJUNAL DIVERTICULOSIS WITH HÆMORRHAGE

A. P. WATERSON
M.B. Camb., M.R.C.P.
FORMERLY HOUSE-SURGEON, LONDON HOSPITAL

MASSIVE gastro-intestinal hæmorrhage presents a diagnostic as well as a therapeutic problem. Estimates of the proportion of cases attributable to peptic ulceration of the stomach or duodenum vary from 59 to 90% (Ivy et al. 1950), and œsophageal varices are also a common cause. But there are many other possibilities, one of which is illustrated by the following case.

CASE-RECORD

A Civil Service clerk, aged 59, was admitted to the London Hospital shortly after midday on June 15, 1948, in coma.

History.—For about five months he had complained of increasing lassitude and of central abdominal discomfort, which he later described as "a pulling on the navel." Three months before admission a hydrocele on the right side had been tapped. Ten days before admission he vomited once (there was apparently no obvious blood in the vomit) and soon after this he passed a copious black tarry stool. Next day he passed some bright-red blood, with clots, and his stools on subsequent days were tarry. He was sigmoidoscoped four days before admission, but without much success, because of a rather loaded bowel. He was not seriously ill until ten hours before admission (2 A.M. on June 15), when he began to lose bright-red blood per rectum; this hæmorrhage continued. His bowels were normally regular; he had had no abdominal injury, recent acute infection, or dietary indiscretion; and he rarely took aspirin, because it always gave him acute abdominal discomfort. He had not had any recent acute emotional disturbance. He had been gaining weight in the past few years. There was no significant family history.

Condition on Admission.—He was an obese elderly man in coma, with gross pallor of the skin and mucosæ, a weak pulse, and a blood-pressure of 100/65 mm. Hg.

Treatment and Progress.—He was given an immediate transfusion of 1 pint of plasma followed by five pints of blood. Next day he spoke on being roused but was rather confused; his blood-pressure had risen to 170/100 mm. Hg. Three days after admission he was much better, with Hb 10·5 g. per 100 ml. Eight days after admission sigmoidoscopy to a distance of 22 cm. revealed no abnormality. He was well at this time, but two days later, on getting up, he felt faint and passed two tarry stools; that evening he became pale and shocked, with sighing respiration, and his blood-pressure fell to 90/60. He was given a further transfusion of 3 pints of blood. Next morning, about 8 A.M., he passed about 3 pints of bright-red blood, including some clots, into the bed. A third transfusion, of 5 pints of blood, was started. That afternoon he vomited 10 fluid oz. of dark-brown "coffee-ground" material; however, by midnight he was conscious and rational. Two days later (June 28) he had another transfusion, this time of 3 pints of blood, and two days after that (June 30) his Hb was 7·6 g. per 100 ml. At about 3 P.M. on that day he suddenly complained of a feeling of impending death, became pale, and sweated profusely; his pulse became weak and rapid, while his blood-pressure fell to 80/60. He was given another 4 pints of blood and his condition improved; he passed a small black stool (about 1½ fluid oz.) that evening. Next day his general condition was fairly good, and his blood-pressure had risen to 160/95 mm. Hg; but it was decided to perform an exploratory laparotomy, with a view possibly to emergency partial gastrectomy. Penicillin 100,000 units twice daily was started. The bleeding-time and clotting-time were both normal.

Operation (Mr. E. C. B. Butler).—The abdomen was opened through a right upper paramedian incision under thiopentone and cyclopropane anæsthesia with curare. No abnormality was found in the stomach or duodenum. There were numerous saccular diverticula, 1·0–5·0 cm. in diameter, in the first 3 or 4 ft. of the small intestine below the duodenojejunal flexure, on the mesenteric border, with evidence of recent fibrinous peritonitis over many of them. The part most severely affected was that immediately below the duodenojejunal flexure, and here one diverticulum contained a concretion which could be extruded easily into the lumen of the bowel and was small enough to be passed without difficulty. The small intestine contained no blood except in the lowest 1 or 2 ft. of the ileum; the cæcum and colon contained much dark-red blood but were otherwise apparently normal. The liver and spleen both appeared normal. It was considered that the source of the bleeding was the diverticulum containing the enterolith. Resection of the affected segment of bowel would have been the treatment of choice, but it was thought inadvisable to embark on this in a fat elderly man debilitated by severe hæmorrhage. The abdomen was closed without drainage.

Postoperative Course.—The patient was given 3 pints of blood during and after the operation, making a total of 23 pints since admission. There was no recurrence of the bleeding. On July 19 his Hb was 11·6 g. per 100 ml. On July 22 (three weeks after laparotomy) he was discharged from hospital free from abdominal pain. He has since been seen regularly and has had no more intestinal hæmorrhage; and four years after operation he was in good health. However, because resection was impracticable, he may possibly have a recurrence.

COMMENT

Diverticulosis of the jejunum has been reviewed fully, with a report of 13 cases, by Orr and Russell (1951). It may be diagnosed during life radiologically after an opaque meal, or it may be found as an associated abnormality at necropsy, or it may draw attention to itself by causing intestinal obstruction (Gordinier and Sampson 1906), perforation (Butler 1937, Scholefield 1946), or severe bleeding (Braithwaite 1923, Tengwall 1931, Klidjian 1946, Kozoll et al. 1950). Berger et al. (1951) have reported 2 further cases of hæmorrhage, but it is impossible to be certain in one of their cases that the jejunal diverticulosis was the only or the primary cause of the hæmorrhage. Of Orr and Russell's (1951) patients, 4 had had hæmorrhage, never so severe as to threaten life. Klebs (1869) described the association of diverticula of the small intestine with the point of entry of arteries, and Fischer (1900) pointed out the very close anatomical relation of blood-vessels to even the smallest diverticula in a case of diverticulosis of the ileum; it is not difficult to see why serious hæmorrhage may occur.

The formation of enteroliths in the diverticula is a source of further trouble; in Klidjian's (1946) case it was apparently the diverticulum containing a concretion from which the bleeding had come, and Armitage et al. (1950) attribute the recurrent attacks of abdominal pain in their patient to intestinal obstruction caused by an enterolith becoming alternately impacted in the ileum and released. In the present case the bleeding probably came from the diverticulum in which the enterolith was; certainly, after this had been dislodged at operation, there was no more hæmorrhage.

Jejunal diverticulosis, though rare, should be borne in mind as a cause of massive intestinal hæmorrhage. Kozoll et al. (1950) describe how failure to recognise it cost their patient a second laparotomy. Gastro-intestinal hæmorrhage is a clinical event, not an ultimate diagnosis.

I am indebted to Mr. E. C. B. Butler for permission to publish this case.

CEREBRAL DISEASE DUE TO FUNCTIONING ISLET-CELL TUMOURS

J. E. Richardson
M.S. Lond., F.R.C.S.
ASSISTANT DIRECTOR, SURGICAL UNIT, LONDON HOSPITAL

With pathological reports by

Dorothy S. Russell
M.D. Lond., Sc.D. Camb., F.R.C.P.
DIRECTOR OF BERNHARD BARON INSTITUTE OF PATHOLOGY, LONDON HOSPITAL

The interest of the following six cases lies in the similarity of the clinical course. Relations used identical phrases to describe the onset; house-physicians made similar notes about the appearance of the patients on admission; and consultants seem to have gone through similar mental processes and reached the same conclusion. It is odd that such a constant syndrome should be so little appreciated; but islet-cell adenomas are usually small and must often have been overlooked at necropsy.

These six cases are the only ones recognised in the London Hospital in the last five years. Each presented as a neurological problem. Patients attending a teaching hospital are a selected sample. The first four cases were recognised as unusual and thus referred to the large neurological and neurosurgical clinics under Sir Russell Brain and Mr. D. W. C. Northfield; the fifth patient attended a hospital for nervous diseases. Possibly other patients in the region with islet-cell adenomas presented with psychological disturbances and were referred to mental hospitals (Fraser et al. 1938). The symptoms of the disease must largely be determined by the constitutional susceptibility exposed to the stress of the functioning tumour.

CASE-RECORDS

Case 1 (L.H. record no. 21051. 48).—*A married woman,* aged 43, was transferred to the London Hospital neurosurgical unit on April 14, 1948, from Queen Mary's Hospital, Stratford, with a provisional diagnosis of "hypothalamic tumour." An accompanying letter from Dr. H. J. Goldsmith, the house-physician, stated that she was originally thought to be suffering from the after-effects of a hypoglycæmic attack, but that this diagnosis had been reversed by the consultants who had seen her.

Background.—Her husband, a bus conductor, said that they had been married for 23 years. Their only son was grown up, and his wife had gone out to work again in a wholesale grocery. She was a sensitive person but, apart from a left Bell's palsy at the age of 23, her health had always been good. Menstruation was normal and there had been no recent change in weight. In October, 1947, she began to get peculiar sensations in her right leg. She would sit down and grasp her right foot, which was inverted. There were several of these attacks, mostly in the mornings. Each attack lasted several minutes. At the same time she seemed excited. She spoke of having morbid thoughts "of things that would not happen." During November, nearly every Sunday morning, there were attacks in which her arms and legs shook for several minutes. The day before Christmas she could "hear, think, and see" but could not move or speak. On Christmas morning her speech was thick and unintelligible. She was sweating but not trembling. She permitted passive movements of her limbs but was incapable of active ones. After about 15 minutes she said "I can move my arms now." On the morning of Dec. 26, 1947, she complained of stiffness of her legs, with inversion of the right foot. There were also occasional spontaneous arm and foot movements. On Dec. 29 she was seen in the London Hospital neurological outpatient department, but no evidence of any anatomical lesion was found, and her husband seems to have got the impression that the attacks were considered to be hysterical. She continued to be drowsy in the mornings. On March 26, 1948, she was particularly drowsy. When asked "*What are you doing in bed?*" she gave a hysterical laugh, and for the next three hours her hands trembled. This was followed by loss of consciousness until 4 o'clock next morning, when she woke up, had a meal, and said: "I musn't have another turn like this, Mum." On March 28, 1948, she spoke to her husband on waking and decided to stay in bed as it was a holiday. At 10.30 A.M. she was found unconscious, and on March 30, without having regained consciousness, she was admitted to Queen Mary's Hospital, Stratford.

On admission her temperature was 97·8°F, pulse-rate 92 per min., and blood-pressure 160/100 mm. Hg. Her limbs were hypotonic, and there were feeble withdrawal movements to painful stimuli. There was no response to speech. The eyes made occasional roving conjugate movements, and there was sluggish lid closure on corneal irritation. The pressure and contents of the cerebrospinal fluid (C.S.F.) were normal on lumbar puncture.

Treatment and Progress.—Initial treatment was based on the supposition of barbiturate poisoning, but chemical tests did not confirm this. On April 6, 1948, the fasting blood-sugar level was 38 mg. per 100 ml. During the next week the patient passed gradually into a state of decerebrate rigidity. There were attacks of generalised sweating in which her skin went very red. There was constant slight variable pyrexia. The blood-pressure fluctuated between 150 and 240 mm. Hg systolic and 120 and 160 mm. Hg diastolic; the pulse-rate remained about 80. A revised provisional diagnosis of irreversible damage due to hypoglycæmia was made; but, since various consultants considered this unlikely, the patient was transferred to the London Hospital neurosurgical unit. From April 13 to 23 her temperature fluctuated from 99° to 101°F and her pulse-rate from 94 to 132. Ventriculograms were substantially normal. The lesion was thought to be an infiltrating glioma situated high in the brain-stem and probably involving the hypothalamus. On April 24, the patient was transferred back to Queen Mary's Hospital.

Readmission.—On May 16, 1948, Dr. Goldsmith wrote suggesting readmission to the London Hospital for a further encephalogram. The patient was said to be slightly more attentive, less drowsy, and able to recognise people and single words. The similarity to the picture described by Cairns et al. (1941) as akinetic mutism was emphasised. The fasting blood-sugar level on May 5 was 72 mg. per 100 ml. Feeding by gastric tube during this time included two pints of milk plus 110 g. of glucose a day. From June 8 to 19 the patient was again observed in the London Hospital; little change was found. The look in her eye was described as intelligent and observant, but there was no response to voice or to painful stimuli. At times she made meaningless noises when disturbed. There was extreme decerebrate rigidity with generalised sweating. The blood-pressure was 200/130 mm. Hg, the pulse-rate usually 100–130, and the temperature about 100°F. A ventriculogram showed little abnormal. Vascular degeneration secondary to chronic nephritis was suggested but was excluded by renal-function tests. On June 19, 1948, the patient was transferred back to Queen Mary's and on June 26, she died. The body was sent to the London Hospital for necropsy. Dr. Goldsmith, who had never abandoned the original diagnosis of an islet-cell adenoma, asked that the pancreas should be specially examined.

Necropsy (P.M. 221. 48).—The necropsy was made 48 hours after death. The body, which had been in the cool chamber for only part of this time, was that of a moderately nourished woman with two ulcerating bed-sores on the dorsum of either foot. The chief findings were degeneration of the central nervous system from hypoglycæmia, and an islet-adenoma of the pancreas. A trephine opening was present in each parietal bone. There was a slight excess of fluid in the subarachnoid spaces. There was slight grey thickening of the leptomeninges in the cisterna interpeduncularis. The main cerebral arteries were normal, and the spinal cord was of normal external appearance. A well-defined soft pinkish-red nodule, measuring 1·0 × 0·8 cm., was found near the inferior border of the body of the pancreas, which was small and soft. Two thrombotic vegetations were present on the free margins of the anterior and posterior cusps of the mitral valve, together with slight, microscopically inactive, chronic rheumatic endocarditis of this valve. There was slight general atheroma. The lungs, liver, spleen, and kidneys were slightly congested. Two small adenomas were found in the thyroid gland. The other endocrine glands appeared normal. The stomach showed congestion and post-mortem digestion. Scattered submucous hæmorrhages, up to 1 cm. in diameter, were present in the lower ileum. The trigone of the bladder was extremely congested. In the upper 28 cm. of 41 cm. of the right femur the red marrow was hyperplastic.

Examination of brain and spinal cord after fixation showed that the brain had remained unusually soft in spite of prolonged fixation in formaldehyde. The cerebral hemispheres were symmetrical, the convolutions being uniformly slightly atrophied. Descending degeneration of the pyramidal tracts was found in the basal parts of the pons, shrinkage of the pyramids in the upper medulla, and creamy opacity of both lateral columns of the spinal cord, corresponding to the crossed pyramidal tracts, and of the direct tract on the right side. Both lenticular nuclei were shrunken and reddish-brown. In other respects the central nervous system appeared normal.

Histology.—The *brain* showed massive loss of neurones in the cerebral cortex, confined to the hippocampal gyri, where in Ammon's horn there was extensive laminar necrosis accompanied by an active microglial reaction shown by impregnation with silver. These cells were laden with sudanophil droplets. There was also here a moderate proliferation of astrocytes. In other parts of the cerebral cortex there was no massive loss of neurones, though individual cells had been destroyed and were replaced by small groups of reacting microglial cells. Gross post-mortem degeneration precluded further estimates of stages of significant neuronal degeneration; in the subcortical white matter diffuse areas of partial demyelination were associated with disseminated droplets of sudanophil lipoid and small aggregates of fat-laden phagocytes in adjacent perivascular spaces. The degree of demyelination varied in different parts of the cerebrum. A patch of complete necrosis beneath the right area striata was occupied by numerous compound granular corpuscles, and in one focus these had taken the place of the overlying cortex. There was great loss of neurones in the lenticular nuclei, especially in the globus pallidus; the large cells of the latter had completely disappeared apart from a few "ghosts." In silver preparations there was intense microglial proliferation, diminishing in the putamen. Slight gliosis was present. In the hypothalamus the supra-optic nucleus (one side only was examined) was intact, though the cells were in stages of chromatolysis (probably a post-mortem change). The paraventricular nucleus could not be recognised; but, since the ventricular wall had been lost through softening, it was by no means certain that this nucleus had been completely destroyed. No further observations could be made on this region, because of gross softening. Short stretches of the cerebellar cortex were devoid of Purkinje cells, but most had survived. Apart from this there were no noteworthy changes in the cerebellum. The descending pyramidal degeneration throughout the brain-stem and spinal cord was incomplete; many microglial cells with swollen bodies infiltrated the tract and were, in places, so closely aggregated that they resembled multinucleate foreign-body giant cells. There did not appear, however, to be complete fusion of their cytoplasm. The *adenoma of the pancreas* was composed of a solid mass of small polygonal cells. Although post-mortem degeneration was fairly advanced, the resemblance to islet-cells was obvious. The cells were supported by an anastomosing framework of connective tissue and blood-vessels, which was not so prominent as usual in tumours of this class. Elsewhere the islets were numerous and conspicuous.

Comment.—It is regrettable that post-mortem degeneration was so advanced in case 1. Death took place during a spell of hot weather, and there was delay in transferring the body to the cold chamber. The changes in the central nervous system, however, corresponded closely to those recognised in death following a hypoglycæmic crisis (Lawrence et al. 1942). In the series cited the length of coma did not exceed 17 days and subcortical demyelination was not observed. But Hsü and Ch'eng (1938) found this change in three cases when the patients survived carbon monoxide poisoning for 1–4 months; and O'Brien and Steegman (1938) found advanced demyelination of the cerebrum and partial demyelination of the pyramidal tracts in a woman who died 16 months after nitrous oxide anæsthesia, during which time she had gross impairment of cerebral function progressing to a state of decerebrate rigidity. In case 1 it is concluded that repeated hypoglycæmic attacks led to a final phase in which irreversible changes in the neurones were responsible for the clinical picture observed during the last 3 months of life.

Case 2 (L.H. record no. 36469. 50).—A married woman, aged 35, was admitted in coma to Whipps Cross Hospital on Aug. 31, 1950. Next day, still in coma, she was transferred to the London Hospital with a provisional diagnosis of a tumour of the third ventricle. She was under the care of Dr. A. E. Clark-Kennedy.

Background—According to her husband's story, they had been married 10 years. His wife had always been a healthy happy woman. She had never had fits, and he knew of no head injury. There were three children, aged 9, 6, and 4 years. The first time he noticed anything wrong was about three months before admission. He had left his wife asleep when he went to work, and when he got home at 4 P.M. she was still half asleep and sweating profusely. At first he was unable to rouse her. Later she recovered enough to eat an ice-cream, and after this she seemed normal again except that she could not remember what had happened during the day. During the next 2 months she made no complaints and behaved normally; then, about a month before admission, she had two similar attacks within 4 days. He found it impossible to wake her up until about 2 P.M., and each time he noticed that she was sweating profusely. In the next 3 weeks she had two further attacks. The attack which brought her into hospital was the fifth; it began on the morning of Aug. 31. This time he was unable to rouse her and sent for the doctor. At 9 P.M. she was admitted to Whipps Cross Hospital. According to the letter from Whipps Cross Hospital she made a partial recovery soon after admission but relapsed.

On admission to the London Hospital she was comatose and breathing stertorously. There was some sweating. Her face was flushed but not cyanosed. Her temperature was 103·4°F, pulse-rate 100, and blood-pressure 135/80 mm. Hg; no masses were felt in the abdomen; the heart and lungs appeared healthy. In so far as they could be tested the cranial nerves were normal. The limbs were held in extension and adduction, and passive movements were resisted. All the tendon-jerks were brisk, and there was an extensor plantar reflex on both sides. The C.S.F. pressure was normal and the C.S.F.-protein level was less than 20 mg. per 100 ml. There was no increase in the number of cells.

Treatment and Progress.—On Sept. 1, 1950, an intravenous injection of 100 ml. of 25% dextrose was given in the belief that this was a hypoglycæmic attack. There was no response; if anything, the coma deepened. Next morning the blood-sugar level was 100 mg. per 100 ml. and the blood-urea level 30 mg. per 100 ml. At 2 P.M. burr holes were drilled in both parietal bones. The C.S.F. pressure in the left ventricle was normal; the right ventricle was not found. After this the patient was put on nasal feeds. At 9 P.M. her blood-sugar level was 64 mg. per 100 ml. On Sept. 3 it was 180 mg. per 100 ml., and on Sept. 5, it was 118 mg. per 100 ml. The coma persisted. On Sept. 6, her temperature rose to 104·5°F and on Sept. 7 to over 105°F. Her pulse-rate and respirations increased, and on the 7th day after admission she died.

Necropsy (P.M. 324. 50.)—The necropsy was made 3 days after death. The body was that of an obese woman. The chief findings were purulent bronchitis, irreversible hypoglycæmic coma, and islet-cell adenoma of the pancreas. A dark-red nodule, measuring 1·3 × 0·7 c.m, was found on the anterior surface of the pancreas 2 cm. from the end of the tail and containing a pale creamy area, 0·3 cm. in diameter, in its substance. The rest of the pancreas had undergone post-mortem autolysis. The suprarenals, especially the left, showed central softening. The other endocrine glands appeared normal. The thymus was adipose and contained islands of glandular tissue visible microscopically. The myocardium, liver, spleen, and kidneys showed post-mortem degeneration. There was a splenunculus 1 cm. in diameter near the tail of the pancreas. There was slight general atheroma. No abnormality was visible in the brain (cut after fixation). Congestion, œdema, and purulent bronchitis were present throughout the lungs; microscopically there was early purulent bronchopneumonia in the left lower lobe.

Histology.—The *islet-cell tumour of the pancreas* lay in the border of the pancreas, being separated from the gland proper by a zone of fibro-adipose tissue. It was a solid mass, subdivided into two lobules of unequal size, of homogeneous character. Acini of compact polyhedral cells were separated by a highly vascular reticular stroma of connective tissue. The tumour cells were of even size, with eosinophil cytoplasm and oval or round nuclei with a rather coarse chromatin network and nuclear membrane. Because of the long interval between death and necropsy, specific staining of cytoplasmic granules was unsatisfactory. The islets in the adjacent pancreas were not remarkable; the remainder of the tissue showed moderate post-mortem degeneration. The *liver* showed moderate diffuse fatty change in the parenchymal cells, and many Kupffer cells were slightly distended by sudanophil droplets. A few groups of parenchymal cells contained granules of glycogen. The anterior lobe of the *pituitary gland* was conspicuously engorged; the glandular elements appeared to be normal, but post-mortem degeneration was considerable. The *brain*, in a coronal section through the right basal ganglia, crus cerebri, and hippocampal gyrus, showed diffuse congestion. In Ammon's horn there was advanced laminar necrosis of the neurones. These had either completely disappeared or were in stages of advanced degeneration and necrosis. There was no cellular reaction to the necrosis. In the optic thalamus a further area of necrosis, adjacent to the upper part of the internal capsule, was well defined and contained loosely grouped compound granular corpuscles. In the right lobe of the cerebellum there was a patchy loss of Purkinje cells; many of those present were in advanced stages of degeneration, with chromatolysis and karyolysis. The granule cells were well preserved.

Comment.—The islet-cell tumour of the pancreas had the characteristic appearances of the benign type, in situation, size, and microscopical appearances. That it was a functioning tumour cannot be doubted both from the clinical history and from the changes of anoxic type found in the brain. The special vulnerability of Ammon's horn is generally recognised in this connection, and the pattern of damage in case 2 conforms closely to those reported by Lawrence et al. (1942) in their series with hypoglycæmic manifestations. The focus in the optic thalamus must have been slightly older than that in Ammon's horn, in view of the phagocytic cells in the area, though these were scanty. The Purkinje cells of the cerebellum are recognised as being especially sensitive in anoxic and allied states; the patchy loss found in case 2 is therefore in conformity with the other changes found.

Case 3 (L.H. record no. 42178. 50).—A married woman, aged 36, was admitted to the London Hospital in coma on Oct. 26, 1950. Her history had been taken 12 days before in the neurosurgical outpatient department, and she was already on the waiting-list for admission under the provisional diagnosis of "hypothalamic tumour or paroxysmal hyperinsulinæmia."

Background.—According to her outpatient record she was happily married and had three children. Her general health was good and her appetite excellent. Menstruation had ceased abruptly in December, 1949, and since then she had gained about 3 st. in weight. Her husband described her attacks. The first one took place on the day before Christmas, 1949. She sat down in a chair after breakfast with a fixed stare and took no notice of what was said to her. From time to time she shut her eyes. After about 20 minutes she "came to" quite suddenly and carried on with her work as if nothing had happened. Three months later (March, 1950) there was a similar attack. In May, 1950, there were nine further attacks all within the space of 3 weeks. Each time the patient was described as sitting in a chair in a dreamy state with her eyes opening and shutting. From time to time she would jerk her legs in and out and throw her arms about. She would keep muttering over and over again: "What is the matter with me?" If her husband bathed her head in cold water the movements would stop, but she would not regain consciousness fully. An attack usually lasted about 5 hours. At that time she never fell down, bit her tongue, or hurt herself. She was incontinent of urine once, and once she was seen to be sweating. In August, 1950, she was admitted to another regional hospital, but no evidence of anatomical disease was found. Her electro-encephalogram (E.E.G.) was said to be grossly abnormal and compatible with epilepsy. A psychiatrist thought that her behaviour suggested rather hysteria than schizophrenic withdrawal. In the week after the patient had attended the London Hospital outpatient department the attacks became more frequent. Her husband complained that he had to get up at 5 A.M. to make her wake by 8 A.M. For 4 days before admission she was in a continuous dreamy state, muttering and talking about her activities of the week before. On the day before admission she had three more violent fits. Her arms and legs made clonic movements, her face and right eye twitched, she bit her tongue, and she frothed at the mouth. Between these fits she remained comatose.

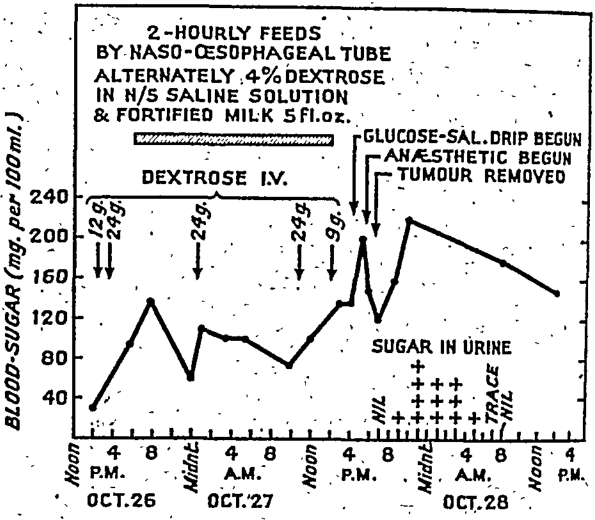

Fig. 1—Preoperative and postoperative blood-sugar levels in case 3.

On admission she was flushed but not sweating, her temperature was 100°F, her pulse-rate 110, and her blood-pressure 130/85 mm. Hg. No mass was felt in the abdomen, and her heart and lungs were normal. The specific gravity of her urine was 1·030; there was neither albumin nor sugar, but the Rothera test was positive. Her eyes were described as "roving." The pupils were dilated and equal; they reacted to light and accommodation. There was no facial weakness. The limbs were hypertonic, the tendon-jerks exaggerated, the plantar reflexes extensor, and the abdominal reflexes absent.

Treatment and Progress.—An islet-cell adenoma of the pancreas was diagnosed and confirmed by a blood-sugar level of 33 mg. per 100 ml. Intravenous dextrose was given, and within an hour there was a partial recovery of consciousness. The patient knew her name and address and her husband's name and age.

Operation.—The day after admission she was transferred to the surgical unit, and an adenoma of the pancreas, situated at the junction of the head and neck on the main duct, was excised. No other tumour was felt in the pancreas. The immediate preoperative and postoperative blood-sugar levels are shown in fig. 1.

Operation Specimen (S.D. 4880. 50).—This was a solid mass of tissue, 1·3 cm. in diameter and weighing 1 g., surrounded by tags of adipose tissue, and with a brown granular fairly homogeneous cut surface. Microscopically the adenoma, which measured 0·7 × 0·5 cm., was almost entirely enclosed by a fringe of normal pancreatic tissue from which it was well demarcated. The tumour was composed of trabeculæ and solid acini of small polygonal cells, closely resembling islet cells, and supported by an abundant vascularised stroma.

Convalescence and Follow-up.—During the next 3–4 days the patient slowly regained full consciousness, and 12 days after operation she was discharged to convalescence. She has attended the follow-up clinic at intervals. On Feb. 26, 1951, her E.E.G. still suggested epilepsy. She was last seen on March 20, 1952. Her weight seems to be keeping fairly constant at about 11 st. 2 lb. She describes herself as "very well indeed," and there have been no further dreamy states or fits.

Case 4 (L.H. record no. 36140. 50).—A married woman, aged 55, was seen in the London Hospital neurological outpatient department on Feb. 21, 1951. A cerebral tumour was provisionally diagnosed, and she was admitted at once under the care of Dr. Kenneth Perry.

Background.—According to the house-physician's notes, she was well built, well covered, and healthy-looking, with average intelligence. She had married at the age of 22, but there was only one child. She lived at home and looked after her husband. Menstruation ceased in 1949. In September, 1950, she had a hysterectomy for carcinoma of the fundus. Recovery from this was complete and satisfactory. In the next 3 months her weight fell from 13 st. to 12 st., but according to a note made in January, 1951, "she felt all the better for having lost some fat." The first sign of further trouble was on Feb. 4, 1951, when she woke up at 8.30 A.M. and went into the bathroom. After that she remembered no more until she found herself downstairs with her husband kneeling beside her. According to the husband's story he found his wife lying unconscious on the bathroom floor, "rolling about, tearing her hair, and talking nonsense." She did not regain full consciousness until about 12.30 P.M. In the afternoon she had severe biparietal headache, but she managed to do various household jobs. By the evening the headache had almost disappeared. On Feb. 9 and Feb. 17, 1951, second and third attacks came on. Both of them closely resembled the first, and both lasted about three hours. In between she felt perfectly well except for some anxiety about what was wrong. On Feb. 21, 1951, the day of admission, there was some clouding of consciousness. She remembered getting up in the morning, but after that her mind was a blank until she woke up in the ward. She was described in the outpatient notes as "rather stuperose."

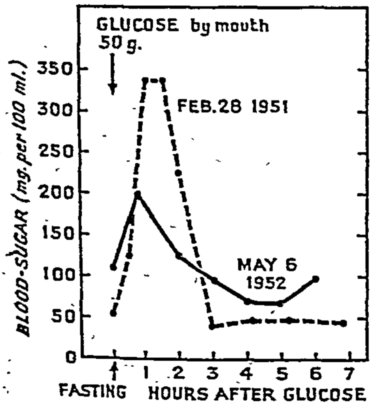

Fig. 2—Sugar-tolerance tests in case 4 before (Feb. 28, 1951) and after (May 6, 1952) removal of islet-cell adenoma of pancreas on March 2, 1951. Test on Feb. 28, 1951, followed small feeds at midnight and at 3 a.m.; there was no coma. On May 6, 1952, patient had fasted since 8 p.m. on May 5.

On admission physical examination revealed nothing of note. Her blood-pressure was 150/90 mm. Hg.

Progress.—Next day was uneventful, but on the day after that she had an attack at 5 A.M. in which she struggled, shouted, and kicked her legs. A few hours later she was quite normal and remembered nothing about it. The C.S.F. was normal on lumbar puncture. On the 4th day after admission she had an attack about noon, when she became drowsy and difficult to rouse. She is said to have murmured "Bread and butter" in answer to every question. Shortly afterwards she became restless and from time to time screamed in a high-pitched voice. Meanwhile her eyes were tightly closed. On Feb. 27, 1951, she was very drowsy and sweating at 8 A.M., when her blood-sugar level was only 33 mg. per 100 ml. At 10 A.M. she was given 60 g. of glucose by stomach-tube. Within 5 minutes she was quite rational.

Operation.—On Feb. 28, 1951, she was transferred to the care of Mr. Alan Perry, who removed a tumour from the lower border of the pancreas on March 2. The remainder of the pancreas was carefully palpated, but no other tumour nodules were felt. During the operation a continuous infusion of 5% glucose was given, but the quantity is not known. At the end of the operation the blood-sugar level was 125 mg. per 100 ml. 3 hours later it was 200 mg. per 100 ml.; and at 9.30 P.M., 7 hours after the operation, it was 300 mg. per 100 ml., and there was much sugar in the urine but no ketones. The result of a preoperative sugar-tolerance test is shown in fig. 2.

Operation Specimen (S.D. 905. 51).—This was a soft, purple, apparently encapsulated nodule, measuring 2·2 × 1·5 × 1·3 cm. and weighing 2·27 g., with strands of connective tissue attached to its surface. On section the cut surfaces were in part purple, soft, and finely granular, the rest being yellowish-white, firm, and almost rubbery. Microscopically a narrow zone of normal pancreas extended over the surface of the tumour in a few places. In its architecture and cytology the tumour closely resembled that in case 3, except that the collagen fibres of the stroma were more prominent and formed broad anastomosing bands throughout part of the tumour. In the interstices here the tumour cells were often in stages of degeneration.

Convalescence and Follow-up.—Recovery from the operation was uneventful, and there had been no further attacks of drowsiness or unconsciousness when the patient was last seen in September, 1952. The result of a sugar-tolerance test on May 6, 1952, is shown in fig. 2.

Case 5 (L.H. record no 11218. 52).—A man, aged 36, was transferred from the Belmont Hospital to the medical unit of the London Hospital on March 31, 1952, with a provisional diagnosis of islet-cell tumour.

Background.—He was married but had no children. His eldest brother had died in 1949 from "cancer of the lymph-glands." His two other brothers and his two sisters were well. He had recently become the manager of a small firm and enjoyed his work. He smoked 30 cigarettes a day and drank spirits occasionally. His previous health was good. There was no history of any important illness. The first symptoms occurred in January, 1952. He got up one morning and sat in an armchair. When his wife brought him a cup of tea, he did not answer her and "appeared to be in a trance." He remained like this for over 2 hours and then gradually came round. He remembered this attack and said that the $2^1/_2$ hours seemed like $2^1/_2$ minutes. Afterwards he felt "very weary." There were no muscular spasms, and he did not pass urine or bite his tongue. In February, returning from work at 6 P.M., after having had his tea at 4 P.M., he complained to his wife of double vision; the images were vertically displaced. The same thing

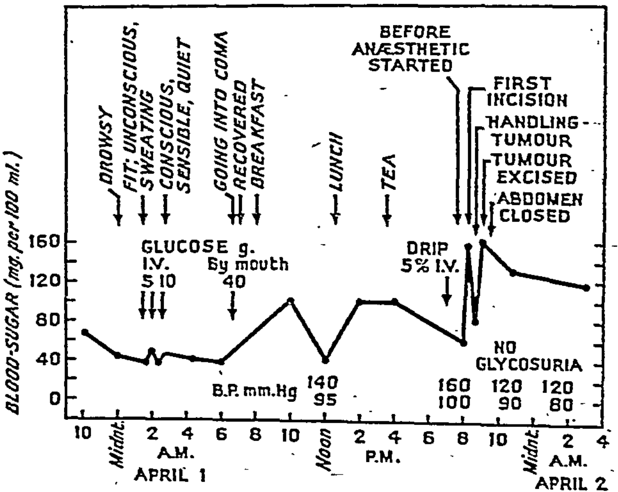

Fig. 3—Immediate preoperative and postoperative blood-sugar levels in case 5.

happened on the 2 following days. As a result of this he saw his own doctor and was referred to a hospital for nervous diseases. After a neurological examination and E.E.G. he and his wife were told the condition was functional. A week later attacks began to occur every morning. They tended to come on earlier and to leave him feeling weaker. When his wife shook him, he only muttered "all right, all right." She noticed that he sweated freely. In his later attacks, which lasted up to 4 hours, he sometimes passed urine in bed. Finally he began to get additional attacks at midday and in the evening. On the last occasion he had an attack on the way home and had to be helped home by two men as he walked "drunkenly" along the road. He knew where to go and recognised his wife. He was relieved to see her and then fell asleep for 10 minutes. When he woke up he said that he had had a dreadful dream and described what had happened. He was advised to go into Belmont Hospital, where Dr. M. N. Pai saw an attack and diagnosed hypoglycæmia.

On admission to the London Hospital the patient seemed quite normal and was described as intelligent and coöperative. His blood-pressure was 140/95 mm. Hg. At midnight he became drowsy and disorientated; he laughed, rolled his eyes, and smacked his lips, and his arms and legs twitched. He was flushed and sweating and finally passed urine. Soon after being given intravenous glucose he was well orientated again, smiling and talking amiably. During the attack his pupils were dilated but reacted to light and accommodation. Immediately after the attack the cranial nerves were normal.

Operation.—In the evening of April 1, 1952, he was transferred to the surgical unit and underwent laparotomy. The spleen and tail of the pancreas were removed. There were many nodules in the liver, and a part of one was removed for examination. The immediate preoperative and postoperative blood-sugar levels are shown in fig. 3.

Operation Specimens (S.D. 1438. 52).—The primary tumour replaced the tail of the pancreas, forming a mass measuring 5·5 × 3·5 × 3·0 cm. (after three portions each measuring up to 1·9 × 0·6 × 0·3 cm. had been removed for fixation in fluids other than formaldehyde) which infiltrated adjacent structures but did not invade the attached spleen. Its texture was firm and rather rubbery. A separate portion, from the liver, included a nodule, measuring 1·3 × 1·0 × 0·8 cm., of firm white granular growth. Microscopically the growth in the pancreas was composed of trabeculæ and solid acini of polygonal cells, which differed from those in the previous cases only in the varying size of the cells and of their nuclei and in a slight aberration in their chromatin-content. Mitoses were rare. There was considerable degeneration in many areas, with advanced pyknosis. The collagenous stroma was abundant, forming large hyaline masses in the centre of the tumour. Groups of the tumour cells infiltrated the adjacent pancreas, extending into the peripancreatic adipose and connective tissues both directly and by permeation of veins, lymphatics, and perineural sheaths. An adjacent lymph-node was almost completely superseded by tumour, in which the disparity in nuclear size was pronounced, some being of giant character, but again mitoses were very scarce. The metastasis in the liver was a solid mass of cells closely resembling those of the parent tumour; the collagenous stroma was scanty. Superficially the tumour abutted on the liver capsule; beneath this the liver parenchyma was well demarcated, and compressed by the tumour, but on the deep surface the tumour was intimately related to the liver cells.

Convalescence and Follow-up.—The patient made a good recovery and had no further attacks and never any glycosuria. He was given a 2000-calorie diet from April 3, 1952, and a 2500-calorie diet from April 11. His blood-sugar level rose and remained over 100 mg. per 100 ml., but his fasting blood-sugar level in the morning on April 17 was 47 mg. per 100 ml., and on April 19 at 8 A.M. 53 mg. per 100 ml. His wife, who was seen on May 20, said he was again having attacks in the morning. They responded rapidly to sugar.

In June he had further attacks of hypoglycæmia: it is hoped to report his subsequent course and treatment with cortisone at a later date.

Case 6 (L.H. record no. 22594. 51).—A man, aged 45, was admitted under the care of Dr. Kenneth Perry to the London Hospital in coma at 12.15 P.M. on June 8, 1951. He died at 1.30 A.M. on June 9, without regaining consciousness. The provisional diagnosis was cerebral hæmorrhage.

Background.—He was a single man employed as a street vendor. His mother died at the age of 40 with "sugar in the water." He lived alone in a room; previously he had lived with his father. His father died in February, 1950, aged 72. Of his three brothers, two were dead and the third, aged 52, was alive and well. He seldom saw his brother. He served in the Royal Artillery in 1942–43 and was discharged as medically unfit. His brother did not know the reason for his discharge from the Army. In 1944 the family first noticed he was having "fits." On the first occasion he got out of bed without any clothes and wished to run across the road. He was stopped and shortly afterwards became "queer and fainted." He was well again within a few hours; he remembered nothing of the attack. He was referred to St. George in the East Hospital. A letter from this hospital stated that he was admitted on May 8, 1946, semicomatose after an epileptiform fit. On May 11, 1946, his blood-sugar level was 30 mg. per 100 ml. A Wassermann reaction was negative; there was no abnormality in the C.S.F.

Operation.—He was readmitted on June 25, 1946, and underwent laparotomy on Oct. 16. No obvious pancreatic tumour was found; so the body and tail of the pancreas were removed. After operation his blood-sugar level was normal. Microscopy of the specimen was inconclusive but suggested "an excessive number of islets of Langerhans."

Follow-up.—He attended as an outpatient and was apparently well until December, 1947. Little is known about him from that time until his death. His neighbours thought he had "fits." In June, 1951, he was not seen for a week; so the police were called. His room was entered; he was found in coma and brought to the London Hospital. He was unkempt and had pressure sores on the left chest and trochanter. His temperature was 97·8°F, pulse-rate 104, and respirations 30 a minute. His blood-pressure was not registrable. His abdomen bore the scar of the previous operation. His pupils were dilated and did not react to light, and the corneal reflexes were absent. So far as they could be examined the other cranial nerves were normal. The left arm was spastic and the right flaccid, and the abdominal reflexes were absent. In the lower limbs the knee-jerks and ankle-jerks were absent and the plantar responses extensor. The urine contained neither sugar nor ketones, but there was a trace of albumin; the blood-sugar level was 437 mg. per 100 ml. (both urine and blood estimations were repeated). Lumbar puncture showed the C.S.F. at low pressure, containing protein 70 mg. per 100 ml. and sugar 306 mg. per 100 ml. (the accuracy of these estimations is open to doubt because they were done at night by an inexperienced house-physician).

Necropsy Findings.—The necropsy was not done in this hospital; the chief findings were bronchopneumonia and a tumour "adherent to the peritoneal surface and the posterior wall of the stomach close to the cardia. It was generally speaking rather soft and hæmorrhagic and in one place was partly calcified." No abnormality was noted about the pancreas. There was no gross disease of the brain. The pathologist wrote that a suggestion had been made in his laboratory that the tumour was composed of islet cells and that death was due to hypoglycæmia. He thought, however, that this was "rather a wild shot." Subsequent microscopy of the tumour confirmed the strong resemblance to an islet-cell adenoma.

Owing to the lack of accurate clinical and pathological details case 6 is not considered in the discussion.

DISCUSSION

The cells of the central nervous system are highly sensitive to a fall in the blood-sugar level. At first the disturbance is only functional; later the damage is irreversible.

In all the present cases the pattern of symptoms suggested widespread damage to the brain, with hypothalamic disturbance in particular. The pronounced vegetative disorders—sweating, pyrexia, tachycardia, flushing, and, possibly, clouding of consciousness—led experienced neurological specialists to place the lesion in the hypothalamus in four cases. It is difficult to decide whether the predominance of the latter symptoms is due to a special susceptibility to hypoglycæmia of this part of the brain, or whether it is the dramatic manifestations in disease of this region which attract attention. In both fatal cases there were pyrexia and tachycardia. In case 2, the only fatal case in the London Hospital, there was terminal hyperpyrexia. There was thus in case 2 a close resemblance during the last stages to the effects produced when the hypothalamus is accidentally damaged during operation on neighbouring parts of the brain. In the brains examined at necropsy this region does not appear to suffer disproportionate anatomical damage.

Hypoglycæmia stimulates the production of adrenaline, which converts liver glycogen into glucose (Cannon et al. 1924). It has been suggested that an excess of circulating adrenaline is responsible for many of the symptoms (*Lancet* 1950, Thorn et al. 1943). The course of the present cases is against this hypothesis. The patients were sweating and flushed, not pale. Their symptoms were unlike those of an adrenaline-producing tumour. There was no evidence of paroxysmal hypertension. There is no mention in the notes of anxiety or of an anxiety type of trembling.

The course was rapid. Case 3 took 10 months to reach the comatose stage, or 7 months if the first solitary attack is excepted. Case 2 reached a stage of permanent coma in 3 months and died a week later. Case 1 reached the stage of permanent coma in 5 months but took another 2 months to die. The early attacks have been consistently in the morning; later, as in case 5, the attacks may come on some hours after a meal. This is a time when there is a functional hypoglycæmia, which probably, in the presence of the tumour, precipitates the attack.

One of the reasons why the diagnosis is missed is that the blood-sugar level is not necessarily low, and there may be no response when intravenous glucose is given. In case 4, who was seen 17 days after the first attack, the symptoms were paroxysmal and there was a prompt response to glucose. Case 5 also responded to glucose 2½ months after the onset of symptoms. In case 3 the response to glucose was only partial; in fact, she did not recover full consciousness until several days after the adenoma had been removed. In both patients with benign tumours who were successfully operated on there was transient postoperative glycosuria. This is a reassuring sign for the surgeon, who must always be anxious lest small adenomas of islet tissue have been left behind.

In cases 1 and 2 there was no biochemical evidence of hypoglycæmia and no response to intravenous glucose. In case 2 no low blood-sugar level was recorded. In case 1 there was a solitary reading of 38 mg. per 100 ml., but this could not be repeated or confirmed. It is difficult to explain this return of the blood-sugar level to normal. Prolonged hypoglycæmia of this severity possibly also damaged the insulin-producing cells of the adenoma.

If cases 1 and 2 had been correctly diagnosed, their lives might have been saved. Possibly, however, they would only have survived as idiots. The structural damage seen in the brains examined at necropsy shows that early diagnosis and treatment are of the greatest importance in the full recovery of the patient. The preoperative and postoperative E.E.G. in case 3 suggest permanent structural damage.

SUMMARY

Six cases with islet-cell tumour are recorded.

The pattern of symptoms, time of attacks, and course of the disease were consistent.

The evidence suggests that a disorder of the hypothalamus, rather than excess of adrenaline, is responsible for some of the clinical manifestations.

In the advanced cases the blood-sugar levels and response to glucose were inconsistent, leading to confusion.

The necropsy findings in two cases are described.

I wish to thank the physicians and surgeons of the hospital who allowed me to use their cases; and particularly Mr. D. W. C. Northfield and Dr. Denys Jennings for their help.

EXAMINATION OF RIB BONE-MARROW FOR TUBERCLE BACILLI

KENNETH MARSH
D.M. Oxfd
CONSULTANT PHYSICIAN, CHEST CLINIC, CAMBERWELL, LONDON

G. E. BARTON
A.I.M.L.T.
ASSISTANT, PATHOLOGY DEPARTMENT, ST. WULSTAN'S HOSPITAL, MALVERN, WORCS

Two recent papers in America (Horowitz and Gorelick 1951, Hausmann 1951) as well as the publications of Choremis and Pantazis (1951, 1952) in Greece have drawn attention to the possibility of finding *Mycobacterium tuberculosis* in bone-marrow. It is to be expected that *Myco. tuberculosis* could be demonstrated in bone-marrow in miliary and acute hæmatogenous tuberculosis, but it is generally considered that one would be unlikely to find the bacillus in the bone-marrow of adult patients with the ordinary fibrocaseous or cavitatory type of pulmonary tuberculosis.

Schleicher (1946) found miliary tubercles in aspirated bone-marrow in 8 cases, and Peterson and Canfield (1945) suggested that it was possible to use bone-marrow for the differential diagnosis of miliary tuberculosis and typhoid fever. Horowitz and Gorelick (1951) examined the bone-marrow from various patients with the Ziehl-Neelsen technique and made cultures of it on suitable media, such as Löwenstein, Petragnani, Petroff, and Dubos. These patients had far-advanced pulmonary disease with toxæmia, or had a fever of unknown origin where laboratory investigations had been unrevealing. They claimed to show tubercle bacilli in the bone-marrow of 14 of 20 patients by direct examination of the aspirated material, but in only 5 of these 14 was the diagnosis confirmed by culture.

Choremis and Pantazis (1951) reported a positive blood-culture in 62·4% of 324 cases of tuberculosis, and 5 cases positive out of 17 in which sternal marrow had been cultured. Most of their patients were young children. Later Choremis and Pantazis (1952) got positive bone-marrow cultures from 16 of 65 children, most of whom had a primary complex, tuberculous pneumonia, or miliary tuberculosis. Smears were made of the aspirated material to make sure that it was bone-marrow, but Ziehl-Neelsen staining was not done.

On the other hand, Leitner (1949), in his study of 54 cases of hæmatogenous tuberculosis, obtained only one positive culture from aspirated sternal bone-marrow.

In addition Hausmann (1951) was unable to demonstrate tubercle bacilli by means of direct smear, marrow digest cultures, and surface scraping cultures taken from segments of ribs from 69 consecutive thoracoplasty stages of 34 patients. He therefore suggested that there would probably have been no risk of implanting tubercle bacilli into the recipient's tissues if any of the ribs studied in his series had been used as homogenous bone grafts. In fact, in 5 instances, rib fragments from thoracoplasty patients were successfully used as homogenous bone grafts for tuberculous lesions of bone.

INVESTIGATION

The purpose of the present investigation was to discover whether or not the bone-marrow of the ribs removed at thoracoplasty or pulmonary resection from patients known to have or to have had a positive sputum contained tubercle bacilli. It was also hoped that, if any of the bone-marrow gave a growth of *Myco. tuberculosis*, it might be possible to determine whether or not these tubercle bacilli were resistant to streptomycin, if the patient had a streptomycin-resistant strain of tubercle bacilli in his sputum. Bone-marrow was also aspirated in 3 cases of acute disseminated tuberculosis in adults.

28 men and 14 women had thoracoplasties, and 5 men and 5 women had resections. Additional bone-marrow was cultured from 6 men and 7 women who had had two stages and 1 woman who had had three stages. The total number of cultures from 52 surgical patients was 66. In addition, cultures from the bone-marrow of 3 cases of acute disseminated tuberculosis were set up; these 3 patients had not received chemotherapy at any time during their illness. 25 of the 28 men who had thoracoplasties had positive sputum during their stay in hospital before operation; 13 of these were also positive at operation. Of the 5 who had resections only 1 had negative sputum during his stay in hospital and previous to operation. 6 of the 14 women who had thoracoplasties had positive sputum while in hospital, but only 4 were positive at the time of operation. Of the 5 women who had resections 4 had had positive sputum, and 3 of these were also positive at operation. 19 men who had thoracoplasties had had previous chemotherapy with streptomycin and *p*-aminosalicylic acid before admission to this hospital, and 10 had similar chemotherapy at the time of operation, of whom 4 had had previous chemotherapy while in this hospital. Of the women 14 had had chemotherapy previous to admission, and 5 had it at the time of operation. Of the 5 men who had resections all received chemotherapy at the time of operation and 3 had had it before admission. Of the 5 women who had resections all were receiving chemotherapy at operation and 4 had had it before admission. Altogether 25 patients were receiving chemotherapy at the time of operation. The accompanying table gives these details.

PROCEDURE AND TECHNIQUE

At St. Wulstan's hospital it is usual for thoracoplasties to be done in two stages at fortnightly intervals, and in all seven ribs are removed. One surgeon prefers to do an eight-rib thoracoplasty in three stages.

All the ribs removed at thoracoplasty or resection were sent direct to the laboratory in a sterile container. They were split longitudinally with ordinary carpenter's pincers. Portions of each bone containing the most marrow were placed in a universal container which was then almost filled with sterile distilled water (30 ml.). It was well shaken and placed in the refrigerator at 4–5°C to ensure the separation of the marrow from the bone. The container was again shaken vigorously and the thick bone-marrow suspension poured off into a centrifuge tube, leaving the bone fragments in the universal container. The suspension was centrifuged at 3000 r.p.m. for about 5–8 minutes, the supernatant fluid being discarded, leaving a column of bone-marrow 2 cm. long in the bottom of the centrifuge tube (the actual amount yielded was not constant but was usually about 1·5 ml.). Smears were made from this deposit and stained by the normal Ziehl-Neelsen procedure, after which 3% sulphuric acid was poured on to the deposit in the ratio of 2 parts of acid to 1 of deposit. After thorough mixing with a sterile platinum sputum loop the mixture was allowed to stand at room-temperature for 5–10 minutes, and was next centrifuged at 3000 r.p.m. for 5 minutes. The supernatant fluid was discarded and the deposit was resuspended in a corresponding volume of sterile distilled water and neutralised with 2% sodium hydroxide, phenol red being used as indicator. The neutralised suspension was centrifuged once more, and the deposit was next cultured direct to the Löwenstein slopes, three or four good loopfuls (4–5 mm. loop) being used.

DETAILS OF PATIENTS FROM WHOM BONE-MARROW WAS OBTAINED

Surgical operation	No. of patients	Sex	No. with positive sputum		No. receiving chemotherapy			No. of specimens of bone-marrow examined
			Before operation	At operation	Type A	B	C	
Thoracoplasty	28	M	25	13	19	4	10	34
,,	14	F	6	4	14	0	5	22
Resection	5	M	4	4	3	0	5	5
,,	5	F	4	3	4	0	5	5
Total ..	52	..	39	24	40	4	25	66

Type A = Chemotherapy before admission only.
Type B = ,, after ,, ,,
Type C = ,, at time of operation.

In addition bone-marrow was aspirated from 3 men with acute disseminated tuberculosis who had positive sputum and had never received any chemotherapy. Cultures were negative.

Bone-marrow was aspirated in the region of the spinous processes of the lumbar vertebræ. The material was examined and inoculated in the same way as that removed from the ribs taken at thoracoplasty.

Several controls were set up by inoculating with a known strain of *Myco. tuberculosis* bone-marrow taken at thoracoplasty. From the resulting preparation suitable films were made and stained by the Ziehl-Neelsen technique, and cultures were put up.

RESULTS

In no case was it possible to demonstrate the presence of *Myco. tuberculosis* either by examination of the bone-marrow smear or by culture, but in the controls films showed the presence of *Myco. tuberculosis* and the cultures all proved positive.

Since these patients, undergoing surgical treatment, had neither the acute fulminating tuberculosis that Choremis and Pantazis (1951, 1952) found in their patients nor the widely disseminated tuberculosis that Horowitz and Gorelick (1951) observed among their patients, hæmatogenous dissemination was most unlikely, and therefore one would not expect to culture tubercle bacilli from bone-marrow.

This work thus confirms the results obtained by Hausmann (1951).

It is suggested that ribs removed at thoracoplasty or at resection could be used in orthopædic units for grafting in tuberculous disease of bone without risk of implanting tubercle bacilli into the tissue of the recipient.

I am indebted to Dr. T. W. Lloyd, medical superintendent, St. Wulstan's Hospital, Malvern, where this work was done, for permission to publish these results, and to Dr. *Colin* White for his helpful advice.

From the National Institute for Medical Research, Mill Hill, London

THIS note is a postscript to a report (Gledhill et al. 1952) of the resolution of the ætiological agent of mouse hepatitis (Gledhill and Andrewes 1951) into two components—one (S) relatively stable, the other (L) more labile. Neither component inoculated alone into weaned mice caused evident illness, but when they were combined fatal hepatitis was produced. It now appears that the L component is identical with *Eperythrozoön coccoides*—a mouse parasite related to *Hæmobartonella* and variously regarded as a bacterium or a small protozoon. Our interest had already been aroused by finding L present in the blood in very high titre, when histological study led, as described below, to the finding of eperythrozoon in large numbers.

Histological studies of tissues from animals infected with the S and L components, together or separately, have yielded interesting results. With the techniques so far used in this study, no changes have yet been found with the L agent. With S small areas of hepatic necrosis occur, which differ only in degree from the massive lesions caused by the complex infection itself; both infections, and particularly the latter, were accompanied by varied cytological changes which will be described in detail later. The most unusual pathological feature of the experimental disease and of that due to the S component is the appearance of an endothelial and mesothelial reaction throughout practically all the organs and tissues; this begins within 24 hours of inoculation and has practically disappeared by the 5th day. The endothelial reaction is focal and is restricted to venous channels of all sizes; it is characterised by the formation of multinucleated giant-cells which arise directly from the endothelium, project into the vessels, and readily become detached. Examination of films of peripheral blood for these giant cells in animals infected 3 days previously with "mouse-hepatitis virus" revealed the presence of enormous numbers of *E. coccoides*, with characteristic ring forms. Many mice infected with S and L separately and combined have now been examined. In the L series *E. coccoides* appear in the blood within 2–3 days of inoculation In the S series no eperythrozoa have been found. In animals infected with "mouse-hepatitis virus" *E. coccoides* appear within 24 hours and increase in numbers until death, the terminal stage of the disease being accompanied by many small rod and coccal-forms which may preponderate over the typical ring elements. When S and L are combined to produce fatal hepatitis, the same morphological picture is found. So far it has not been possible to dissociate the activity of the L agent from *E. coccoides*, and it seems likely that they are identical. The L agent and the eperythrozoa react similarly to chemotherapeutic agents, including neoarsphenamine.

Many speculations arise immediately from this association; at present it is sufficient to emphasise the following observations:

1. *E. coccoides* occurs in the blood in experimental mouse hepatitis without previous splenectomy; and it can be passed without splenectomy in normal mice more readily than is usually believed.

2: Eperythrozoa in plasma can pass through a collodion membrane of average pore size 0·46 µ and 0·36 µ, and under ideal conditions probably also through membranes of 0·3 µ—a degree of filterability hitherto unsuspected.

3. Mice of the P strain, which are relatively resistant to hepatitis, are carriers of *E. coccoides*, while those of the V.S. strain, in which the disease can be readily transmitted, are not carriers of eperythrozoa and do not yield *E. coccoides* after splenectomy.

We have not yet elucidated the mechanism whereby the S virus and the eperythrozoon act synergistically to produce fatal hepatitis. It appears, however, that the S is present to about a hundredfold higher titre in the livers of mice in which there is concurrent infection with eperythrozoa. It may be that all strains of *E. coccoides* will behave as described here; but this remains to be proved.

ROYAL SOCIETY OF MEDICINE

Basis of Allergic Reactions

THE pathology section of the Royal Society of Medicine met on Nov. 18 under the chairmanship of Prof. G. PAYLING WRIGHT, president of the section, to discuss cutaneous allergy.

Dr. W. N. GOLDSMITH said that eczema was an epidermal hypersensitivity reaction of the late or delayed type. The process was chiefly cellular, and in some instances—e.g., fixed drug eruptions—the reaction was strictly localised to circumscribed areas of the skin. Sensitising agents could be simple substances (even elements such as nickel or chromium) or more complex organic chemicals, such as paraphenylenediamine. Many of these substances showed a pronounced affinity for protein, and the actual allergen might be a complex of the substance with protein. Desensitisation had been attempted with mixtures of serum and the sensitising substance. Products of the skin itself—e.g., blister fluid—had been shown to act as sensitisers.

In animals intraperitoneal injection of picryl chloride had produced epidermal sensitisation. Where islands of skin had been created by means of deep incisions, the application of such substances to the islands failed to produce hypersensitivity, whereas application to the surrounding skin produced hypersensitivity both locally and in the islands. It had been suggested that this proved that the antibodies were elaborated centrally. However, a subject who had been sensitised by the application of 9-bromofluorene for 24 hours developed redness and blistering at the site of application 13 days later; and the process extended steadily towards the periphery. Dr. Goldsmith supposed that this was due to the slow diffusion of the allergen, successive areas becoming sensitised after the requisite time interval. This gradual progression was possible only if the antibody was produced locally in the skin.

In this type of reaction, passive transfer by serum usually failed, and where it succeeded the reaction was urticarial, not eczematous. Cross-transplants of skin had been made in uniovular twins, one of whom had been sensitised epidermally. The sensitised transplant lost its hypersensitivity in the normal host, whilst the normal transplant took on the hypersensitivity of the recipient. Similarly, a sensitised animal rendered parabiotic with a normal caused the latter to become hypersensitive. The agent was therefore diffusible, but it did not cross the placenta and its molecules were probably large. It did not reside in the plasma, since passive transfer failed; but possibly it was transported by lymphocytes. Hypersensitivity was not induced by injection of such lymphocytes into the skin itself, but followed intraperitoneal injection in animals. It was not clear how the antibody passed from the lymphocytes to the epidermis.

The injection of histamine did not cause eczema, nor was histamine released by the eczema reaction. Antihistamine substances did not have a preventive action.

In addition Hausmann (1951) was unable to demonstrate tubercle bacilli by means of direct smear, marrow digest cultures, and surface scraping cultures taken from segments of ribs from 69 consecutive thoracoplasty stages of 34 patients. He therefore suggested that there would probably have been no risk of implanting tubercle bacilli into the recipient's tissues if any of the ribs studied in his series had been used as homogenous bone grafts. In fact, in 5 instances, rib fragments from thoracoplasty patients were successfully used as homogenous bone grafts for tuberculous lesions of bone.

INVESTIGATION

The purpose of the present investigation was to discover whether or not the bone-marrow of the ribs removed at thoracoplasty or pulmonary resection from patients known to have or to have had a positive sputum contained tubercle bacilli. It was also hoped that, if any of the bone-marrow gave a growth of *Myco. tuberculosis*, it might be possible to determine whether or not these tubercle bacilli were resistant to streptomycin, if the patient had a streptomycin-resistant strain of tubercle bacilli in his sputum. Bone-marrow was also aspirated in 3 cases of acute disseminated tuberculosis in adults.

28 men and 14 women had thoracoplasties, and 5 men and 5 women had resections. Additional bone-marrow was cultured from 6 men and 7 women who had had two stages and 1 woman who had had three stages. The total number of cultures from 52 surgical patients was 66. In addition, cultures from the bone-marrow of 3 cases of acute disseminated tuberculosis were set up; these 3 patients had not received chemotherapy at any time during their illness. 25 of the 28 men who had thoracoplasties had positive sputum during their stay in hospital before operation; 13 of these were also positive at operation. Of the 5 who had resections only 1 had negative sputum during his stay in hospital and previous to operation. 6 of the 14 women who had thoracoplasties had positive sputum while in hospital, but only 4 were positive at the time of operation. Of the 5 women who had resections 4 had had positive sputum, and 3 of these were also positive at operation. 19 men who had thoracoplasties had had previous chemotherapy with streptomycin and *p*-aminosalicylic acid before admission to this hospital, and 10 had similar chemotherapy at the time of operation, of whom 4 had had previous chemotherapy while in this hospital. Of the women 14 had had chemotherapy previous to admission, and 5 had it at the time of operation. Of the 5 men who had resections all received chemotherapy at the time of operation and 3 had had it before admission. Of the 5 women who had resections all were receiving chemotherapy at operation and 4 had had it before admission. Altogether 25 patients were receiving chemotherapy at the time of operation. The accompanying table gives these details.

DETAILS OF PATIENTS FROM WHOM BONE-MARROW WAS OBTAINED

Surgical operation	No. of patients	Sex	No. with positive sputum		No. receiving chemotherapy			No. of specimens of bone-marrow examined
			Before operation	At operation	Type			
					A	B	C	
Thoracoplasty	28	M	25	13	19	4	10	34
,,	14	F	6	4	14	0	5	22
Resection	5	M	4	4	3	0	5	5
,,	5	F	4	3	4	0	5	5
Total ..	52	..	39	24	40	4	25	66

Type A = Chemotherapy before admission only.
Type B = ,, after ,, ,,
Type C = ,, at time of operation.

In addition bone-marrow was aspirated from 3 men with acute disseminated tuberculosis who had positive sputum and had never received any chemotherapy. Cultures were negative.

PROCEDURE AND TECHNIQUE

At St. Wulstan's hospital it is usual for thoracoplasties to be done in two stages at fortnightly intervals, and in all seven ribs are removed. One surgeon prefers to do an eight-rib thoracoplasty in three stages.

All the ribs removed at thoracoplasty or resection were sent direct to the laboratory in a sterile container. They were split longitudinally with ordinary carpenter's pincers. Portions of each bone containing the most marrow were placed in a universal container which was then almost filled with sterile distilled water (30 ml.). It was well shaken and placed in the refrigerator at 4–5°C to ensure the separation of the marrow from the bone. The container was again shaken vigorously and the thick bone-marrow suspension poured off into a centrifuge tube, leaving the bone fragments in the universal container. The suspension was centrifuged at 3000 r.p.m. for about 5–8 minutes, the supernatant fluid being discarded, leaving a column of bone-marrow 2 cm. long in the bottom of the centrifuge tube (the actual amount yielded was not constant but was usually about 1·5 ml.). Smears were made from this deposit and stained by the normal Ziehl-Neelsen procedure, after which 3% sulphuric acid was poured on to the deposit in the ratio of 2 parts of acid to 1 of deposit. After thorough mixing with a sterile platinum sputum loop the mixture was allowed to stand at room-temperature for 5–10 minutes, and was next centrifuged at 3000 r.p.m. for 5 minutes. The supernatant fluid was discarded and the deposit was resuspended in a corresponding volume of sterile distilled water and neutralised with 2% sodium hydroxide, phenol red being used as indicator. The neutralised suspension was centrifuged once more, and the deposit was next cultured direct to the Löwenstein slopes, three or four good loopfuls (4–5 mm. loop) being used.

Bone-marrow was aspirated in the region of the spinous processes of the lumbar vertebræ. The material was examined and inoculated in the same way as that removed from the ribs taken at thoracoplasty.

Several controls were set up by inoculating with a known strain of *Myco. tuberculosis* bone-marrow taken at thoracoplasty. From the resulting preparation suitable films were made and stained by the Ziehl-Neelsen technique, and cultures were put up.

RESULTS

In no case was it possible to demonstrate the presence of *Myco. tuberculosis* either by examination of the bone-marrow smear or by culture, but in the controls films showed the presence of *Myco. tuberculosis* and the cultures all proved positive.

Since these patients, undergoing surgical treatment, had neither the acute fulminating tuberculosis that Choremis and Pantazis (1951, 1952) found in their patients nor the widely disseminated tuberculosis that Horowitz and Gorelick (1951) observed among their patients, hæmatogenous dissemination was most unlikely, and therefore one would not expect to culture tubercle bacilli from bone-marrow.

This work thus confirms the results obtained by Hausmann (1951).

It is suggested that ribs removed at thoracoplasty or at resection could be used in orthopædic units for grafting in tuberculous disease of bone without risk of implanting tubercle bacilli into the tissue of the recipient.

I am indebted to Dr. T. W. Lloyd, medical superintendent, St. Wulstan's Hospital, Malvern, where this work was done, for permission to publish these results, and to Dr. Colin White for his helpful advice.

THIS note is a postscript to a report (Gledhill et al. 1952) of the resolution of the ætiological agent of mouse hepatitis (Gledhill and Andrewes 1951) into two components—one (S) relatively stable, the other (L) more labile. Neither component inoculated alone into weaned mice caused evident illness, but when they were combined fatal hepatitis was produced. It now appears that the L component is identical with *Eperythrozoön coccoides*—a mouse parasite related to *Hæmobartonella* and variously regarded as a bacterium or a small protozoon. Our interest had already been aroused by finding L present in the blood in very high titre, when histological study led, as described below, to the finding of eperythrozoon in large numbers.

Histological studies of tissues from animals infected with the S and L components, together or separately, have yielded interesting results. With the techniques so far used in this study, no changes have yet been found with the L agent. With S small areas of hepatic necrosis occur, which differ only in degree from the massive lesions caused by the complex infection itself; both infections, and particularly the latter, were accompanied by varied cytological changes which will be described in detail later. The most unusual pathological feature of the experimental disease and of that due to the S component is the appearance of an endothelial and mesothelial reaction throughout practically all the organs and tissues; this begins within 24 hours of inoculation and has practically disappeared by the 5th day. The endothelial reaction is focal and is restricted to venous channels of all sizes; it is characterised by the formation of multinucleated giant-cells which arise directly from the endothelium, project into the vessels, and readily become detached. Examination of films of peripheral blood for these giant cells in animals infected 3 days previously with "mouse-hepatitis virus" revealed the presence of enormous numbers of *E. coccoides*, with characteristic ring forms. Many mice infected with S and L separately and combined have now been examined. In the L series *E. coccoides* appear in the blood within 2–3 days of inoculation In the S series no eperythrozoa have been found. In animals infected with "mouse-hepatitis virus" *E. coccoides* appear within 24 hours and increase in numbers until death, the terminal stage of the disease being accompanied by many small rod and coccal-forms which may preponderate over the typical ring elements. When S and L are combined to produce fatal hepatitis, the same morphological picture is found. So far it has not been possible to dissociate the activity of the L agent from *E. coccoides*, and it seems likely that they are identical. The L agent and the eperythrozoa react similarly to chemotherapeutic agents, including neoarsphenamine.

Many speculations arise immediately from this association; at present it is sufficient to emphasise the following observations:

1. *E. coccoides* occurs in the blood in experimental mouse hepatitis without previous splenectomy; and it can be passed without splenectomy in normal mice more readily than is usually believed.
2. Eperythrozoa in plasma can pass through a collodion membrane of average pore size 0·46 μ and 0·36 μ, and under ideal conditions probably also through membranes of 0·3 μ—a degree of filterability hitherto unsuspected.
3. Mice of the P strain, which are relatively resistant to hepatitis, are carriers of *E. coccoides*, while those of the V.S. strain, in which the disease can be readily transmitted, are not carriers of eperythrozoa and do not yield *E. coccoides* after splenectomy.

We have not yet elucidated the mechanism whereby the S virus and the eperythrozoon act synergistically to produce fatal hepatitis. It appears, however, that the S is present to about a hundredfold higher titre in the livers of mice in which there is concurrent infection with eperythrozoa. It may be that all strains of *E. coccoides* will behave as described here; but this remains to be proved.

Medical Societies

ROYAL SOCIETY OF MEDICINE

Basis of Allergic Reactions

THE pathology section of the Royal Society of Medicine met on Nov. 18 under the chairmanship of Prof. G. PAYLING WRIGHT, president of the section, to discuss cutaneous allergy.

Dr. W. N. GOLDSMITH said that eczema was an epidermal hypersensitivity reaction of the late or delayed type. The process was chiefly cellular, and in some instances—e.g., fixed drug eruptions—the reaction was strictly localised to circumscribed areas of the skin. Sensitising agents could be simple substances (even elements such as nickel or chromium) or more complex organic chemicals, such as paraphenylenediamine. Many of these substances showed a pronounced affinity for protein, and the actual allergen might be a complex of the substance with protein. Desensitisation had been attempted with mixtures of serum and the sensitising substance. Products of the skin itself—e.g., blister fluid—had been shown to act as sensitisers.

In animals intraperitoneal injection of picryl chloride had produced epidermal sensitisation. Where islands of skin had been created by means of deep incisions, the application of such substances to the islands failed to produce hypersensitivity, whereas application to the surrounding skin produced hypersensitivity both locally and in the islands. It had been suggested that this proved that the antibodies were elaborated centrally. However, a subject who had been sensitised by the application of 9-bromofluorene for 24 hours developed redness and blistering at the site of application 13 days later; and the process extended steadily towards the periphery. Dr. Goldsmith supposed that this was due to the slow diffusion of the allergen, successive areas becoming sensitised after the requisite time interval. This gradual progression was possible only if the antibody was produced locally in the skin.

In this type of reaction, passive transfer by serum usually failed, and where it succeeded the reaction was urticarial, not eczematous. Cross-transplants of skin had been made in uniovular twins, one of whom had been sensitised epidermally. The sensitised transplant lost its hypersensitivity in the normal host, whilst the normal transplant took on the hypersensitivity of the recipient. Similarly, a sensitised animal rendered parabiotic with a normal caused the latter to become hypersensitive. The agent was therefore diffusible, but it did not cross the placenta and its molecules were probably large. It did not reside in the plasma, since passive transfer failed; but possibly it was transported by lymphocytes. Hypersensitivity was not induced by injection of such lymphocytes into the skin itself, but followed intraperitoneal injection in animals. It was not clear how the antibody passed from the lymphocytes to the epidermis.

The injection of histamine did not cause eczema, nor was histamine released by the eczema reaction. Antihistamine substances did not have a preventive action.

Cortisone was more effective in epidermal than in dermal reactions; but local application was ineffective, although patch-test reactions might be inhibited.

Dr. W. S. Feldberg, F.R.S., described a substance—'48/80'—which on injection caused the release of histamine without tissue damage. It caused an increase of capillary permeability, which resulted in local œdema, and permitted the escape of colloidal dyes from the blood into the tissues. Animals so injected showed regional differences in response to the drug; the most œdematous areas corresponded with those which normally contained most histamine. Injection of histamine did not produce this pattern of œdema, which seemed to be due to the action of histamine at the site of release. Animals injected with increasing quantities of 48/80 became depleted of histamine so that the induction of anaphylaxis was no longer accompanied by œdema. Also, animals rendered light-sensitive with hæmatoporphyrin did not react to exposure to light after histamine depletion with 48/80. Nevertheless not all the effects of allergic reactions should be attributed to histamine alone, since it had been shown that antigen-antibody reactions released another pharmacologically potent substance—5-hydroxy-tryptamine (serotonin).

Prof. J. R. Marrack discussed the antibodies involved in allergic reactions, limiting his remarks to those found in reactions of the hay-fever type. These were incomplete antibodies, which did not precipitate or agglutinate when mixed with antigen. In-vitro work with them was difficult because of the impurities present in antigen.

Even recrystallised ovalbumin might have several antigenic components. This could be shown by adding a solution of the antigen to a tube containing a column of antiserum solidified with agar; if the antigen were impure, a number of zones of precipitation could be made out. It was therefore often uncertain that the antibodies detected or measured in vitro were those responsible for the biological reaction, and in-vitro tests should always be checked against the biological reactions.

Dr. J. F. Ackroyd described the experimental steps by which the mechanism of 'Sedormid' purpura had been elucidated. The drug caused in hypersensitive people thrombocytopenia with hæmorrhages throughout the body; this hypersensitivity persisted for 12 years or more.

If sedormid and the whole blood of a hypersensitive patient were mixed, there was no clot retraction (this was not so with normal blood); the platelets were seen to be agglutinated and lysed, and complement was used up in this stage. Normal platelets were unaffected by the abnormal serum unless sedormid were added, and platelets from the sensitised case suspended in normal serum were not lysed by sedormid. The serum component was found to be present in the gamma-globulin fraction of the proteins.

His hypothesis was that sedormid combined with the platelets to form an antigen which was, however, of low antigenicity, so that only a few people became sensitised by it. In this small minority, taking sedormid rendered the platelets antigenic and thus capable of union with the specific serum antibody: their resulting agglutination and lysis led to the thrombocytopenia. In such people patch-testing with sedormid produced local purpura without thrombocytopenia, so that the vascular element appeared to be independent of the platelet effect. A similar mechanism possibly affected the vascular endothelium.

Dr. R. R. H. Lovell discussed the effects of cortisone and A.C.T.H. on cutaneous allergy. Patients had been given 200 mg. of cortisone or 150 mg. of A.C.T.H. for a week before testing. Reactions to tuberculin (P.P.D.) were significantly diminished, as were reactions to local applications of atropine. There was some reduction of the reaction to a direct irritant—manganese butyrate. Triple-responses to histamine, morphine, and grass pollen were not diminished. It seemed clear that the hormones affected the chain of events comprising the delayed type of reaction.

Supervoltage Therapy

The radiology section of the Royal Society of Medicine met on Nov. 21, under the chairmanship of Dr. Constance Wood, president of the section, to hear two accounts of the therapeutic use of powerful X rays.

Mr. G. W. Blomfield (Sheffield) has for three years used a van de Graaff machine. This is an electrostatic moving-belt generator that builds up a high potential of frictional electricity which is applied in increasing stages along an accelerator tube. The electron beam is passed through this tube and thereby speeded up to produce 2-million-volt X rays from the target—ten times more powerful than conventional X rays. Mr. Blomfield said that three years was too short a time in which to collect statistically valuable clinical results with a stable technique, particularly since the follow-up of treated cancer had to cover many years. But survival statistics were not the only criterion in radiotherapy. The rate at which radiation could be given, its penetration of the tissues, and the shape of the isodose curves in them were all important. So was the patient's comfort and the avoidance of high-dose effects, such as skin burns and necrosis or radiation sickness. They had chosen the 2 MeV instrument as the largest which still had some manœuvrability and was likely to be economic. In fact the total annual running cost, including salaries as well as replacements (chiefly new belts), was about £3700, which worked out at about £8 10*s.* per patient or 14*s.* a treatment, which he thought was reasonable. The instrument produced only slight skin reactions, gave a sharply defined beam with little lateral spread, which meant greater precision in irradiating malignant tissue only, and delivered a bigger dose to the deeper tissues. At 10 cm. the depth dose was twice that from a conventional 200 kV apparatus. These characteristics made supervoltage therapy a useful adjunct to radium in the treatment of carcinoma of the cervix, since it could reach secondary growths in the parietal pelvic lymph-glands without harming the head and neck of the femur. A lead filter was used to reduce the dose in the centre of the beam, and two applications of about three minutes from different positions ensured that the glands received an effective dose, while the filter spared the uterus to some extent. During 1950 112 cases were treated with 55% survival so far, including 2 patients with a stage-4 carcinoma who had received supervoltage therapy alone. Other patients treated in 1950 included 26 with infiltrating and fixed bladder carcinoma (11 still alive without recurrence); 20 with intracranial tumour (7 still alive); and 13 with carcinoma of larynx (5 still alive), who received 6000r in five weeks. In general about 1000r a week was a large enough dose, but in each of 50 patients artificial menopause was successfully induced with single doses of 350–450r.

Prof. J. S. Mitchell, F.R.S., and his team at Cambridge are using a synchrotron which is over ten times more powerful than the van de Graaff instrument, and works on a different principle which requires no moving parts. The electron beam is made to circle faster and faster inside a hollow ring by means of a powerful oscillating magnetic field, and is given further speed from passing at one point through a small coil in which a radio-frequency alternating current flows. When it hits the target 30-million-volt X rays are emitted.

Professor Mitchell explained that the synchrotron had presented so many problems that most of the time since its installation in November, 1949, had been spent on working out techniques and simplifying the controls. Only 5 patients had been treated between May, 1951, and March, 1952. It was difficult to make the machine reliable, and its low output of 5–10r per minute at a focal skin distance of 1 metre meant that treatment times were long and therefore that extensive clinical trials would be hard to achieve. He had chosen 30 MeV as a useful power from calculations made in 1946 which showed that as the power was increased above the conventional level the skin would be more and more spared while a greater proportion of the total radiation would be delivered centrally where it was wanted. From this point of view the synchrotron was even better than the 2 MeV van de Graaff accelerator, and it gave an even sharper beam. Thus it was easy to give a high dose to a tumour while largely sparing surrounding tissues. This also simplified treatment technique, since a single field of application often sufficed. But since the skin was spared it was difficult to gauge how the tumour inside was reacting to irradiation, and this lack of clinical control was disturbing. The fact that the beam occupied a fixed position was very inconvenient. Noise was less than expected, and patients did not seem to mind it.

They had worked out the isodose curves in phantoms, measuring the dose in various ways and also using a new audible dose-rate meter which sounded off in proportion to the dose-rate. It was doubtful whether the r unit could still be used in this high-power radiotherapy, because of secondary effects of unknown magnitude in the tissues—for instance, the production of positrons, neutrons, and induced radioactivity. Measurements suggested that some of these effects were negligible in soft, and probably in all, tissues. Absorption of radiation per unit mass by horse-bone was the same as by water to within 1%, but there was back scatter from bone which increased the soft-tissue dose locally by about 10%. Another factor which might prove important was that the instrument emitted its X rays in brief rapid pulses and not continuously.

For making collimators and applicators they used lead shot packed in plastic holders. The instrument was isolated in a room with walls up to 6 ft. thick, and the patient was observed through a water window by means of mirrors and could signal to the operator with a bell. The cases so far treated included a parotid carcinoma which had recurred after two separate courses with 220 kV X rays, a malignant glomus jugularis tumour at the skull base which had recurred after operation, and an inoperable glioblastoma where the patient was still alive fifteen months after irradiation. In this case radiation left no mark on the skin; and Professor Mitchell wondered what had gone on within the skull, particularly as in a case of pharyngeal carcinoma treatment left no sign externally on the face and neck but produced a visibly fierce reaction inside the mouth in the tumour area. There was no doubt that the 30 MeV synchrotron had a place in therapy for such cases as these, and also perhaps for carcinoma of the bronchus and the bladder; it would not be suitable for the treatment of breast cancer.

CENTRAL SOCIETY FOR CLINICAL RESEARCH AND AMERICAN FEDERATION FOR CLINICAL RESEARCH

THE Central Society for Clinical Research and the midwestern section of the American Federation for Clinical Research met in Chicago on November 6–8. Some 58 papers were given.

Thyrotropin in Diagnosis of Obscure Hypothyroidism

R. D. LEVY and W. JEFFRIES (Cleveland, Ohio) had measured I^{131} uptake over the thyroid gland with and without injection of pituitary thyrotropin in normal people, and in patients with hypothyroidism, with pituitary myxœdema, and with exophthalmos developing after removal of the thyroid gland. They found that a single injection of thyrotropic hormone (T.S.H.) produced a significant increase in the rate of uptake of I^{131} in people with normal thyroid function whether or not they had been taking thyroid. Euthyroid people, even after having taken as much as 0·26 g. of thyroid for over eighteen months, uniformly had a significant response to T.S.H., whereas in those with primary hypothyroidism there was little if any increase in uptake. Normal response to T.S.H. was also seen in pituitary myxœdema and in postoperative exophthalmos.

Nature of Circulating Thyroid Hormone

W. P. DEISS, E. C. ALBRIGHT, and F. C. LARSON (Madison, Wisconsin) had given I^{131} to euthyroid and hyperthyroid persons, and thereafter separated the plasma-protein fractions by paper electrophoresis. The pattern of radioactivity in the fractions was measured after cutting the paper into strips. In three days virtually all the radioactivity appeared in an area just ahead of the α_2-globulin peak; the radioactivity at this site gradually increased. The same sequence of localisation appeared in the hyperthyroid subjects. In them, however, the radioactivity appeared sooner, increased more rapidly to much higher levels, and then declined sharply. Radioactive thyroxine added to serum in a test-tube was bound to a protein in the α-globulin section.

Raben-Westermeyer Growth Hormone

JEROME W. CONN and his colleagues (Ann Arbor, Michigan) said that Raben and associates had reported the isolation of a hog-pituitary fraction which was growth-promoting in animals, was not diabetogenic in adult dogs, and caused nitrogen retention without effecting carbohydrate metabolism. Conn studied the metabolic effects of this preparation in a 17-year-old boy with panhypopituitarism due to a calcified craniopharyngioma who also had diabetes mellitus—a rare association. He described a metabolic state resembling that in the Houssay rat. A detailed metabolic balance study over a twenty-four-day period showed: (*a*) significant anabolism of body protein with the Raben pituitary-growth preparation; (*b*) no intensification of the diabetic state; (*c*) no intensification of the anabolic effect of growth hormone by administration of insulin; (*d*) a definite protein-anabolic effect of insulin alone in the diabetic pituitary dwarf, who without insulin maintained nitrogen equilibrium. Conn believed that the Raben preparation, when given intramuscularly at a pH below 4, could be expected to induce growth in human pituitary dwarfism without inducing diabetes mellitus.

A.C.T.H., Cortisone, and Aspirin in Rheumatic Fever

H. B. HOUSER and other colleagues of C. H. RAMMELKAMP (Cleveland, Ohio) gave a preliminary report of their long-term study of the comparative effects of A.C.T.H., cortisone, and aspirin on the course of acute rheumatic fever. 152 young airmen with acute rheumatic fever were observed for nine weeks. Treatment with the three agents was started during the first week of illness and was continued for six weeks. The daily dose of A.C.T.H. was 120 mg. initially and was reduced at specified intervals so that at the beginning of the sixth week the dose was 20 mg. daily. Intramuscular cortisone was reduced gradually from 300 mg. on the first day to 50 mg. per day during the sixth week. Aspirin was reduced during the first week from gr. 1 per lb. body-weight per day to a maintenance dose of gr. $^1/_2$ per lb. per day. Aspirin was most effective in relieving symptoms and signs of joint involvement. Fever subsided most promptly after aspirin therapy, although there was no great difference among the groups in the prevalence of fever after the fifth day of treatment. A.C.T.H. was most effective in returning the erythrocyte-sedimentation rate to normal. Abnormal auriculoventricular conduction occurred with similar frequency among the three groups, but the duration of abnormalities was longer in the aspirin group. There was no distinct difference between the three groups in the appearance or disappearance of murmurs or of other signs of acute carditis. After treatment clinical or laboratory relapses occurred in the majority of patients in all groups; with few exceptions these relapses subsided promptly. None of the drugs used had any great advantage over the others in the early treatment of rheumatic fever.

Conversion of Mesobilirubinogen to Stercobilinogen

PAUL LOWRY, R. ZIEGLER, and CECIL WATSON (Minneapolis, Minnesota) said that Baumgartel, in Germany, had claimed that cellular dehydrogenases converted bilirubin to mesobilirubinogen in the liver, and that fæcal bacteria converted bilirubin directly to stercobilinogen. Since the keystone of Baumgartel's hypothesis was the supposed inability of fæcal bacteria to convert mesobilirubinogen to stercobilinogen, Watson and his colleagues studied the effect of such organisms on N^{15}-labelled crystalline bilirubin. They showed convincingly that fæcal bacteria reduced both bilirubin and mesobilirubinogen to stercobilinogen. Since Watson had repeatedly crystallised mesobilirubinogen from human fæces, there was little reason to postulate an extra-intestinal site for its formation, or to doubt its intermediary relationship between bilirubin and stercobilinogen.

Refractory Macrocytic Anæmia

D. L. HORRIGAN and ROBERT W. HEINLE described a new disease entity—a refractory macrocytic anæmia with a defect in vitamin-B_{12} binding which responded to normal plasma. A patient who had had unexplained anæmia for eighteen years did not respond to crude liver-extract, nor to iron. Free HCl was present in fasting gastric contents. Hæmatological findings during relapse included macrocytic anæmia, reticulocytosis, and normoblastic bone-marrow hyperplasia. Slight but significant remissions were obtained with *single* injections of normal human plasma or with *single* injections of vitamin B_{12}. Such remissions were not maintained either with vitamin B_{12} intramuscularly every one to two weeks, or with oral folic acid 10 mg. daily. Normal blood levels were maintained, however, when the patient was given vitamin B_{12} combined with fresh human plasma, at short intervals. Healthy persons and the patient were studied after intramuscular administration of 0·5 µg. of Co^{60}-labelled vitamin B_{12}. In the normals 0–10% of the injected vitamin was excreted in the urine, and altogether 60% was excreted in twenty-four hours. These observations suggested that: (*a*) the anæmia in this patient resulted from deficiency of vitamin B_{12} caused by failure of proper binding of the vitamin; and (*b*) normal plasma contained a factor which corrected this defect.

Hæmophilia-like Disease after Pregnancy

PAUL G. FRICK (Minneapolis, Minnesota) described an instance of a hæmophilia-like disease following pregnancy with transplacental transfer of an acquired circulating anticoagulant. The disease appeared in a woman three months after her first normal pregnancy and was studied from the time of its onset until recovery two and a half years later —sixteen months after sterilisation by X rays. The venous clotting-time was markedly prolonged, and the prothrombin consumption was minimal. Bleeding-time, prothrombin-time, prothrombin concentration, platelet-count, clot retraction, tourniquet test, and plasma-fibrinogen concentration were all within the normal range. There was no evidence of parenchymal liver dysfunction. The lack of response of the clotting abnormality to fresh blood or plasma led to the suspicion of a circulating anticoagulant, which was demonstrated by the delaying effect of the patient's blood on the coagulation-time of normal blood. Cohn's fraction I containing active antihæmophilic globulin had no effect on the patient's clotting mechanism. The anticoagulant was therefore believed to inhibit the action of the antihæmophilic globulin (thromboplastinogen). The patient delivered a second child fifteen months after the onset of the disease, and the anticoagulant was demonstrated in the baby's blood during the first two and a half months of its life. The findings strongly suggested an immunological mechanism in the development of the anticoagulant.

Endothelial Permeability to Albumin

J. A. SCHOENBERGER, H. V. KROLL, and ROBERT M. KARK (Chicago, Illinois) reported on their studies in man on endothelial permeability to radioactive-iodine-tagged albumin injected intravenously or intraperitoneally. They used I^{131}-tagged human albumin to study endothelial permeability in health and in various diseases associated with ascites and œdema. The material was injected in tracer doses first intravenously and a few weeks later intraperitoneally. In healthy volunteers the intraperitoneal injections were made through the posterior vaginal fornix or through the anterior abdominal wall after a small pneumoperitoneum had been established. The studies disclosed a dynamic equilibrium between albumin in intramuscular and extravascular sites. Mathematical analysis of the curves yielded quantitative estimates of the rate of exchange of albumin across the peritoneal membrane and also out of the vascular endothelium. Quantitative differences in permeability between healthy individuals and patients with ascites were found. In patients with ascites repeated studies were made during reablement. These disclosed changing permeability which was correlated with electrophoretic studies of the passage of various-sized protein molecules from the plasma to the ascitic fluid. Large protein molecules (such as globulins) distributed themselves equally between plasma and ascitic fluid when permeability was poor, but did not pass the endothelial barrier freely when permeability was improved.

Concentration of Antibiotics in Brain

W. E. WELLMAN and his colleagues (Rochester, Minnesota) had sought to find out whether neopenil (the diethylaminoethyl ester hydriodide salt of penicillin G), a new form of penicillin for parenteral use, was concentrated in the brain. The patients they studied were in hospital because of psychiatric disorders, and prefrontal lobotomy was done for therapeutic reasons. Before operation, these patients received for prophylaxis one of the following drugs: neopenil, procaine penicillin G in aqueous suspension, aureomycin, terramycin, dihydrostreptomycin, or erythromycin. They found that only neopenil and aureomycin were consistently detectable in significant amounts in brain tissue.

L.E. Phenomenon in Penicillin Hypersensitivity and Serum-sickness

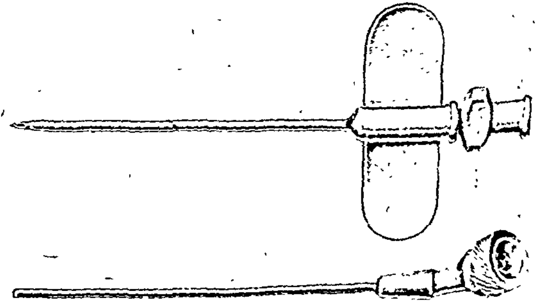
JOHN R. WALSH and HYMAN J. ZIMMERMAN (Omaha, Nebraska) had studied 8 patients with penicillin reactions and 1 with serum-sickness following the administration of tetanus antitoxin. Of the 8 patients with penicillin reactions, 4 had mild disturbances characterised only by urticaria; the other 4 had fever, adenopathy, joint pain, and skin lesions which ranged from erythema multiforme to a generalised exfoliative dermatitis. In each of these 4 patients with severe penicillin reactions the plasma L.E. factor was demonstrated, and, furthermore, L.E. cells were found in the concentrated heparinised bone-marrow. Study of the 4 patients with mild penicillin reactions failed to reveal the L.E. plasma factor or L.E. cells in heparinised marrow. Likewise, study of the heparinised bone-marrow of the patient with serum-sickness revealed L.E. cells; but an attempt several days later to demonstrate the L.E. plasma factor was unsuccessful.

New Inventions

AN ADAPTER FOR AN INTRAVENOUS NEEDLE

MANY anæsthetists consider that a cannula of the Guest type is the easiest to introduce into a vein, and that it causes less damage to the vein wall than an intravenous needle.

The use of the adapter shown in the accompanying figure will allow this cannula to be used for intermittent injections and yet remain patent should an intravenous infusion be required. The adapter consists of an inner cannula with a rubber diaphragm at one end, similar to a Gordh needle.



Venepuncture is performed with the cannula and introducing needle connected to a syringe. The syringe and needle are then steadied and the cannula pushed on up the vein. The needle is then removed and the adapter inserted. Should the adapter become blocked (though there is very little tendency for this to happen) it may easily be replaced. Two sizes of adapter have been used, one to fit a standard case Guest cannula and one to fit a 19-gauge cannula of similar design, which is used for the back of the hand in adults and for children.

My thanks are due to Dr. J. Challis and the anæsthetists of the London Hospital for their encouragement in the design of this needle, and to Messrs. A. L. Hawkins who have made the cannula sets.

Reviews of Books

Fitness for the Average Man

Sir ADOLPHE ABRAHAMS, O.B.E., M.D., F.R.C.P., honorary medical adviser to the British Olympic Athletic Teams. London: Christopher Johnson. 1952. Pp. 170. 10s. 6d.

THIS is in the main what its title suggests—a book about health for ordinary men—but it is also in part a book about athletes and athletics as seen at close quarters by a physician. "Moderation in all things, including moderation," says Sir Adolphe, and follows at least the first part of this dictum. Sober, sobering, and not unduly familiar facts, and sane reflections upon them, fill the very readable pages; and the average man who wants sound, well-based advice on food, exercise, alcohol, cold baths, tobacco, and health will find it here. Medical readers may be more interested in the later chapters on women and athletics, infant prodigies, champions among athletes, and the psychology of record-breaking. They will seldom find grounds for disagreement; but there is a passage seeming to imply that, in training, the very cells of "heart, lungs, muscles, nerves, and the rest" are replaced by new ones better suited to athletic needs —surely a questionable piece of physiology? Such qualities and faculties as "will-power, judgment, courage and self reliance" are placed where the layman, but not Sherrington, puts them—in the central nervous system.

Phosphorus Metabolism

A Symposium on the Role of Phosphorus in the Metabolism of Plants and Animals. Vol. I. Editors: WILLIAM D. MCELROY and BENTLEY GLASS, the McCollum-Pratt Institute of Johns Hopkins University. Baltimore: Johns Hopkins Press. London: Oxford University Press. 1952. Pp. 762. 80s.

LIFE depends on the mechanisms by which energy is released, transferred from one system to another within the cell, and utilised for special purposes. Realisation, during the past few decades, that many of these mechanisms depend on the reactions of relatively few types of phosphorus compounds has made the study of phosphorus metabolism of immense importance, and caused it to advance with bewildering rapidity. This book contains the communications made when American experts on phosphorus metabolism met for a symposium at Johns Hopkins University in June, 1951.

An introduction by Otto Meyerhof is followed by four dozen separate contributions, in ten main groups dealing with such topics as the metabolism of polysaccharides and disaccharides, of hexosephosphates, of pentose and triose phosphates, and of phosphorus-containing coenzymes; active acetate; oxidative phosphorylation during electron transport; the chemistry and thermodynamics of phosphate bonds; and the utilisation of phosphate-bond energy in biological systems. (Phospholipids, phosphoproteins, and nucleic acids were left for a later symposium.) Each main topic is presented by a well-known authority, and shorter papers follow on special parts of the field: general discussions, reported in detail, close each section. There is a subject index and an index of the participants. A most valuable feature is an 80-page summary by one of the editors of the ground covered by the symposium.

L'insuffisance cardiaque chronique

Études physiopathologiques. ANDRÉ COURNAND, cardio-pulmonary laboratory, Columbia University, New York; JEAN LEQUIME, Université de Bruxelles; PAUL REGNIERS, Université de Gand, Clinique Médicale. Paris: Masson. 1952. Pp. 262. Fr. 1400.

IDEAS on the mechanism of cardiac failure have been much modified by new methods of clinical investigation —methods which can bring to diagnosis the precision of the laboratory.

The first part of this work is devoted to the detailed description of procedures which for the most part are still little known to the clinician. Successive chapters are devoted to catheterisation of the heart and great vessels, the recording of intracardiac pressures, the determination of cardiac output, blood volume, and circulation-rates, and finally modern tests of lung function. The second part deals with the problem of chronic cardiac insufficiency. After reviewing usefully the physiological factors affecting the regulation of the circulation in health, the authors analyse their results and describe fully their studies over a wide range of acquired diseases of the heart and lungs, comparing their findings with those of all the principal workers in this field who have published their work. Isolated failure of the left or right ventricle and combined failure of both ventricles are separately considered. The inadequacy of cardiac output studies alone and the importance of the blood volume and of intracardiac and venous filling pressures are clearly explained, and modern concepts of various syndromes are discussed—e.g., that of cor pulmonale and the importance of anoxæmia in the development of pulmonary hypertension in emphysema. Finally the authors formulate a coherent theory of cardiac insufficiency.

This is an important book, authoritative and up to date. It should be warmly welcomed by all who are actively engaged in the investigation of the hæmodynamics of the heart and circulation in health and disease, by all cardiologists, and by all who wish to keep abreast of modern work and are interested in the underlying basis of their clinical observations and treatment. The French is easy to understand; and the bibliography is full, and derived from Continental, British, and American sources.

New Knowledge of Hygiene in Diet

J. SIM WALLACE, M.D., D.SC., F.D.S., R.C.S., F.A.C.D., vice-president, Food Education Society. New York: Dental Items of Interest Publishing Company. London: Henry Kimpton. 1952. Pp. 264. 36s.

THIS book by the late Dr. Sim Wallace sets out at length his theory of the relationship between diet and dental caries. In the closing decades of the last century he came to the conclusion that dental decay was a disease of civilisation, resulting from over-refinement of food and consequent dysfunction of the masticatory apparatus.

Since we do not need to chew our food in order to digest it, the natural tooth-cleansing from vigorous mastication does not occur and the teeth become clogged with food, much of it in the form of sticky, easily fermentable carbohydrates, from which acids are produced to attack and disintegrate the hard tooth substance. From this view he argued that the only way to prevent the ravages of dental caries was to institute a counter-revolution in the community's dietary habits. He believed that it was essential to popularise a régime of coarser foodstuffs, resembling the primitive diet for which our jaws and teeth were evolved.

It seems unlikely that such a far-reaching reform of entrenched habits could ever be effected on a large enough scale to influence the dental health of the community as a whole; and it is by no means certain that the change would not reintroduce digestive ills to which our forefathers were subject. Our best hope of solving this serious problem would seem to lie in the pathologist and biochemist discovering the nature of the process or processes covered by the term dental decay. We shall have to know more about the disease and its causation than we do at present before we can usefully attempt to find a cure. This is not to say that Dr. Wallace's contribution to the theory of the disease was not of great value, nor that we cannot with advantage follow his advice on dietetics.

Biologie d'anopheles gambiæ. Recherches en Afrique-Occidentale française.

World Health Organization Monograph Series No. 9. M. H. HOLSTEIN, Dr. ès Sc. Geneva: World Health Organisation. 1952. Pp. 176. 10s.

Anopheles gambiæ carries malaria with the greatest ease. The acknowledged model and pattern of her profession in Africa, she is not over-fastidious in her choice of breeding-places, and therefore multiplies prolifically in sun or shade; she seeks man rather than animals for the blood-meals she needs, and she picks up and matures man's malaria parasites to a degree hardly paralleled by other species in other continents. She needs a hot climate, it is true, but, as in Brazil twenty years ago, if she invades suitable new territory she can convert a modest malaria incidence into a raging epidemic. She responds to D.D.T. with a degree of irritation and repulsion which makes control by the methods of D.D.T. residual spray, so successfully used from South America to India and beyond, somewhat problematical. She is probably the most formidable factor in malaria at present known, and needs much study if we are to find and exploit her biological weaknesses.

This monograph surveys the vast literature (388 references) which clusters round this pest, and covers morphology, biology of all stages of development, the rôle of the mosquito in transmission of malaria, and the question of various races. *Anopheles melas*, of course, has long been differentiated, but Dr. Holstein now describes and distinguishes two other forms, one multidentate and man-loving, the other paucidentate and animal-loving. This distinction may be important.

He also describes his investigations, carried out in French West Africa, into the ability of the female to survive the long dry season by æstivation, the differentiation of races, and other biological problems. No serious student of African malaria can afford to be without this book; and, though the French text is clear and lucid, English readers will be interested in the announcement on an accompanying leaflet that an English edition is being prepared.

Metabolism and Function in Nervous Tissue

Biochemical Society Symposium No. 8. Editor: R. T. Williams. 1952. Cambridge: University Press. 1952. *Pp. 102. 12s. 6d.*

In this symposium, held at the end of last year, eight biochemists read papers which show how actively research is being pursued into the metabolism of the brain. As Sir Rudolph Peters, F.R.S., said in his opening remarks, it is only recently that sustained work has been carried out in this field, more than half a century after the fundamental studies of Thudichum; but the present lively interest promises a great deal. The contributors were Dr. R. V. Coxon, of Oxford, on carbohydrate metabolism; Dr. H. Weil-Malherbe, of Runwell Hospital, on glutamic acid; Mr. H. M. McIlwain, D.Sc., of the Institute of Psychiatry, Maudsley Hospital, on phosphates and nucleotides; Mr. G. H. Sloane Stanley, Ph.D., of the same institute, on lipids; Dr. Derek Richter, of Whitchurch Hospital, Cardiff, on the relation of metabolism to cerebral function; Mr. R. M. C. Dawson, Ph.D., also of Cardiff, on the use of radioactive isotopes in studying metabolism of nervous tissue; and Prof. H. A. Krebs, F.R.S., and Mr. R. E. Davies, Ph.D., of Sheffield, on biochemical aspects of the transport of ions by nervous tissue. The papers are severely technical and are not concerned with clinical matters, but they raise many questions in the clinician's mind, and they have clearly great potential importance for the pathology of some, and the treatment of almost all, forms of mental disorder.

Phantasy in Childhood

Audrey Davidson and Judith Fay. London: Routledge & Kegan Paul. 1952. Pp. 188. 18*s*.

Dr. Davidson and Miss Fay wish to pass on in simple language some of Mrs. Melanie Klein's psycho-analytical hypotheses, using as illustrations the remarks and behaviour of little children whom they have looked after. The children seem to have been mostly separated from their parents, or the luckless offspring of marriages that had failed; and it is not always clear whether we are meant to regard the reported fantasies as dependent on emotional privation (e.g., in a child who longs for his divorced mother) or as the inevitable and normal accompaniments of a stage of development. The prominence given to the mouth, the breasts, the excreta, and the genitals is, of course, to be expected in a psycho-analytical work; but a sceptical reader might wonder whether the suggestions made to the child were as correct an interpretation of what he or his unconscious meant as the authors assume. The book will be found most informative by those who would like to know how psycho-analytically trained psychiatrists and teachers approach the task of caring for young children and understanding them: it will be touch and go whether the reader then considers the book tedious and the mode of thought uncritical, or, on the other hand, discerns a genuine insight and a profound body of truth in it.

Food and Population and Development of Food Industries in India

Director: V. Subrahmanyam. Mysore: Central Food Technological Research Institute. 1952. Pp. 357. 10s.

Dr. V. Subrahmanyam, the director of India's new food technological research institute at Mysore, organised there two symposia in May, 1951. The subject of the first was Food and Population and of the second Development of Food Industries. This book records 45 contributions made by chemists, agriculturalists, industrialists, doctors, Civil Servants, and politicians; and the very variety of the contributors emphasises that Indians are now fully aware of their food problems and are working out all manner of solutions.

The production of a nutritious substitute for rice from tapioca-starch and defatted groundnut cake is an ingenious technical advance which may have far-reaching effects on both agriculture and health. Enormous strides are being made in the vegetable-oil industry, and new methods of preserving and storing foodstuffs are being developed. An energetic "grow more food" campaign is educating the people in methods of self-help. Improved seeds are giving higher yielding crops. Plans are being made to meet the food emergencies which must inevitably arise in an uncertain future. Many see the need for family planning, and urgent pleas were put forward for the establishment of birth-control clinics on a large scale.

This is a stimulating and exciting book. The new India is making enormous strides in applied science, and setting about her urgent problems in human biology with energy and ingenuity. A great fight against poverty and disease is in progress, and this book records a promising start. It is a disappointment that none of the speakers found time to pay tribute to Sir Robert McCarrison: thirty years ago he was fighting this their battle almost alone.

Renal Function (*Transactions of the Third Conference October 18–19, 1951*. New York: Josiah Macy Foundation, 1952. Pp. 210. $3.50.).—This record, edited by Stanley Bradley, of the third Josiah Macy Foundation conference on renal function, follows the pattern of the two preceding publications in presenting informally the views of the experts in this field and the trends of their research. The accent of the conference was on the physical factors relating to kidney function. Five of the seven topics discussed have a physical bias, and to understand much of what is presented requires a special knowledge of physics and mathematics. Some of the sections, and particularly those concerned with the processes of filtration and diffusion, will interest workers concerned with capillary circulation through other organs.

The Principles of Line Illustration (London: Burke. 1952. Pp. 212. 25*s*.).—Articles for publication often arrive with really beautiful drawings which are totally unsuitable for reproducing because the artist has studied neither the block-maker's requirements nor the effect of reduction on his work. Mr. L. N. Staniland, A.R.C.S., shows how this waste of effort may be avoided, for he sets out lucidly almost everything that need be known about drawing for print. He describes the different kinds of line drawings, how to produce them both on ordinary paper and on scraper board, how to illustrate flowers, animals, and other biological specimens, and how to make graphs, diagrams, maps, and lettering. The book is well written, well printed, and, of course, well illustrated.

Must Man Wage War? (London: Watts. Thrift Books. 1952. Pp. 93. 1*s*. 6*d*.).—This is a clear-headed, humane, and factual study, by Prof. F. A. E. Crew, F.R.S., of the problem of war, its effects, its preparation, and its significance for the human race. In its lucid exposition of the strategems by which men are led to accept war as a pattern of behaviour, and its unhysterical but forthright speaking on such subjects as propaganda and atomic and germ warfare, it is a courageous and a disturbing stimulus to thought and action. We know most of the facts to which Professor Crew points; and the survival of humanity may depend on our ability to respond rationally to them. One can only wish this book the widest possible circulation in the shortest possible time.

THE LANCET

LONDON: SATURDAY, NOV. 29, 1952

Hospital Costs

The number of noughts in the national budget makes it increasingly meaningless to the citizen and removes it from the reality of daily life. The cost of the National Health Service is perhaps more easily appreciated if it is described as 10% of the money at the Government's disposal for all national purposes. Of this 10% half goes to the hospitals, and the individual hospital consultant is largely responsible for a medical service costing, on the average, some £30,000 to £40,000 a year. The N.H.S. does not include representatives of the community elected to safeguard the taxpayer's pocket, and the public has to trust all those who work the service to watch its interests. Actually, members of our profession have good reason to favour economy, both because they are taxpayers themselves and because they know how much needs to be done with the limited allowance of money. Both the sharp increase in hospital costs and the state of the national purse make it important for every consultant to accept responsibility for the financial as well as the professional efficiency of his unit. It has become only too clear that, for a nation situated as ours, further progress in medical and other social services can be achieved only by getting better value for the money spent.

The business efficiency of hospitals is relatively low, and whenever a spotlight is focused on, for example, catering or laundry it is found that reorganisation may save thousands of pounds a year and still provide better service. The purely medical routines, too, often benefit by critical scrutiny, for the combination of a busy consultant and junior assistants is not always conducive to changes. From a financial standpoint, there is a twofold need: (1) to assist management by providing hospital staff with a stimulus to combine efficiency with reasonable economy (i.e., good housekeeping); and (2) to provide regional boards and the Ministry of Health with figures that will enable a comparison to be made between hospitals doing similar work. Hitherto it has been difficult to assess and contrast the financial needs of hospitals; and, indeed, the necessity did not become generally apparent until they were united on a national scale. A partial solution of the problem was attempted by the Ministry in its Costing Returns, consisting of hundreds of pages of closely printed figures, purporting to compare the hospitals of the country under many headings of expenditure; and, though these tabulations contain as many fallacies as there are holes in a sieve,[1] they have served a purpose in that they drew public attention to the need for a better system of costing in hospitals and for comparing units. Long before their publication, the Ministry had invited both the Nuffield Provincial Hospitals Trust and King Edward's Hospital Fund to advise on how to do better. The reports of these bodies,[2,3] published this week, form a very valuable contribution, and it is interesting that, approaching the subject independently, they both make the same major recommendations. They suggest that the accounting system for hospitals should be based on the departments and services of the hospital, and, to permit of comparisons, that the expenditure of departments should be broken down, where appropriate, to costs per unit of work. Thus, instead of having returns based on expenditure on salaries, maintenance, provisions, and so on, we should have figures related to the actual cost of specific hospital departments; for example, expenditure on the general surgical wards would be related to inpatient days, expenditure on the electrocardiographic department to the number of electrocardiograms, and expenditure on the boiler-house to the number of thousand pounds of steam raised. Furthermore, they propose that, in all hospitals with more than 50 beds, budgets should follow the same pattern, and that normal accountancy principles should be introduced into the preparation of the annual balance-sheet. These recommendations by the two great hospital foundations are backed by their practical experience in a variety of hospitals over an appreciable period. It will be remembered that the recently published report of the committee of Regional Hospital Board Treasurers[4] was willing to retain the present Ministry costing returns while also introducing departmental budgeting; but this decision has been severely criticised by the *Accountant.*[5]

There are many advantages in the proposals of the Fund and the Trust. Returns produced on such a basis would restore a measure of confidence in comparative costs, which has been lost under the former system. They would also introduce into hospital administration a basic lesson from industry—i.e., the need to link executive and financial responsibility. The efficiency of a large industrial unit depends on each head of a department being responsible for the economical working of his section,[6] and on the ability of the board of directors to observe his efforts from the departmental returns. The present administrative hierarchy of hospitals under the N.H.S. has seriously undermined the status of departmental heads, such as the chief pharmacist, the chief engineer, and the catering officer, who may be almost unknown as individuals to boards of governors or hospital management committees. This arrangement is not conducive to getting their best contribution to proper housekeeping, and the introduction of departmental costing would do much to give them the recognition that is their due. The recent

emphasis has been on joint staff consultative committees, which may be valuable for improving morale but as means of ensuring economy are far less effective than is personal responsibility. The concept of departmental costing also has particularly important repercussions on the hospital's annual budget—a point made very clearly in the King's Fund report:

> "The budget of a hospital or group is at present regarded as a sum of money to cover the estimated expenditure to be incurred during the next financial year; as a document laying down limits which must not be exceeded. This, in our opinion, is not a budget; it is an appropriation of funds. We regard a budget as a constructive plan of action, which has, in its several parts, been agreed by the heads of all departments concerned and approved by the management. It is an expression, in accounting terms, of the plan and future policy of the hospital and a pre-requisite to sound management. This view of a budget places emphasis on the financing of the cost of care rendered to patients rather than on that of financing the hospital as an institution. Within a hospital or group it must be flexible to meet changing conditions in the volume and incidence of service rendered, and to allow of just comparisons."

There are certain technical differences between the two reports, the chief of which concerns the method of distributing the cost of general services. The Nuffield Provincial Hospitals Trust prefers to express the departmental figures in terms of "prime cost"—i.e., expenditure on salary and wages of staff working in a department and on the materials actually used in the department. Thus a medical department would include only medical salaries and salaries of nurses and ward orderlies and the cost of all materials used in the wards, such as dressings, linen, and crockery. This system means that each responsible member of the staff is made aware of the expenditure incurred by him for his department and of variations in the expenditure that can be controlled by him: costs over which he has no control are excluded. This simple system does indeed seem preferable to the technique advocated by the King's Fund, whereby a proportion of general service charges (e.g., heating, laundry, and catering), is allocated to each department according to its claims on these services. Allocations that might be based on semi-arbitrary decisions would tend to undermine a sense of individual responsibility and also reduce confidence in comparative figures. The King's Fund report suggests a greater number of departmental units to be costed—an arrangement not favoured by the Trust. Certainly it seems undesirable to cost each ward separately, because a position might arise in which ward sisters sought to avoid patients who made expensive demands on their stock. There are in fact too many variables to allow a useful comparison between individual wards.

The proposed costing system would be a further step away from the method of Treasury control formerly exercised, which could hardly have been better designed to inhibit economy. The essence of the Treasury system was control of payments (not expenditure) by reference to detailed yearly estimates which were broken down into many inelastic groups. As the Fund clearly points out, this system left the way open for waste and inefficiency; for, in a last-minute scramble to spend balances in hand, money was frittered away on short-term palliative maintenance work, pieces of equipment, furniture, and so on—orders small enough to be completed within the financial year. It was also especially stultifying to long-term planning and to the careful husbanding of resources towards this end, since there was an absolute prohibition against carrying forward unspent balances. Working and budgeting in terms of departmental medical services to the community is a sensible and logical approach, and would go far to release hospital services from the sterilising Treasury system.

One essential test to apply to any proposed change in the N.H.S. is whether or not it will facilitate the growth of the dangerous virus of national uniformity. There is, in fact, a risk that the proposed system of costing might facilitate this growth; but the advantages of the system seem to outweigh its dangers, though these must be kept constantly in mind. We may add that it would have been a virtual impossibility for any Government department to have undertaken the surveys worked out by the Nuffield Provincial Hospitals Trust and the King's Fund, and their efforts afford yet another example of the value of the independent observer. The reports of the two foundations will provide medical historians with further evidence of the valuable contribution they are making to the British hospitals services. A tribute should also be paid to the Ministry of Health for its perspicacity in seeking independent assistance in a difficult and contentious field.

Transplantation

THOUGH the human body is often beset with autonomous new growths of great vigour, it is seldom able to transgress the rules and to support life from the tissues of another individual. Only quite limited grafts of highly specialised tissues have so far been a success—for example, blood-transfusion, corneal grafting, and the transplantation of homologous cartilage, bone, and blood-vessels, which are now an accepted part of surgical practice. The career of most of these implants as distinct pieces of tissue is short; indeed it is questionable whether they need be alive at the moment of grafting. Most of our knowledge of transplantation is based upon experiments in animals; but these, it seems, differ as much from man in their response to homografting as in the diseases from which they suffer. The only explanation of these phenomena that is based upon observed facts, rather than on abstractions, is that of MEDAWAR.[1] He has shown that skin homografting evokes an immune response in the host. If this response has already been produced by a preliminary exposure to skin or white blood-cells from the same donor, the survival-time of a second graft is much shorter. There is also evidence that if the reticulo-endothelial system of the recipient is inactive at the time of grafting, the survival period is significantly prolonged.[2] Total body radiation or the administration of nitrogen mustard will depress the activity of the reticulo-endothelial system, but as a result the body also loses its resistance to bacterial infection during the phase of marrow aplasia. Under these circumstances antibiotics alone are seldom sufficient to control a massive infection; but when they were used in the treatment of people irradiated by the explosion of the atomic bomb at Hiroshima[3] they did, in borderline cases, allow time for the reticuloendothelial system to recover. JACOBSON et al.[4] found that the recovery-rate in irradiated pure-strain mice was greatly increased by the intraperitoneal insertion, after exposure, of splenic homografts from one-week-old mice of the same strain, and hæmopoiesis in the marrow and spleen returned to normal much sooner than in the few control mice that survived. It remains to be seen whether animals of mixed strain will respond in the same way. Homologous rat ovaries have been implanted in the spleen, where they developed into tumours, which in some cases metastasised to the liver.[5] More limited "takes" were obtained by FAWCETT,[6] who placed fertilised ova under the renal capsule of adult mice. The cheek pouch of the golden hamster (a highly inbred species) has also been described[7] as a favourable site for homografts and even heterografts, though no explanation has been suggested. In general it seems that fœtal tissues have a better chance of surviving as homografts, but are their antigenic properties necessarily less than those of adult tissues? Some evidence to suggest that they are was provided by KEMP[8] who observed that red-cell agglutinogens could be demonstrated in the human fœtus at 37 days, and that the sensitivity of these cells to immune sera increased progressively thereafter.

[2] Dempster, W. J., Lennox, B., Boag, J. W. *Brit. J. exp. Path.* 1950, 31, 670.

Organ transplantation occupied CARREL in his most active years; using a precise technique, as he did in tissue-culture work and in vascular surgery, he advanced the subject far ahead of his time. Endocrine transplants interested HALSTED; he believed that they would "take" more readily if the recipient was in physiological need of them. The endocrine basis for this law is now quite familiar; for example, A.C.T.H. is found to be present in excess in Addison's disease. BROSTER's case[9] of adult-adrenal transplantation and other instances in which fœtal adrenals have been used are later examples of this possibility. Kidney homografts function only for a short time, even though their vascular pedicle may remain intact for very much longer. DEMPSTER has developed the technique of this operation in dogs, using autogenous kidneys; but the disposal of the ureter is a difficult point, even with autografts, and hydronephrosis is a common cause of late failure. Homotransplanted kidneys usually fail after only a few days, during which they produce a urine of fixed specific gravity. DEMPSTER describes a "toxic hypertensive state" which develops in dogs at this stage if they lack their own kidneys. Extensive degenerative changes are found in the transplant, and the tubules are damaged much earlier than the glomeruli. In the few examples[10][11] of human kidney homotransplants that have been recorded, the graft has survived very much longer than in the dog; but these kidneys did not function normally, and it is uncertain whether they served to clear away the products of previous renal failure during their period of activity, or whether resolution was due to recovery of the patient's own kidneys. Skin homografts in man also survive longer than in animals—for periods of from three to six weeks. Under favourable circumstances therefore, skin donors can be a great help in providing skin cover for extensive burns, particularly in children. WOODRUFF[12] made the interesting observation that the areas of homologous skin were not affected in an intercurrent attack of chickenpox, while the autogenous strips were. He agrees with most other authorities that ABO blood-groups apparently play no part in the compatibility of other tissues. He adds, however, that, as in MEDAWAR's experiments, blood-transfusion in humans may produce immunity to that particular donor at least. An exception to these general rules is provided by grafts inserted into the anterior chamber of the eye. Homologous skin[13] and thyroid[14] can survive indefinitely here, though, in the case of the skin, vascularisation of the transplant is a prelude to its destruction. Moreover, a surviving piece of homologous thyroid in the eye is also destroyed soon after another piece from the same donor is inserted subcutaneously. It seems that antibodies, once formed, can reach the anterior chamber, though a homograft inside the chamber need not evoke an immune response. WOODRUFF, however, has also found that long-established anterior chamber transplants are no longer affected by a subcutaneous graft from the same donor, though this itself is destroyed in the usual way. He therefore believes that there is a critical period during which recent homografts in the eye, and perhaps in other sites, are most readily destroyed by the antibodies of the host. There may thus be some way of maintaining conditions which are favourable to the graft until the critical period is over, after which it should have a better chance of permanent survival.

Should homografting fulfil its promise to surgery, the collecting and storing of donor tissues will become of the greatest importance. The Corneal Grafting Act, 1952, allows eye banks to be operated much more easily than before, and comparable legislation may soon be needed for other tissues to be collected in similar circumstances. Storage difficulties have already set a limit to the scope of arterial grafting, for fresh grafts, like stored blood, should not be used after three to four weeks. PEIRCE,[15] in a year's work, collected 50 grafts, but only 3 of these were actually used in patients. The most practical method of husbanding these scarce commodities has so far been to freeze them to −70°C, and to keep them at that temperature by means of solid carbon dioxide. In this way storage may be prolonged indefinitely. Various tissues are known to survive this kind of treatment: arteries,[16] spermatozoa,[17] red blood-cells,[18] and skin[19] can all function successfully when thawed. Techniques for frozen storage of living tissues are complicated, and homograft survival is limited and uncertain, but enough has already been accomplished to illustrate the abundant surgical applications that may finally prove possible.

Kwashiorkor

In 1933 Cicely Williams[1] drew attention to a nutritional disease common among the children of the Gold Coast, where it was known by the vernacular name of kwashiorkor. Since then there have been numerous reports from all parts of Africa, and also from Asian, American, and even European countries, describing clinical syndromes which resemble kwashiorkor in greater or less degree. Some authors have emphasised similarities to the condition originally observed in the Gold Coast: others have laid stress on differences. Unfortunately, most of them have been able to speak from experience of only one area, and their accounts of varying ætiological factors and clinical features have made it hard to know whether the disorders they are describing are essentially the same disease. But whether they are the same or not, they are certainly very important as causes of misery and loss. The time is more than ripe, therefore, for an attempt to correlate the items of knowledge gained in the past twenty years, and we hope for useful results from the conference on kwashiorkor now in progress at Fajara in the Gambia, at which delegates from more than twenty African territories are meeting under the presidency of Prof. B. S. Platt, director of the Medical Research Council's field research station in that place.

It may be recalled that in 1950 a joint expert committee of the World Health Organisation and the Food and Agricultural Organisation recommended the subject for study by the United Nations[2]; and from this initiative comes a report[3] by Dr. J. F. Brock, professor of medicine at Cape Town, and Dr. M. Autret, of F.A.O. Having made an extensive African tour, they define kwashiorkor as a nutritional syndrome, common among the natives of many parts of Africa, in which characteristically there occurs: "(*a*) retarded growth in the late breast-feeding, weaning, and post-weaning ages with (*b*) alterations in skin and hair pigmentation, (*c*) œdema, (*d*) fatty infiltration, cellular necrosis, or fibrosis of the liver, (*e*) a heavy mortality in the absence of proper dietary treatment and (*f*) the frequent association of a variety of dermatoses." Perhaps it is this variety of the dermatoses, determined partly by local vitamin deficiencies and partly by environmental trauma, that has chiefly delayed agreement on the nature of the disease. Clearly there are local variations, related both to local dietary deficiencies (notably the varied intake of the B group of vitamins) and to local prevalence of tropical infections; but Brock and Autret showed that behind these variations there is a clinical entity at least as distinct as beriberi or pellagra. Pragmatically anyhow, the use of the word kwashiorkor has been justified, for it has led to the recognition and treatment of individual cases and to the devising of means of prevention. Physicians who have used it in the same sense as Brock and Autret include such authorities as Clark[4] and Trowell[5] in East Africa, Pieraerts[6] and Dricot et al.[7] in the Belgian Congo, and Bergeret[8] and Bergouniou and Trémolières[9] in French West Africa. Nevertheless there are dissidents, represented by Kahn,[10] of Johannesburg, who recently asked in this journal whether we are justified in "bundling together cases with and without œdema, with and without mucous membrane changes, with and without dermatosis, and so on?" He would restrict the term kwashiorkor to the pigmentary changes in the hair, which in some areas turns from black to russet; but he seems to be in error (with Cicely Williams) in believing that on the Gold Coast kwashiorkor means "red boy" and is solely descriptive of these changes. MacPherson[11] says that in fact it means "possessed by red devils" and is a sinister word knit with Gold Coast magic.

The first task before Brock and Autret was to establish whether or not kwashiorkor was a real medical problem, affecting large numbers of children in many parts of Africa. To this question their answer was an emphatic "yes." They went on to produce much evidence that a widespread lack of protein (particularly animal protein) in the diet during the early years of life is the all-important ætiological factor: as the Governor of the Gambia said in opening the Fajara conference,[12] the general opinion is that the main contributory cause is a deficiency in protein foods, especially at the time of weaning. The relation of deficiency in the diet to the deficiency in pancreatic function which was observed some years ago in children with kwashiorkor[13] and is now being further investigated[14][15] still needs to be worked out; but so far as treatment is concerned, the efficacy of proteins (particularly milk proteins) is almost beyond dispute. The problem of prevention, however, has no equally simple solution. We know that, apart from the heavy mortality, vast numbers of African children are retarded and stunted, both physically and psychologically, by this form of malnutrition: indeed it is no exaggeration to say that the African peoples will never be able to take their proper place in a free world so long as they are thus handicapped. The recent work of Dean[16] encourages the hope that proteins from vegetable sources will suffice for prevention; but before the African child of the future can receive a sufficiency of these there will have to be a revolution in African standards of mothercraft, and several revolutions in African agriculture. This is the kind of fact that we hope the conference, like the W.H.O.–F.A.O. report, will help to drive home.

Annotations

A NEW NEUROSURGICAL UNIT

It is a far cry from the simple equipment of the psycho-analyst to the complicated machinery of the neurosurgeon. Some may see symbolism in the differences; but if ever the various disciplines are to be brought together in a single, comprehensive psychiatry, there is a lot to be said for bringing them together in a single, comprehensive hospital. A new step in this direction has been taken by the Maudsley Hospital where a neurosurgical unit was opened by Lord Waverley on Nov. 20. This joint enterprise between that hospital and Guy's—named the Guy's-Maudsley Neurosurgical Unit—is the first combination in London between an undergraduate and a postgraduate teaching hospital; for the university has hitherto felt that the demands of the two types of student would conflict. At the Maudsley Hospital the unit will have the great advantage of easy access to the laboratories of the Institute of Psychiatry, which is attached to the hospital.

The idea originated some years ago with the late Prof. Edward Mapother's intention to set up a specialised neurological department at the Maudsley Hospital. His death, and the war, prevented this from being put into effect. During the war it was suggested that a unit should be set up at Dartford. Finally, the present scheme took shape. The result is a stimulating example of coöperation among several bodies with different responsibilities. These bodies are Guy's Hospital, the joint Bethlem Royal Hospital and Maudsley Hospital, the South-east Metropolitan Regional Hospital Board, and the Institute of Psychiatry, which is part of the Postgraduate Medical Federation of the University of London. With so many associations nobody could accuse the new unit of parochialism; but to clinch the matter it has obtained from New Zealand its first director—Mr. Murray Falconer.

The unit consists of two ward wings, each of fourteen beds and a cot, and a third wing containing the operating-theatres; all the wings are on ground level. The wards, formed from a building which was already in existence, are in the form of a W, with the theatre block extending from the central point. The theatre block is designed so that the main theatre is in the centre, with the other rooms grouped round it. There is a smaller theatre; the usual anæsthetic, changing, and sterilising rooms; and also electro-encephalographic equipment for electrocorticography as well as routine testing. There is diagnostic X-ray equipment, a small pathology laboratory for quick sections and smears, and a conference room. The buildings were charged to the National Health Service; and the equipment and furnishings were bought from the endowment funds of the two hospitals.

These two hospitals have advantages which put them under an obligation not only to the rest of their region, but to the whole country and, indeed, to the Commonwealth. Their past histories suggest that they will not fail the future.

DWARFISM AND AORTIC MALDEVELOPMENT

CONGENITAL agenesis of the ovary gives rise to a well-recognised syndrome characterised by stunted growth, absent axillary and deficient pubic hair, amenorrhœa, underdevelopment of the sex organs, and increased excretion of gonadotropin and decreased excretion of 17-ketosteroids in the urine. Further clinical features include a barrel-chest, osteoporosis of spine and pelvis, wrinkled skin, cubitus valgus, and webbing of the skin of the neck.[1] In such cases coarctation of the aorta is not uncommon; and in the opinion of Albright et al.[2] this lesion, and not the ovarian insufficiency, accounts for the retardation of growth. On the other hand, van Buchem et al.[3] found that 115 reported cases of ovarian agenesis included only 12 with typical aortic coarctation (a combination that has been named Turner's syndrome). The part played by coarctation in retarding growth seemed questionable; but they found that distinct endocrine disturbances were commonly associated with electrocardiographic abnormalities, and they concluded that surgical treatment for coarctation in a patient with agenesis of the ovary should be preceded by œstrin therapy, which may improve the myocardium and thus reduce the risk of operation.[4]

In most patients with coarctation of the aorta but no other abnormality, the physical development is rather above average. Rokitansky,[5] however, noted an association between infantile aorta and hypogenitalism; and hypoplasia of the aorta commonly accompanies other congenital cardiac defects, such as atrial septal defect, which may cause skeletal and genital maldevelopment. Some patients with aortic hypoplasia die suddenly, and post mortem gross enlargement of the heart is usually found. In many of such cases the only satisfactory explanation seems to be an endocrine disturbance. The relation of developmental aortic insufficiency to endocrine disturbances should be further studied.

TERRAMYCIN

AMONG the newer antibiotics aureomycin and terramycin are often mentioned together as inseparable companions. But the first may appear as Mary, while the other often plays the subordinate rôle of Martha, though terramycin can fairly claim an audience in its own right. It was first isolated in Messrs. Pfizer & Co.'s research laboratories in Brooklyn, after an exhaustive search of thousands of soil samples, in one of which the responsible micro-organism, *Streptomyces rimosus*, was eventually discovered. Now that its structural formula has been established [6] it is possible that its mode of action may be more fully elucidated. There is nothing in the molecule to disturb our faith in the drug. The association of an amino group and a benzene ring usually raises doubts about agranulocytosis, but the modification in terramycin is such that few will entertain fears on this account alone.

In the pure state terramycin is a crystalline amphoteric substance of remarkable stability. It is usually prepared as the hydrochloride, and the dry compound shows no appreciable loss in activity even after prolonged storage at 25°C; the solution, too, maintains its potency over a wide range of pH, especially when kept at 5°C. Absorption from the gastro-intestinal tract is rapid, and what have been described as "significant, continuous blood plasma concentrations" are achieved with doses of 0·25 g. every six hours.[7] It is distributed through most of the body-fluids, though in the absence of meningeal inflammation the amount that reaches the subarachnoid space is probably not very great. The drug is readily excreted in the urine, still in its active form and in high concentrations; and relatively large quantities are also passed in the fæces. The commonest side-effects are nausea, vomiting, and diarrhœa; and occasionally stomatitis and epigastric pain are troublesome. These reactions can be minimised by giving the drug with milk, which in no way impairs absorption. Sometimes monilial infections arise and the drug has to be withdrawn. The remarkable alterations in intestinal flora which have been observed are probably due to the comparatively large amounts of terramycin which remain unaltered in the bowel.

Its antibacterial activity is certainly comprehensive though it is on the gram-positive organisms that it exerts its greatest effect. The conditions which respond to terramycin include pneumococcal pneumonia, primary atypical pneumonia, pneumonia of mixed bacterial ætiology, hæmolytic streptococcal infections, brucellosis, the spirochætal and rickettsial diseases, gonorrhœa, lymphogranuloma inguinale, Vincent's angina and intestinal amœbiasis. On the other hand, it has no action at all on proteus and *Pseudomonas aeruginosa*, or in typhoid and salmonella infections, mumps, measles, chickenpox, smallpox malaria, and trichinosis. Its action on the staphylococcus is of particular interest because so many strains with a high resistance to penicillin are being encountered. In some cases terramycin provides the answer; in others it unhappily fails altogether. On the whole, staphylococcal infections can be controlled well enough by terramycin, but quite often the results are unsatisfactory. Moreover, instances have been reported in which staphylococci have appeared in the sputum of patients who were having terramycin for a pneumococcal pneumonia. But the question-mark before staphylococcal infections is a relatively small blot on the record of a drug that is clearly a valuable addition to our antibiotic resources.

HYALURONIDASE FOR CHRONIC LIMB ŒDEMA

LONG-STANDING œdema of the legs embarrasses patient and doctor alike. When the general causes of œdema—such as heart-disease, anæmia, and hypoproteinæmia secondary to liver or kidney disease—have been excluded, we are left with a large group of œdemas presumed to be of local origin. Sometimes these are familial; sometimes they are associated with obesity, varicose veins, or "poor circulation" in young women. An occult thrombosis of the deep veins of the leg may cause local circulatory failure, even without spectacular superficial varicose veins.[1] Little is known of the pathological anatomy or physiology of these chronic limb œdemas; and even if the initial exodus of fluid from the capillaries is easily reversed by elevation of the limb, changes in the connective tissue ensue and are associated with swelling which no longer pits easily on pressure, nor resolves on elevation of the limb. At this stage the results of treatment are not such as to dull our interest in revolutionary proposals.

Ferrero[2] has published a preliminary report on intra-arterial injections of hyaluronidase in twenty patients with chronic limb œdema. He gives 6–10 injections, each of 250–500 units of hyaluronidase, into the artery supplying the affected limb. A sphygmomanometer cuff on the limb is kept at venous pressure during the injection, and raised to arterial pressure just after the injection, to prevent excessive dilution of the injected material. The cuff is then tightened and relaxed intermittently. Treatment is given either daily or on alternate days. Good results are claimed both in postphlebitic and in "cryptogenic" œdemas. There is said to be no local pain and no general reaction. The sense of weight in the limbs is decreased, mobility improved, and the girth of the limb diminished; in some of the cryptogenic œdemas there was complete resolution. Ferrero suggests that in connective tissue there is a balance between hyaluronic acid and hyaluronidase; in chronic œdema this is upset in the direction of increased hyaluronic acid, with increased "gelation" of the tissues. Injection of hyaluronidase makes the tissue more fluid, and allows resolution of the œdema. Arterial injection, says Ferrero, seems a logical way of promoting what is essentially a local tissue action.

The results and the hypothesis do not necessarily stand or fall together. Confirmation of either or both can come only from further work; and neither can be dismissed out of hand, from what we already know of the action of hyaluronidase on the physical status of connective tissue,[3] the permeability of capillaries,[4] and the absorption of subcutaneous infusions.[5]

THE IRISH NUTRITION SURVEY

DURING and immediately after the late war the people of Ireland seemed to enjoy a relatively high standard of nutrition. But there was the inevitable doubt: is this prosperity, in part, an illusion, and is a section of the population improperly nourished? To answer this question the Irish Medical Research Council sponsored the National Nutrition Survey, which in 1946–48 systematically investigated food consumption and made a widespread clinical survey. The report of the survey has appeared in seven parts. The first four, describing the majority of the dietary investigations, were published in 1949.[6] The remainder[7] have now been issued. Parts five and six describe a dietary survey of farm-workers' families, and of a small group of rural families not engaged in agriculture, but for the most part prosperous. Part seven describes the clinical survey.

The diets of 2893 families were investigated. The over-all average weekly diet for the country comprised: milk 7·1 pints, eggs 5·1, cheese 0·8 oz., fats 10·6 oz., meat 30·7 oz., fish 3·5 oz., flour and bread 88·6 oz., other cereals 10·0 oz., potatoes 135·4 oz., vegetables 30·7 oz., fruit 7·1 oz., sugar 11·6 oz., and preserves 4·5 oz. Such a diet fully meets the most exacting nutritional standards. The calorific value is 3105 and the protein content 99 g., of which 42 g. is from animal sources. The calorific figure agrees with one of 3260 obtained from Ireland's agriculture and trade statistics for the F.A.O. food-balance sheet. This figure relates to production levels, whereas the survey figure is for consumption levels—i.e., after the inevitable losses in distribution and retail sale.

The report includes a separate analysis of 317 families whose economic position was likely to be precarious on account of unemployment or the death of the head of the family. In the unemployed groups the consumption of milk and meat was low, and in some the daily caloric intake was little over 2000. Clearly, although most of the population had ample good food, a small minority was subsisting on unsatisfactory diets.

In the clinical survey nearly 15,000 school-children, 570 adolescent boys and girls, and 320 expectant and nursing mothers were all examined by a single observer. Of all the children examined, the proportion reported to be in good nutritional state was 75%, while those in poor nutritional state came to less than 2½%. This judgment was based on subjective impressions derived from assessment of muscle development and tone, the quantity of subcutaneous fat, the strength of the hand-grip, and the colour of the mucous membranes. These are notoriously hard to judge, but no doubt the employment of a single observer made for consistency. His or her account (anonymity is preserved throughout the report) confirms the conclusion from the dietary study that the well-nourished population contained a small number of under-fed children. In most groups evidence of rickets was found in over 15% of children, and in one group such evidence was found in 29%; but unfortunately diagnostic criteria are not described in detail. Presumably in most children the lesions were old and long healed, and their detection was not incompatible with good, or at least fair, nutrition. Perhaps many of the children had developed rickets during the period February, 1942, to

April, 1943, when Ireland consumed 100% extraction flour without added calcium and there was a high incidence of active rickets in children aged 1–4 years.[8] After the return to 85% extraction flour and the addition of calcium, the incidence of the disease declined greatly. In the towns height and weight showed a statistically significant, but not striking, relationship with social class. In rural areas this correlation was not distinct.

The survey has provided a simple answer to a simple question. The reports, though uniformly silent about names, make clear that the survey depended on an excellent organising committee of the national Medical Research Council, the goodwill of the various public-health departments, and a team of ten women field investigators and one full-time clinician backed by continuous expert statistical advice. Significantly, there was no biochemist and indeed no laboratory work of any sort.

PERSPECTIVE OF DIABETES

Prof. Elliott P. Joslin and his collaborators have perhaps had the opportunity of assessing more cases of diabetes than any other group of physicians in the world. In a preface to the ninth edition of their famous textbook,[9] they mention the 40,000 patients who have consulted them for diabetes, and draw some important lessons from this vast experience. Before the discovery of insulin, coma and tuberculosis were major causes of death in diabetics; now deaths from coma at the New England Deaconess Hospital have fallen to 1·1%, and from tuberculosis to 0·9%. In 75% of deaths nowadays the cause is cardiovascular-renal disease; but they say that when they began treating diabetes they were more hopeless of reducing the death-rate from coma and tuberculosis than they now are of postponing, reducing, or even eradicating premature cardiovascular-renal disease. From 12,281 fatalities they have drawn the firm conclusion that "of those complications which have ravaged our diabetics most can be explained by failure to control the disease." Retinitis, nephropathy, and neuritis, they are able to assert, are among such complications: their prevention depends on continuous control, and the aim of the book is to make such control possible.

The danger, Joslin and his colleagues say, lies in the fact that today almost any diabetic, young or old, will live ten years if he is given a moderately restricted diet plus insulin. But the patient who designs to live two, three, or four decades after the onset of his disease must make the effort to live a model diabetic life. This is especially important with children; for though the measures needed to defeat coma and tuberculosis were relatively simple, the conquest of neuritis, retinitis, nephritis, and cardiovascular degeneration depends not only on diet, exercise, insulin, and education, but also on control of the patient's human nature. Nor is it sufficient merely to convert the patient: his doctor too, "with missionary zeal," must be converted. A charming aspect of this kind of enthusiasm led the Boston Safe Deposit and Trust Company to offer the Quarter Century Victory Diabetes Medal to those who live twenty-five years with their disease and are perfectly well at the end of it. In 1948 insulin itself was only twenty-six years old, and Joslin and his team knew only 1 such patient; now there are 34 holders of the medal, and the number is expected to increase by leaps and bounds. But these observers say they have never seen a diabetic with the disease uncontrolled for twenty-five years who could meet the criterion. On the other hand, a time may come, they suggest, when the diabetics with their diseases well controlled and their health carefully maintained will outlive their contemporaries.

LOCAL TREATMENT OF LEG ULCERS

Celsus used plasters for leg ulcers and Galen applied wine, but both recognised the importance of firm bandaging. Guy de Chauliac in the 14th century tried waxed cloth or diachylon or some cold adhesive plaster, and 200 years later Paré was using ointments to clean the ulcer, pressure pads soaked in wine or oxycrate, and sometimes a lead plate. He insisted, as did Galen, that the ulcer should not be dressed too often and that firm bandaging was essential. Though a variety of dressings were later used for the local treatment of leg ulcers, the principles of treatment remained much the same until Lister's time, when the control of micro-organisms on the surface of the ulcer by means of antiseptics became an increasingly important consideration.

Dickson Wright,[1] however, showed that a leg ulcer would heal, although infected, if the œdema was abolished. He wrote: "There is no need to invoke a stubborn bacterial infection to account for the chronicity of varicose ulcers; it is purely a matter of hydraulics." Nevertheless, an ulcer sometimes becomes offensive and extends rapidly as a result of secondary infection, which, after bacteriological investigation, may be controlled by an appropriate antibiotic. Streptomycin [2,3] and aureomycin [4,5] have been found useful, but there is no advantage to be gained from applying them for more than a few days. Moreover, there is some risk of sensitising the surrounding skin, particularly if penicillin cream is used. Various antibacterial substances have proved effective: *p*-chlorophenol, phenoxyethanol ('Phenoxetol'), silver dinaphthylmethane disulphonate,[6] and ozonide of olive oil.[7] More recently Sommerville and Devine [8] have described the use of 'Furacin' (5-nitro-2-furaldehyde semicarbazone) in a carbowax and propylene-glycol base. Some patients were ambulant and wore supporting bandages; others were kept in bed. The results seem promising, but a furacin dermatitis developed in 8 of the 25 patients they treated. Moreover, it is impossible to assess such treatment without comparing the results with those in a similar group of patients treated by rest or bandages, but without furacin. Local protective dressings are sometimes helpful, and adhesive tape [9] and boiled human amnion [10] have been used for this purpose. Ointments containing unsaturated fatty acids seem to have no value except as soothing dressings. There is a danger that drugs may be absorbed from the raw area, and ointments containing resorcinol have caused myxœdema.[11]

Although various kinds of local treatment may improve matters, it is important that they should be used only as ancillary measures. Anning [12] lately stressed that if attention is given to the circulation of the limb as a whole, the base of the ulcer and its flora may usually be ignored. To cure a leg ulcer, the œdema must be abolished, whatever local treatment may be used, and too often in the past concentration on local treatment has led to neglect of this fundamental principle.

MR. J. D. KING, D.SC., F.D.S., director of the Medical Research Council's dental research unit at King's College Hospital, London, died on Nov. 22, at the age of 45.

THE CAT OR THE CAUSE?

Proposed Return to Corporal Punishment

THERE are dangerous possibilities about the mounting agitation in some quarters for a return to corporal punishment for crimes of violence. An air of emotional fervour about this movement, of a type to which Parliament has sometimes responded in the past and which is in sharp contrast to sober Ministerial statements, means that there is some risk of the sudden passage of new legislation, which, under pressure of strong emotion, may not be wise.

Notoriously, in the dispute about corporal punishment, reasoned argument has failed to sway the issue. It might almost be concluded that people either deeply wish that violent criminals should be flogged and murderers hanged (for these wishes often go together), or they do not; and there is an end of the matter. Perhaps a majority of the judges on the Queen's Bench, some of the magistrates, but not the Law Lords or the Secretary of State, share this wish; most of those engaged in works of social amelioration and reform do not; religious leaders appear to be divided. How can the hypothetical man-in-the-street be other than confused and uncertain in his attitude?

The popular press is often blamed for giving so much lurid publicity to crime and for being selective, conducting campaigns about certain types of crime. There is no evidence that such campaigns affect the incidence of crime, but they must to some extent poison the public attitude. In one sensational incident in New York in which public anxiety over a so-called wave of sex crimes became intense under a vivid press campaign, it was found later that there had been no more than an unusual sequence of similar crimes, the incidence for the year being normal. What harm was done to the public by this experience is a matter for speculation; but certainly little good. Experience indicates that, though publicity may suggest to a criminal a certain detail of action, it will scarcely cause a crime to be committed. However, positive good might follow if the press were to pay more attention to St. Paul's injunction to think on those things which are true, lovely, and of good report.

The parties to this dispute naturally differ as to whether corporal punishment is or is not a deterrent. Proponents often back their argument, implicitly or explicitly, with the concept of corporal punishment as punishment or retribution; opponents back theirs with humanitarian considerations and their concept of civilised behaviour. They agree that prison will protect the public from the criminal for the duration of the sentence, but they differ in regarding prison as being on the one hand primarily a punishment and a deterrent, and on the other hand as a potential opportunity for reform. Some who are uneasy about corporal punishment will pin their faith on making prison a most unpleasant place in which the criminal will spend a very long time.

A DETERRENT?

The defects of statistics as a means of proof have often been emphasised, but it is at least impressive that nobody seems to have produced figures to show that corporal punishment can be a deterrent to crime. Table I, based on Home Office figures for England and Wales, contains several points of interest. It will be seen that the offences for which corporal punishment used to be authorised have actually decreased since corporal punishment was abolished in 1948—this in a period when all other forms of indictable offence, including all other forms of violent crime, have increased. In 1947, of convicted persons liable to corporal punishment, only 6% were sentenced to receive it, and these represented only about 0·01% of all the indictable offences known to the police. One may wonder whether the prospect of corporal punishment appeared more than very remote to the criminal as he went out to commit his crime.

The figures for the war-time whipping of boys under 14 (table II) are truly remarkable, for in 1940 the amount of whipping suddenly rose sixfold to reach a peak in 1941 at eleven times the 1938 level, only to decline as abruptly to reach half its 1938 level in 1945. Meanwhile indictable offences rose by nearly two-thirds between 1938 and 1940 and remained at that level throughout the war. It strains credulity to believe that increasing whipping from 0·3% of offenders in 1938 to 1·3% in 1941 (and reducing it to 0·1% in 1945) warded off a much bigger rise in juvenile crime and held the level steady for two years after the policy was abandoned. It is easy to understand how, under the pressure of increasing crime and of war-time magisterial uneasiness, this form of punishment was adopted. It is less easy to see why it as suddenly disappeared; but at least there is no hint in these figures that whipping was regarded by the magistrates at *that* time as a successful deterrent.

TABLE I—CRIMES OF VIOLENCE AMONG ADULT MALES

—	1945	1946	1947	1948	1950	1951	First 6 months, 1952
Offences for which corporal punishment could be ordered before September, 1948:							
Armed robbery and robbery with violence	..	804	842	..	812	633	359
No. of convicted persons sentenced to corporal punishment	..	35	50	..	..	..	..
Percentage of convicted persons sentenced to corporal punishment	..	4·4	5·9	..	..	..	..
Offences for which corporal punishment could not be ordered in 1945–48:							
Felonious wounding	..	..	..	646	..	1078	..
Malicious wounding	..	..	..	3547	..	4445	..
Rape	..	..	..	252	..	335	..
Indecent assault on females	..	..	..	5659	..	7287	..
Total no. of indictable offences known to the police ..	478,394	..	..	..	..	524,506	..
Percentage of convicted persons sentenced to corporal punishment ..	0·01	..	..	..	..	..	..

Statistics of murder for the years 1939 to 1945 (table III) show some of the reasons why hanging, which was practised at that time without some of the hesitations which have lately appeared, may equally *not be an* effective deterrent. First, people were brought to trial for only about half the known murders; presumably many of these had evaded punishment by committing suicide. Secondly, while 174 guilty persons were deemed to be sane, 209 were, at some stage of the proceedings, deemed to be insane. Thirdly, only about half of the sane persons convicted of murder were executed: of those charged with murder the proportion executed was only 1 in 6, and for every 11 murders there was only 1 execution. 12 executions per year among 40 million people; for 900 murders, 82 executions: what a problem in calculating risks for the 19% of murderers caught and deemed sane!

TABLE II—WHIPPING IMPOSED BY MAGISTRATES' COURTS, BOYS UNDER 14 YEARS OF AGE

—	1938	1939	1940	1941	1942	1943	1944	1945
Number of sentences	48	58	302	531	314	165	37	25
Number of boys found guilty of indictable offences	14,724	16,724	23,167	23,083	20,382	21,058	22,525	22,922
Proportion of offenders per 100,000 of age-group	798	930	1304	1324	1184	1234	1330	1361
Percentage of convicted offenders sentenced to whipping ..	0·33	0·35	1·30	2·31	1·54	0·79	0·17	0·11

Figures, excluding calculations of percentages and proportions, taken from the Home Office's *Criminal Statistics for England and Wales*, Cmd. 7227. H.M. Stationery Office. 1947.

For a deterrent to be effective, either there must be an appreciation and dislike of the consequences, combined with self-control, or else there must be sheer fear of those consequences. Common sense and psychology agree that if all men possessed the qualities of intellectual appreciation, self-control, and foresight, there would be fewer murders and crimes of violence. Criminals who are capable of calculating risks are far more likely to go in for confidence tricks, fraud, and the like. Violent crime is largely a matter of primitive emotional forces, of very great strength. Moral standards and the adult's positive desire for good come from the child's birthright of love and trust in the home, which, if denied or betrayed there, may engender such hatred and hostility in an individual that the forces of morality, with all their strength, are swept aside. Violent crime is not merely a matter of low moral standards, of slackness, or of work-shyness, but arises from intense antisocial emotions. How can it be hoped that a problematical punishment in the future—a highly abstract eventuality for the primitive person concerned—will have a strong deterrent effect?

RETRIBUTION?

When all the available evidence is to the contrary, adherence to the opinion that these punishments are deterrents can only signify a deep need to justify a belief held for emotional reasons. If it could now be recognised that corporal punishment is advocated out of sympathy for the victim, because of a need for revenge, a primitive desire to mete out to the thug what he has done to another, a notable advance would have been made. Then the British people would be faced with a clear-cut issue—whether direct acts of retribution are or are not a desirable principle of justice. They could consider whether society can afford to sink to the level of, and to take revenge on, its criminal members; whether, in striving to return to more civilised standards of behaviour after a war, even a small matter like the flogging of fifty men each year may not be undesirable. If there is no justification in expediency, there is no escape from the moral issue, unless some bold spirits should wish to attempt to justify the expediency by flogging ten or a hundred times the number of criminals in an attempt to secure a deterrent effect.

TABLE III—MURDER OF PERSONS AGED ONE YEAR AND OVER, SEVEN YEARS, 1939–45 INCLUSIVE

Murders known to the police:		
Total no. of murders known to the police..	900	
Average number of murders per year ..	129	
No charge preferred (murderer committed suicide, &c.)	426	
Total number of persons brought to trial..	474	
		Percentage of the persons brought to trial
The trial:		
Found insane on arraignment	84	18
Found not guilty	102	21
Found guilty but insane by the jury ..	114	24
Found guilty	174	37
		Percentage of sane persons convicted
The sentence:		
Aged under 18 years and detained during H.M. pleasure	14	8
Sentenced to death	160	92
Sentences quashed by Court of Criminal Appeal	11	6
Found insane on enquiry and sent to Broadmoor Asylum	11	6
Reprieved by action of the Secretary of State	56	32
Executed	82	47
Average number of executions per year ..	12	..
Total number of guilty persons found insane..	209	
Total number of guilty persons found sane ..	174	
Proportion of known murders to executions	11 : 1 (approx.)	
Proportion of charges of murder to executions	6 : 1 ,,	
Proportion of convictions of murder to executions	2 : 1 ,,	

PREVENTION?

The essential distinguishing feature of the cool calculating criminal—the conscienceless rogue—is that he is conscienceless; and of the violent thug that he has emotional reactions and relationships more appropriate to a child of two or three than to his adult body. No-one would dream of blaming a child for having rickety legs, and modern research is now showing that psychological medicine, too, has its deficiency diseases. To hold that criminals are just "plain wicked" is a counsel of despair; and the present-day need of society is for research into causes, not for "cats."

The incidence of crime in a community shows some relation to the rate of change of social institutions therein. A rise in the level of crime is associated with rapid industrialisation, social revolution, and war, and the war-time training in and approval of violent behaviour among the young males is no doubt associated with the steeper secondary rise experienced when peace returns. The effect of war-time disturbances of home life is likely to last for many years—indeed so long as the young men and women involved are active in crime. Other factors that produce more local and temporary variations in the crime-rate include social injustice, political tension, and the moral attitudes of the community.

The prevention of criminality thus requires a many-sided approach. The main object must be to improve the mental hygiene of family life, which may be attempted through economic, sociological, and religious activities. But one of the very important tasks is to improve the quantity and quality of recruits to the police forces and to seek a reorientation towards the more truly preventive aspects of their work.

Even effective prevention, however, does not solve the problem of the existing criminal, for whom, it must be stated, the approved-school and borstal systems are giving only mediocre results and prison is often almost disastrous. A long sentence may give merely a respite from criminal activity and is more likely to demoralise than rehabilitate the criminal. From the very conditions of prison life, psychological treatment in prison does not hold out any great hope of success; but a more concerted effort to raise, not lower, the prisoners' self-respect deserves serious trial. The Home Secretary has pointed out that the Criminal Justice Act envisages such efforts, but that there has not yet been opportunity to bring them into being.

Only organisational difficulties—and they are formidable—appear to stand in the way of attempting to make prisons self-supporting, to make inmates work for their living. To introduce a new spirit of this type might breathe new life into the Prison Service and counteract the demoralising effect on staff of the purely custodial care of caged human beings. Continued neglect of such an experiment is perilous for society.

A CHANGE OF ATTITUDE

It would be well if the current agitation for an arbitrary change in the law, with no thought for principle, were quickly brought to an end. The public needs a respite from fears aroused by the fantasy that the country is being overwhelmed by violent lawlessness, a fantasy which is far removed from the fact. Much good would follow from more objectivity in the press, and less exploitation of the situation for the sake of the circulation; more circumspection, especially in public utterances, by leading judges and magistrates; and more thought by the general population about the moral and spiritual values of our civilisation, including recognition of the effect of the more primitive emotions on our thoughts and conclusions.

GENERAL MEDICAL COUNCIL

OPENING the 185th session last Tuesday, Prof. DAVID CAMPBELL, the president, remarked that the Dentists Bill had not gone further than the first reading in the House of Commons before the close of the Parliamentary session. It would, therefore, have to be renewed in Parliament as though it were being introduced for the first time; and it appeared probable that the council would have to continue to carry out its duties in relation to the dental profession for an indefinite period.

The next edition of the *British Pharmacopœia* would be published on March 1, 1953, and have effect from Sept. 1, 1953. A quarter of a century ago the Macmillan Committee, whose report was accepted by the council, urged that the body preparing future issues of the *British Pharmacopœia* should not only be composed of thoroughly qualified persons but should also be such as to command the confidence of all the interests concerned. The committee to select the new Pharmacopœia Commission would, therefore, consist of representatives of the council, the Pharmaceutical Societies of Great Britain and Ireland, and the Medical Research Council.

The council had decided to put into operation that part of the Act of 1950 which empowered them to appoint visitors, not being members of the council, to medical schools and examinations. It proposed to select men of special qualifications and of experience on particular subjects, and to arrange for them to visit both the schools and the examinations.

The Appointed Day for introducing the compulsory period of service as a house-officer was to be Jan. 1, 1953. Approved hospitals and institutions numbered 634—456 in England and Wales, 104 in Scotland, 24 in Northern Ireland, and 50 (approved by the Medical Registration Council of the Republic) in Eire. The total number of posts was 3048—280 in Eire and 2768 in the United Kingdom. Of the United Kingdom posts 926 were in general medicine, 972 in general surgery, 342 in midwifery, and 528 in the various specialties (171 primarily medical and 357 primarily surgical). Holders of recognised Commonwealth or foreign diplomas would be able to claim registration if they had been employed for the prescribed period in hospitals approved by licensing bodies of this country, and if they satisfied the council that they had rendered satisfactory service under the conditions applicable to holders of diplomas granted in the British Isles. Applicants holding recognised Commonwealth or foreign diplomas who could not claim full registration on this basis could claim such registration if they had acquired otherwise substantially equivalent experience of the practice of medicine and surgery.

No doubt, at the beginning some of the machinery might creak; but, given the coöperation of student, medical school, and hospital authority, it should soon run smoothly. The student might be assured that the authorities of his school would do everything they could to help him to secure suitable posts; but that would not free him from using his own judgment and himself seeking employment, as those before him had done. It was certain that all licensing bodies and schools would prefer each student to take posts for 6 months in general medicine and 6 months in general surgery; and if that was impracticable, they would insist that 6 months should be spent in either general medicine or general surgery. Before accepting any particular post included in the list published by the council, the applicant should consult the authorities of his school as to whether the combination of posts he proposed would be recognised by his licensing body to enable him to qualify for full registration. Hospital authorities could help greatly by synchronising as far as possible their appointments with the periods at which final examinations were held. By effecting a revision of existing staff arrangements and providing the requisite residential accommodation, they might also secure the recognition of hospitals not yet approved and thus add to the number of suitable posts. The ultimate responsibility lay with the licensing bodies. The council's sole object was to perfect the administrative machinery and to do all in its power to enable these bodies to ensure that this measure would lead to a higher standard of medical care and practice.

DENTAL TREATMENT OF CHILDREN

THE British Dental Association found, from the answers to a questionary, that private practitioners were willing to set aside about 10,000 hours per week for the dental treatment of school-children; and in a memorandum[1] to the Government it suggested that this might help to provide a short-term solution to the problem of obtaining enough treatment for this priority group. In their reply the Ministers of Health and Education and the Secretary of State for Scotland state "certain principles which they consider to be fundamental to the proper organisation of a dental service for the priority classes and to which in their view both short term and long term policy must have regard.

"The first is that as has been shown by experience the most effective way of providing treatment for school-children is in clinics closely associated with school routine so as both to ensure the attendance of children in need of it and to cause the least interruption of their education. Treatment for younger children can most effectively be provided by a clinic service forming part of the local health authorities' general arrangements for the care of mothers and children, so as to encourage attendance and meet the convenience of the mothers.

"Secondly, it is imperative, particularly in present economic circumstances, to achieve the utmost economy in expenditure and here again experience has shown that children can be treated in clinics at a substantially lower cost than when treated by private dentists remunerated for each item of treatment on the scale of fees in operation under the general dental service.

---

[1] *Brit. dent. J.* Oct. 21, 1952, suppl. p. 53; see leading article, *Lancet*, Oct. 25, 1952, p. 811.

"Thirdly, one of the fundamental difficulties facing all branches of the dental services at the present time is the shortage of dentists. In the treatment of children dental manpower can be used more economically in clinics than in private practice. As the Association themselves recognise the public dental officer working in a clinic can make the best possible use of ancillary help such as chairside assistants and oral hygienists. In such a system the public dental officer can play his full part and achieve a most useful and satisfying position with responsibility for the full care of the child's teeth. Under the Association's proposals it would seem that responsibility would be divided, the volume of treatment the public dental officer could undertake would be materially reduced, and he would be able to do little more than 'act as co-ordinator.'

"The Ministers therefore feel that the improvement of the special priority service for children must be sought on the lines of expanding the existing clinics rather than of transferring part of the service to private surgeries; and it is for this reason that clauses 5 and 6 have been included in the Education (Miscellaneous Provisions) Bill now before Parliament.

"The Ministers, however, are most anxious that the maximum number of dentists should have an opportunity of working in these clinics either whole or part time and as the Association know circulars were issued to all local health authorities and education authorities earlier this year urging them to invite dentists to give their services in this way. The Ministers are therefore particularly glad to see that the questionnaire circulated by the Association has elicited that there are a total of 583 practitioners willing to work part time in the clinics and the Association have already been invited to ascertain the names and addresses of these practitioners and to supply them to the Departments so that every effort can be made to secure their services.

"The Ministers note from the results of the Association's questionnaire that a large number of dentists share their views that the dental care of the priority classes should take first place in the public provision of dental treatment. They would like to see the private dental practitioners of each district together agreeing to accept collective responsibility for the dental care of the district's children (in so far as might be necessary to supplement the services already provided by the local authorities) and for this purpose offering part time service in the dental clinics organised by the responsible health and education authorities."

TRIALS OF INFLUENZA VACCINE

The Medical Research Council, in conjunction with the Ministry of Health, is organising trials this winter of a vaccine against influenza A.[1] This vaccine, selected as a result of investigations last winter, is suitable to the strain most likely to give rise to influenza in the coming months.

The trials are due to start early in December in volunteer groups throughout the United Kingdom. The volunteers involved are likely to total about 15,000 and will include smaller groups in hospital nursing staffs and the universities with larger groups in industry and the Services. In addition a special trial is to be carried out in villages in the Isle of Lewis, Scotland.

Two vaccines will be used—one the new vaccine, and the other (as a control) a vaccine of the type which has been available for a number of years. Half of the volunteers will be inoculated with the one vaccine and half with the other. They will then be supervised for 3 months. In many cases, particularly in the industrial groups, responsibility for treating illness during this period will rest with general practitioners. All general practitioners called in to see volunteers are asked to fill in the simple record form with which they will be provided. All concerned are asked to make effective use of the laboratories of the Public Health Laboratory Service for diagnosis and the determination of virus strains.

More detailed information is obtainable from the secretary of the Medical Research Council's committee on clinical trials of influenza vaccine, at the Ministry of Health, 14, Russell Square, London, W.C.1 (tel.: Museum 6811, ext. 23).

Medicine and the Law

Negligence Claim Settled

If allegations of negligence are made against hospitals or medical practitioners and are presently withdrawn on the offer of an agreed sum, the medicolegal interest of the proceedings disappears, unless it be worth while to record the kind of mistake which was alleged and the amount of the agreed damages.

In Ross *v.* Tunbridge Wells Group Hospital Management Committee and another (*Times*, Nov. 21), the plaintiff's claim arose out of the death of her husband. His age was 40; it was stated that he had never consulted a doctor in his life or suffered anything worse than a common cold. He entered hospital on his dentist's advice for extraction of a wisdom tooth. His heart, it was said, stopped on the operating-table; it was got going again, but he died after 48 hours. Counsel for the plaintiff widow, opening the case as one of the most extraordinary that could come before the courts, stated that the deceased was given a preliminary anæsthetic by injection before being brought into the theatre. For anæsthesia in the theatre a Boyle's apparatus was used with a combination of nitrous oxide and oxygen. It was suggested that carbon dioxide was somehow mixed with the oxygen. When a further gas—cyclopropane—was administered, the patient collapsed. It appeared most likely, said counsel, that the patient was asphyxiated by the introduction of the carbon dioxide.

The defendant hospital's committee and the second defendant denied the negligence. On the morning of the second day of the hearing, counsel (who had first seen the judge in his private room) announced a settlement. Plaintiff's counsel said that a substantial sum (representing in his view the amount which his client might have expected, if successful, to recover) had been offered by the defendants. This sum the plaintiff was prepared to accept, and accordingly the allegations were withdrawn. He asked for an order that £1000 be paid to her immediately. It was a term of the settlement that her costs should be taxed as between solicitor and client. The judge observed that in his opinion the parties had been well advised to come to terms. He added that the sum mentioned was almost exactly the figure which he himself had provisionally assessed as the amount the plaintiff might recover if she succeeded in establishing the defendant's liability.

A Varied Claim

For surgeons perhaps the main interest in the case of Moon *v.* Bristol United Hospitals and Fairman[1] was that an allegation was made against a professional man on somewhat speculative grounds, that his evidence was not challenged, and that the claim against him was dismissed with costs before the end of the trial.

Mrs. Moon asked for damages against the hospital defendants and the surgeon on various grounds. Her husband underwent tonsillectomy on Feb. 1, 1949. At 2 A.M. next day he complained that his arms and legs were useless. He also suffered a burn on the abdomen from a hot-water bottle. The paralysis having been mistakenly attributed to hysteria, he was removed to a mental hospital but was soon brought back, the records diagnosing his case as "complete spinal cord lesion following extraction of tonsils." Later he was able to go home, but had daily treatment at the hospital. His condition deteriorated; he was admitted to the Bristol Royal Infirmary where he died on Dec. 27, 1950. Post-mortem examination revealed widespread cancer in the pelvic region. The allegation of negligence in the mistaken diagnosis, resulting in the removal to the mental hospital, was disposed of by an offer of compensation which the widow accepted. The allegation of negligence on the part of Mr. H. D. Fairman, the operating surgeon, took the form of suggesting that the patient was allowed to slip or fall or slide off the operating-table head first into a bucket. Mr. Fairman's evidence repudiated this suggestion; a witness who had assisted him said he did not remember that there had been any untoward incident. The judge asked plaintiff's counsel whether in the circumstances he alleged want of care against Mr. Fairman or not. Counsel replied that he did not reject Mr. Fairman's evidence. The judge then told the jury that there was no evidence against Mr. Fairman and the case against him was dismissed. Counsel for the defendant hospitals contended that Mr. Moon died of cancer and that the death had nothing to do with the operation. The paralysis, he argued, was just misfortune and nobody's fault. It was stated that the deceased had a protruding intervertebral disc; the jury were shown X-ray photographs of the spine taken before and after the operation. As regards the burn caused by the hot bottle, there was evidence that the deceased had asked a fellow-patient to fill his bottle; the fellow-patient had done so "with good intent"; the burn resulted from this action more benevolent than wise.

---

[1] See *Lancet*, Nov. 15, 1952, p. 993.

[1] *Manchester Guardian*, Nov. 10, 13, 14, 15, 19, 20.

Summing up to the jury, the judge commented on the absence of evidence from the anæsthetist. In the end the jury awarded £2000 on the claim of negligence against the hospital and £2000 for the loss of expectation of life. The judge gave judgment on the first £2000, with costs against the hospital, Mr. Fairman also to have his costs from the hospital board. No final judgment, however, was given on the second £2000. The judge is to hear legal argument in London (probably next year) as to the widow's right to damages for loss of expectation of life if the cancer had not supervened.

Another Hot-water Bottle Case

In Hickey *v.* North Liverpool Hospital Management Committee the plaintiff was a young married woman who went to hospital for the birth of her second child. According to the judge's findings, at some stage of her labour and the subsequent surgical treatment the patient was burned on the left hip by a hot-water bottle, the burn causing an indolent ulcer. Apparently at one time there were four stone hot-water bottles, filled from the hot-water tap, in the bed, each enclosed in a flannel jacket. There was evidence of the custom to place the bottles not actually in contact with the patient but with a blanket between it and her. At the stage mentioned there was a bottle at either hip and two bottles in the region of the plasma drip. The judge seems to have drawn the inference that as only one bottle had caused a burn, there must have been some negligence in respect of that bottle. If in cases of extreme shock, he thought, the blood-vessels do not dilate, the condition should have been the same in one as in another part of the body, supposing that heat of a similar degree were applied in similar conditions. He awarded special damages of £2 and general damages of £150 with costs. The patient had required some treatment as an outpatient after leaving hospital; a small operation under an anæsthetic had been necessary to clean the ulcer and encourage healing.

The judge referred guardedly to expert evidence from witnesses who, in his words, "frankly agree that their opinion is not the generally accepted opinion of the medical profession although of course their prophecies may in due course be believed." This seems to be an allusion to the theory that in very severe shock heat may be useless and even injurious.

Parliament

The Preregistration Year

IN the House of Commons on November 19, Mr. IAIN MACLEOD, Minister of Health, formally moved an order, which prescribes 12 months as the period of preregistration service made compulsory for newly qualified doctors, by the Medical Act, 1950. No objection to the proposed span of service was raised, but support was offered with discrimination as well as goodwill, and the debate ranged widely and usefully over practical difficulties that may need adjustment.

Mr. ARTHUR BLENKINSOP suggested that on the introduction of the intern year the opportunity should be taken to examine the whole medical curriculum so that too severe an extra strain should not be imposed on the student. The Goodenough Committee, he recalled, in sponsoring the preregistration year, had recommended that the training period should be no more than four and a half years. He also wondered whether the country as a whole was ready for the operation of this proposal. Was the Minister satisfied, he asked, that suitable posts were available for all who would need them? He hoped that the posts would not merely be a continuance of the old house-officer appointments but would enable the interns to move around in the hospital and get a valuable extra training.

Dr. BARNETT STROSS was also concerned that the student should make the best use of this extra year. What the student needed was not more theory, but further practical education with limited responsibilities. The intern, Dr. Stross suggested, should not be limited to surgery for six months and medicine for six months, but should go widely round the departments and learn more about treatment. Dr. Stross also pointed out that a medical student with a family might be receiving over £500 a year in grants at present, and it would be anomalous if under this scheme he dropped in the first six months to £350, with exactly the same responsibility, and his total remuneration for the second six months was only £400.

SATISFACTORY SERVICE

Mr. JOHN HYND believed that if an intern had completed 12 months' service it should be assumed that he had been satisfactory. In his view interns were no longer students; they were practising doctors taking the first stage of their practical experience in a hospital, which provided special facilities and opportunities not afforded in ordinary practice. Could there be some provision that any intern not considered satisfactory should be warned? Perhaps the best solution would be to drop the reference to satisfactory service altogether. It was also important that there should be some arrangement to carry the young doctor over the period when his education grant finished on qualification to the time when he obtained a post.

Mr. SOMERVILLE HASTINGS was anxious that the interns' time should be fairly divided between medicine and surgery. They must also have time, not only for study and thought, but for rest and recreation as well. Personally he had never been so tired as he was when he held his first six months' surgical appointment. The Goodenough report had made this point strongly and had suggested that in a teaching hospital the young doctor should only be in charge of perhaps 20 beds, and in a non-teaching hospital of perhaps 30. He felt that if an intern's services were not regarded as satisfactory during one of his two appointments he should be given another chance. Litigation for alleged neglect in hospitals had increased enormously since the introduction of the National Health Service, and he was afraid that those who lived on litigation would soon learn that there were such things as unregistered interns and would be ready to apply for compensation where these junior people had been involved. He thought every intern should be insured in a medical protection society.

POSTS AND ALLOWANCES

Mr. MACLEOD said it was everybody's opinion that by and large there would be enough posts next year in the preregistration service, but they might not be in exactly the right places. Only 200 students would qualify in the first three months of next year and it would be easier to start the scheme and deal with any teething troubles at a time when comparatively few people were qualifying. How the students were to get the posts, and whether they should apply for them and perhaps be interviewed before qualification, were difficult problems. In many things they would have to learn from experience. Often the qualified student would be able to spend part, or, with luck, all his preregistration year in the hospital where he had studied as an undergraduate. Mr. Macleod had invited hospital authorities to coöperate with the universities and medical schools to ensure that the newly qualified doctors should not have to wait an unreasonable time before they took a hospital post. Most of the interns would be ex-Service students who had been eligible to receive modified allowances from the Ministry of Education as house-officers after qualification. That system was to be continued for preregistration service, and a married man with one child would probably get about £414 compared with the £427 that he had been receiving during training. The Minister of Education would also pay for a period not exceeding two months a sum, based on the usual vocation allowance to newly qualified men who could not get a house-post as soon as they qualified.

Mr. Macleod was sympathetic to the suggestion that the unsatisfactory intern should be warned, but he was not responsible for deciding what form the medical curricula, and indeed this certificate, should take. The point raised by Mr. Hastings about the way in which the preregistration year should be spent was also important, but here again the responsibility rightly lay with the General Medical Council and not with him. But he promised to see that the views expressed by the House were brought to the attention of those responsible. He would examine the possibility that every resident officer should be compulsorily insured by a medical protection society. So far as he knew there had not been any inquiry about the length of general medical training, but there were a number of committees on allied subjects to this which were due to report in the near future.

Army Medical Services

In the House of Commons on Nov. 21, Mr. AUSTEN ALBU raised the question of the efficiency of medical services in the Army, and asked for reassurance that there was adequate supervision of the young doctors engaged in this work. If National Service was to be maintained for any length of time parents must have confidence that their sons would not be subject to unnecessary hazards due to carelessness in medical treatment.

Mr. J. R. H. HUTCHISON, under-secretary of State for War, said that the Army Medical Services were responsible for about 750,000 people, including not only soldiers but also many of their families. The health of the Army had never been better. Statistics of admission to hospital showed a continuous decline, and the health of troops in overseas stations was also impressive. All the National Service medical officers were fully qualified and most of them had had six months' hospital experience. Next year that period would be extended to 12 months. The National Service doctors were doing an extremely good job under the circumstances. There were 900 of them out of a total of 1550 medical officers. He agreed that, owing to the war, there was a shortage of medical officers with five to ten years' practical experience, many of whom were specialists. Measures to improve the situation were under review. The number of administrative commissioned officers in the R.A.M.C. had been expanded to free medical officers for purely medical duties.

Besides the R.A.M.C. officers honorary consultants to the Army were appointed by the Secretary of State for War, after consultations with the Royal Colleges, and the Army owed much to their generous help. Close links also existed with the local civilian services both at home and abroad, and these facilities worked both ways. Mr. Hutchison pointed out that there were fewer patients per doctor in the Army than in civil life, and the doctor was generally within easy reach of his Service patient. There were no waiting-lists for admission to Army hospitals, and we had military hospitals in all our major overseas theatres. For example, in B.A.O.R. there were 1750 beds—enough for 2·1% of the troops—which compared favourably with the beds available per head of the population in civil life. Taken all in all, parents and relatives could have confidence that their boys and husbands were getting the best medical attention.

QUESTION TIME

Reduction of Hospital Staffs

Mr. N. N. DODDS asked the Minister of Health if he would make a statement in view of the widespread concern at the suggestion by his department to regional hospital boards for reducing hospital staff levels.—Mr. IAIN MACLEOD replied: I am anxious that all proper economy should be observed in staffing the hospitals, and am considering what further guidance I should give on this subject to employing boards and committees.

House-officer Posts in Sheffield

Mr. GEORGE JEGER asked the Minister why many non-teaching hospitals in the Sheffield regional hospital area were excluded from the list of approved hospitals and institutions and recognised house-officer posts under the Medical Act, 1950, having regard to the inclusion in the list of hospitals of comparable size and status in the other regions; what advice he gave to the licensing body in the Sheffield region relating to the list of approved hospitals and recognised house-officer posts which resulted in the adopting of criteria different from those applied in other regions, as evidenced by the abnormally low proportion of posts approved in that region; and whether he was aware of the damage to the prestige of many major non-teaching hospitals in the Sheffield region and to their ability to attract medical staff which would be caused by their exclusion from the first published list of hospitals and institutions approved under the Medical Act, 1950.—Mr. MACLEOD replied: Section 2 of the Medical Act, 1950, gives me no jurisdiction in the approval of these posts. The Act leaves the approval of posts for this purpose entirely to the licensing bodies—i.e., the universities and, in England, the Conjoint Board of England (representing the Royal Colleges), and the Society of Apothecaries.

Mental Hospital Staff and Accommodation

In answer to questions Mr. MACLEOD stated that of the 294 mental hospitals and mental-deficiency institutions in the National Health Service 235 reported shortages of nursing staff at Sept. 30 last. 162 were short of male staff and 220 of female staff. All but 12 of the 107 mental hospitals in England and Wales were overcrowded.

Male Nurses

Replying to a question Mr. MACLEOD stated that about 7000 male nurses are employed in hospitals in England, of whom 5500 are in general hospitals, 400 in fever hospitals, and 1100 in sanatoria.

Patients' Access to the Minister

Sir WILLIAM DARLING asked the Minister why he approved Statutory Instrument 1811 under which patients at Broadmoor might not write directly to him, the Board of Control, or any Commissioner without having their correspondence previously inspected by a medical attendant; and if he would reconsider this proposal in the interests of the patients concerned.—Mr. MACLEOD replied: Statutory Instrument 1811 gives effect to one of the recommendations of the Broadmoor Inquiry Committee. The recommendation was accepted by the Government and I cannot agree to reconsider it now.

Hæmophilia Research

Replying to a question, Mr. A. H. E. Molson stated that recent work on hæmophilia by the Medical Research Council had been concerned chiefly with the preparation and clinical trial of concentrated blood-fractions which it is hoped will be more effective in treatment than the transfusions of whole blood or plasma used at present. These products were being tested in a number of different centres and preliminary results had been encouraging.

commend it. The success of this technique seems to depend entirely on the nursing staff. Sister Unsworth, of the Royal Alexandra Hospital for Sick Children, Brighton, who has charge of a ward from which 36 operations are performed each week, tells me that the practice there is to empty the capsules of quinalbarbitone ('Seconal'); the drug is then given with orange juice and concealed on the back of a spoon. In this hospital a failure is very rare. It would be interesting to learn the views and the methods of other ward sisters.

A long-acting preparation of atropine is also valuable when the anæsthetist has a long list of cases.

Dr. Bullough advocates the use of the intravenous route for the induction of anæsthesia. In this case I think it is preferable to add a suitable dose of gallamine triethiodide to the thiopentone, after which anæsthesia may be maintained with nitrous oxide, oxygen, and the minimum of ether.

Hove, Sussex. REX BINNING.

THE CAUSE AND TREATMENT OF LEG ULCERS

SIR,—Dr. High (Nov. 8) introduces an interesting point in regard to the occupation of patients with leg ulcers. While standing still the tonic contraction of the leg muscles has no pumping action on the blood and the venous pressure in the limb remains high. Normal people after standing for some time (e.g., surgeons operating) may develop a little œdema of the ankles, which disappears on walking. The standing policeman occasionally bends his knees. The result of long-continued standing, on individuals who have inherited the tendency, is dilatation of the superficial or deep veins of the lower limbs, the valves becoming incompetent.

I see no reason to believe, like Dr. High, that the benefits of walking when wearing compressive bandages are only psychological. The massaging effect of muscular movement helps to reduce œdema when the limb is compressed. Clearly compression cannot make a valveless pump efficient; but if valves are still present, though incompetent through dilatation of the veins, compression of the limb may help them to function. We know that in the non-thrombotic group dilated veins may contract after a period of rest, regurgitation disappearing for a time. Superficial varices may disappear temporarily after an illness spent in bed.

The striking difference, commonly seen, between patients with severe superficial varicosities but no œdema or skin changes and those with signs of venous insufficiency provides a clue to the cause of this latter trouble. If only the superficial leg veins become dilated, and their valves incompetent, no œdema or ulceration results. If, however, the deep veins (which carry about 90% of the venous blood from the lower limb) become dilated, the venous return is seriously affected. I use the term "varicose ulcer" exclusively in regard to this latter group, in which ulceration results from dilatation of deep veins and not from superficial varices which are probably also present.

Any series of patients seen in hospital and consulting practice is selected by the colleagues who refer them. Only the family doctor sees an unselected series, as I know from six years' experience in general practice. The important point is that, as other workers have also found, the majority of ulcers are post-thrombotic.[1]

Dr. Rivlin (Nov. 8) considers me to be sadly out of touch with contemporary specialist opinion, though how he can judge this I do not know. Probably he means that my views are not acceptable to such practitioners as concentrate on the treatment of superficial varicose veins. Dr. Rivlin also considers that I am putting the clock back. I wonder whether he thinks there has been much advance since he wrote in 1948: "The only certain way of healing a chronic varicose ulcer is to use the elastic-compression-bandage technique."[2]

Leeds. S. T. ANNING.

ARSENIC AND LEAD IN CIGARETTES

SIR,—To destroy insect pests, tobacco plants are often sprayed with lead arsenate. In view of the current interest in possible carcinogens in tobacco-smoke, it may be useful to record an investigation I have made into the lead and arsenic content of ten popular brands of cigarettes. Each sample analysed was the equivalent of one-fifth of the contents of each box (i.e., 2 out of 10, or 4 out of 20), duplicate samples being taken for examination for necessary confirmation. The results were as follows:

Brand no.	*Arsenic (parts per million)*	*Lead (parts per million)*
1	21	138
2	5	57
3	7	68
4	24	122
5	6	55
6	6	73
7	3	53
8	3	61
9	21	124
10	24	139

Except nos. 9 and 10, which were American, the cigarettes analysed were all of popular English brands sold as "Virginian." No doubt many of them contain tobacco which is in fact grown elsewhere than the United States.

In relation to carcinogenesis the wide variation in arsenic content may be important; but I would also call attention to the figures for lead, which are consistently high for all brands examined.

Both arsenic and lead were determined after oxidation with sulphuric and nitric acids, the former being completed by the Gutzeit method and the latter as sulphide colorimetrically in ammoniacal solution in the presence of potassium cyanide. Where the lead figure was very high and confirmation was required, extraction with diphenylthiocarbazone in chloroform was carried out, but this elaboration was generally found unnecessary.

EDWIN H. BUNCE

Consulting chemist; formerly Public Analyst, Government of Burma.

A NEW ANTISEPTIC

SIR,—We were interested to read your annotation on this subject (Nov. 15), particularly as our preparation 'Bradosol' was mentioned. We would like to query the statement that the quaternary ammonium compounds "have no appreciable effect on the pseudomonas group, the tubercle bacillus, or bacterial spores." Whilst this may be true for some of these compounds, bradosol is, *in fact, active in high dilution against Pseudomonas pyocyanea.*

Neipp and Gross,[3] Seidenberg,[4] and independent workers in this country all give figures of the order of 1 : 10,000 for bacteriostatic action over 24 hours and 1 : 100 bactericidal action in 2½ minutes. We appreciate that in these cases bactericidal tests may not be entirely satisfactory, for there is no indication that an inhibitor was used when transferring samples to the final culture medium, but they do at least show that this compound has an efficient bacteriostatic action.

According to Berry,[5] in ordinary circumstances this bacterio-static action is irreversible and leads to death of the organism due to a steady leakage of nitrogen and phosphorus compounds through the bacterial wall on to which the antiseptic com-pound had been adsorbed. This process can only be arrested or reversed if a specific inhibitor is present or if the adsorbed layer is in some way removed. The same writer also points out that revivers are now known for bacteria which have been apparently killed by iodine and formaldehyde, among other compounds, and yet this does not appear to have precluded the widespread use of these older antiseptics. One would therefore feel that quaternary ammonium compounds cannot be condemned solely on this count.

---

[1] Anning, S. T. *Brit. med. J.* 1949, ii, 458, 811.

[2] Rivlin, S. M. *Ibid.* 1948, ii, 723.

[3] Neipp, L., Gross, F. *Schweiz. med. Wschr.* 1949, 79, 980.

[4] Seidenberg, S. *Ibid*, p. 978.

[5] Berry, H. *J. Pharm.* 1951, 3, 697.

Neipp and Gross also quote satisfactory figures for the action of bradosol against *Bacillus subtilis*, a spore-forming organism. Further, Eisman et al.[6] reported on the activity of an aqueous 1 : 1000 solution of bradosol on surgical instruments contaminated with suspensions of various organisms in blood and pus. These included pseudomonas, *Bact. coli*, and the anthrax and tetanus bacilli. Even when the instruments were dried before testing, sterilisation was complete in a little over 10 minutes. The same arguments on inactivators apply also to spore-forming organisms, and here again bradosol is likely to prove at least a highly efficient bacteriostat.

May we also draw your attention to a paper by Gabriel,[7] in which he speaks highly of bradosol as an antiseptic dressing in rectal surgery, a field notoriously liable to postoperative infections. He concludes that, in addition to being a good antiseptic, bradosol seems to inaugurate rapid wound healing by granulation.

We agree with the closing sentence of your annotation and would be only too happy to supply trial material to anyone who is interested in investigating the properties of the quaternary ammonium compounds.

Ciba Laboratories,
Horsham, Sussex.
A. R. G. CHAMINGS.

RÔLE OF THE BRONCHIAL VEINS IN MITRAL STENOSIS

SIR,—I should like to make a few comments on the very interesting paper by Dr. Gilroy and his colleagues (Nov. 15).

The term *Lungenstarre* ("lung rigidity" seems to be a better translation than "stiff lung") was coined by von Basch [8] on the basis of clinical, pathological, and experimental evidence. Engorgement of the small pulmonary vessels, in his view, leads to increased tension in their walls, and this hypertension in turn to impaired elasticity of the lungs (*Starre*), owing to the comparatively large volume which the vascular tree occupies within the lung tissues. von Basch's concept long dominated Austrian and German opinion on pulmonary congestion in mitral disease.

There is another point I should like to raise regarding the mechanism of acute œdema of the lungs. Supposing that Dr. Gilroy and his colleagues are right in their views on the decompressive function of the pleurohilar veins, then acute pulmonary œdema is much more likely to be due to interruption of this mechanism by a neurovascular reflex rather than to acute left ventricular failure. It is difficult to reconcile the maintenance or even exaggeration of a high systolic systemic blood-pressure, so often present in cardiac asthma, as well as the prompt beneficial effect of morphine, particularly if given intravenously, with the idea of sudden weakness of the left ventricle.

It might seem strange that a feature commonly associated with chronic left ventricular strain should be discussed under the heading of mitral stenosis; but dynamically, in long-standing hypertensive or aortic heart-disease, the left atrium is put under similar conditions in view of the increased pressure and increased residual volume in the left ventricle resulting from its reduced output.

Even in acute myocardial infarction when acute pulmonary œdema accompanies or, occasionally, replaces the status anginosus, a coronary-pulmonary reflex may very possibly act as the initial causative agent before—if ever—the left ventricle begins to fail.

DENTAL TREATMENT OF CHILDREN

SIR,—Consideration for your limited space prompts me to reply selectively to your annotation (Nov. 15) and to "School Dental Officer's" rejoinder to my letter.

It is an established fact that the very high wastage factor inherent in the New Zealand dental nurses' scheme nullifies the advantage of her shorter training. It is not clear why this should be so, but it is an entirely unwarranted assumption that wastage among women dental surgeons is of a similar order. The conclusions drawn by your correspondent from this assumption are mere shadow-boxing.

He also attributes an opinion to me which I did not intend to express—i.e., that "children's dentistry can be learnt by gaining skill and experience in treating adults." The point that I wished to make was that *before* any person is permitted to practice fillings and extractions on children she should have undergone that basic training in dentistry which is acquired through working in the conservation department of a dental school, where she will learn to cope with conditions which no amount of academic instruction on manikins, &c., can anticipate. She will learn to appreciate and be thankful for a high degree of coöperation from her first patients, who may sense and make allowances for a beginner's difficulties, even though the work is done under close supervision. Conservation work on children differs from that on adults inter alia in that it is more exacting and must be done in a smaller mouth on smaller teeth with larger pulps in less time than would be acceptable in adults.

The impracticability of teaching extraction on children is so obvious that an amendment to the Dentists Bill was carried in the House of Lords which would have confined such practices to deciduous teeth only. By all means let us teach children's dentistry, but we must not consider children as so much expendable "teaching material" to be practised upon by the raw beginner!

Your belief that the limited number of suitable candidates makes any substantial long-term increase in numbers of dental surgeons impossible is unsupported by facts. The chairman of the Dental Board, Dr. E. W. Fish, stated earlier this year that "there are nearly two and a half times as many applicants to enter the profession as the schools can absorb," and this although not many of these applicants could expect such generous allowances as are made to the New Zealand nurse, who has all her training fees and maintenance paid for her. Present fluctuations in certain dental school intakes do not disprove the fact that about 900 potential recruits to the dental profession must have been lost annually for a number of years through lack of training facilities. (These fluctuations are apparently connected with certain new arrangements recently introduced at school level, and no hasty conclusions should be drawn as to their significance.)

What makes you think, Sir, that the fifty million of these islands cannot—given enlightened public support—produce as many recruits to the dental profession (per capita) of adequate intelligence, as do, for example, the people of the United States of America, where almost four times as many boys and girls apply each year for admission to the dental schools as can be accepted? The training facilities in that country have been sufficient to give their people a ratio of dentists to population of about 1 : 1750 without any reduction in standards, while further expansion of dental schools is under way and a ratio of 1 : 1000 is the declared goal. This must be compared with the present ratio in this country of 1 : 4400!

Dare one suggest as a possible cause of our dilemma that at present, far from having lowered our basic science requirements, particularly in physics and biology, we have in fact been expecting from our dental students similar knowledge to that expected from the student who takes an honours course, in say, nuclear physics or advanced botany ?

London S.W.15. E. ROSENSTIEL.

*** Mr. Rosenstiel confuses the number of applicants for admission to the dental schools with the number of suitable candidates. Before the General Certificate of Education examination results are known each summer, most dental schools no doubt have more applications for the next course of training than they can accept, and some have far more. But the results of the school-leaving examinations reduce the number by weeding out applicants who fail to reach the level of scholastic attainment required for admission to the dental course. Those directly concerned with student selection in the schools find that, when it comes to enrolling students for each course, the number of suitable candidates, taking the country as a whole, is roughly equal to the number of available places. A candidate may not be able to enter the school of his choice ; but if he has reached the requisite scholastic level he seldom fails to find a place somewhere.

The implication of Mr. Rosenstiel's final paragraph is that the standards for admission to the dental schools are set too high and ought to be lowered. We oppose this view on the ground that lowering these standards would entail lowering the standards of dental training. A tutor in one of the dental schools recently traced the fortunes of a score of students and found that only 10% succeeded in completing the course without mishap : about an equal number failed to complete their training, and the rest qualified only after failing at least one of their qualifying examinations. In this particular course this last group of students between them required 32 academic years more than they should have done to qualify as dental surgeons. Had the standards of admission to this school been lower, the wastage of time and training facilities would have been even greater. Though the number of entrants to the schools could no doubt be increased by easing the criteria for admission, it is probable that the additional students admitted could complete the dental course only if the standards of training were also lowered. This seems to us an unacceptable solution of the problem of the shortage of dentists.—ED. L.

"WISDOM IS NOT ENOUGH"

SIR,—In your issue of Nov. 15 Prof. Robert Platt concludes that reason should influence the choice of the ends towards which our endeavour is directed. He adds that for him rationalism means the ability to avoid self-deception. He then goes on to say that there is no need to appeal to supernatural authority to cultivate kindly feeling and veracity—the two qualities he considers would make the world a better place if more generally practised.

With all this most Christians would agree. But his philosophy raises certain problems.

It seems that Professor Platt is preaching the religion labelled humanistic rationalism. He makes human reason the god of this religion. The question arises, how is one to decide whether a particular act is right or wrong when the standards of kindly feeling and veracity of different men vary ? For example, Hitler presumably felt that his standards of kindly feeling and veracity, from the point of view of the good of the German nation, involved the extermination of the Jews. Stalin presumably argues that the State is the arbiter of kindly feeling and veracity, and therefore the State is entitled to remove to Siberia those whom it considers transgress these standards. If there are no supernatural sanctions to evil human acts, why should any State or individual bother about any standard of conduct other than expediency ? (I do not mean that fear of God should be the only motive for conduct—this is contrary to Christian teaching—but that it seems reasonable to suppose that we shall each one of us h to render an account of our deeds some day, for it seems cl that many evil men get away with their misdeeds on this planet).

Philosophical or religious conclusions (the name is immaterial) should be based on a submission of *all* available evidence to rational analysis. No Christian can avoid asking the question "What do you make of the historical evidence, based on long and close investigation, that Jesus Christ was God and claimed that all authority in heaven and earth had been given to him, and that his *resurrection from the dead is part of the evidence in support of his claim ?*" (Lunn gives the matter detailed consideration in his book *The Third Day*, in which will be found references to the important work of Sir William Ramsay).

I am not doubting for one moment Professor Platt's sincerity ; but by his own standards the evidence for such a momentous claim as Christ's must be submitted to careful scrutiny. Professor Platt may well have done this and rejected that claim, but in view of the fact that so many doctors and/or natural scientists are unaware that Christians base their claims on *rational analysis of evidence*, I feel it right to make this point. It has always seemed to me that those who ignore evidence unfavourable to their case are deceiving themselves ; for, as Professor Toynbee has pointed out in his *Civilization on Trial*, religion is the serious business of mankind, whether you call it philosophy or not.

Dundee. A. T. MACQUEEN.

CAROTENÆMIA

SIR,—With reference to Dr. McConaghey's most interesting article (Oct. 11), I would like to record the case of a *young woman*, aged about 20, who had been having mild epileptiform attacks for approximately $4^1/_2$ years.

During these attacks her circumoral region especially, but also to a most striking extent the other parts of her body, became "reddened." When she was first seen, her whole body presented the appearance of generalised "sun tan" pigmentation. The patient had received large doses of vitamins, including riboflavine, from her family practitioner. Two days before an attack about which my opinion was sought, *there* had been an increase in the general pigmentation and a yellow colour had developed around her mouth. *Her* urine was deep-yellow with bright-green fluorescence.

No further investigations were carried out *in this* case. At the time I was unable to discover any previous record of such a syndrome.

I am indebted to Prof. N. L. Edson and Mr. C. M. Todd, of the department of biochemistry in the *Medical School*, Dunedin, New Zealand, for information about the case described here.

Hill End Hospital,
St. Albans. HAROLD PALMER.

BUTAZOLIDINE

SIR,—Clinical trials in *Australia support* the observations of Dr. Currie (July 5) on the antirheumatic action of butazolidine. Striking relief, in all forms of rheumatic disease, develops 24–36 hours after oral treatment has begun and persists for 36 hours after cessation. The maintenance dose is about half the initial dose. With initial doses of 0·6–0·8 g. per day few complications have *occurred*.

Butazolidine, as the first specifically antirheumatic drug, marks a new advance in therapeutics and opens large fields for research into the mechanism of its action. Our thanks are due to Dr. Currie, whose conservative estimate confirms his preliminary report of more than a year ago.[1] And it is fitting that Glasgow, for long the seat of Ralph Stockman's research, should be in the fore-front of this advance.

Melbourne, Australia. MICHAEL KELLY.

DEATH AFTER ANÆSTHETIC WITH HYPOTENSION

SIR,—The following case may be of interest to your readers.

A fit man of 76 was operated on for the removal of an epithelioma of the left ear. The growth was 2 in. in diameter and attached to bone. Two deep cervical glands were palpable. The preoperative blood-pressure was 160/85 mm. Hg, and the temperature and pulse-rate were normal.

Anæsthesia.—'Omnopon' gr. $^1/_6$ and scopolamine gr. $^1/_{300}$ subcutaneously were given as premedication, and anæsthesia was induced at 9.20 A.M. with thiopentone (0·5 g.) followed by pethidine (50 mg.) and *d*-tubocurarine (15 mg.). The cords were sprayed with 10% cocaine, and a no. 9 cuffed tube was passed. Nitrous oxide (4 litres) and oxygen (2 litres) were given through a circle absorber, and the respiration was assisted at first. The table was tilted to about 20° head up, and pentamethonium bromide (50 mg.) was given intravenously before the surgeon started. The pulse was palpable at the wrist throughout the operation, which took 50 min., and the blood-pressure, measured by this means, remained between 50 and 60 mm. Hg during this period. Electrocardiograms taken before, during, and after the hypotensive phase showed no change.

Operation.—The growth and the left pinna were removed, and a block dissection of the glands of the neck on the left side was carried out. The left jugular vein was tied. The defect in the skin was covered with a flap from the occiput and a skin-graft from the abdomen. The operation site was bloodless throughout.

Postoperative Course.—The table was levelled at the end of the operation, and the systolic pressure rose to 70. Atropine (0·6 mg.) followed by neostigmine (2·5 mg.) were given intravenously, although the patient was breathing spontaneously at this time. An hour later the blood-pressure was 90/60. When the patient returned to the ward his skin was a good colour, warm, and not sweating, and the pulse at the wrist was fair. The pharyngeal reflex was absent. The blood-pressure continued to rise steadily, but the patient took longer than usual to recover consciousness. By 3 P.M. he was awake, and his blood-pressure was 120/80. For the rest of the day he seemed perfectly normal, talking lucidly, taking fluid by mouth, and in full control of his limbs. He was quite well when seen again at 9 P.M. The following morning, however, he was lethargic and his speech was slurred. He had a left facial palsy, a flaccid left arm, and a weak left leg. The plantar response was extensor. He was incontinent. His condition deteriorated throughout the second postoperative day, although the blood-pressure was maintained. He lost consciousness, developed a terminal bronchopneumonia, and died on the third day.

Necropsy.—I am indebted to Prof. T. F. Hewer for the report from which the following is taken :

"Thrombosis of left internal carotid artery due to atheroma. Atheromatous narrowing of right internal carotid artery. . . . Cerebral softening due to thrombosis of right middle cerebral artery. There is patchy atheroma in the arch of the aorta, and very marked calcified ulcerated atheroma of descending thoracic and abdominal aorta. At the commencement the left internal carotid artery is completely occluded by blackish brown thrombus lying on top of calcified atheroma. This local thrombus extends for 1·8 cm., beyond which the lumen is merely pin-point. On the right side there is a similar plaque of calcified atheroma, which has reduced the lumen considerably, but there is no thrombus. After fixation, the brain shows recent infarction of the periphery of the right parietal lobe with irregular small hæmorrhages. The right middle cerebral artery shows a recent thrombus fairly near its origin . . . . With marked atheromatous narrowing of the right internal carotid artery and complete occlusion of the left internal carotid artery, the cerebral circulation was obviously impaired, depending mainly on vertebral supply. Artificially induced hypotension during an operation diminished cerebral blood-supply sufficiently to cause thrombosis in an already impaired circulation."

There are two important points, one general and one particular. The first is the delay in recovery of consciousness : if it is a common finding that lowering the blood-pressure during operation prolongs narcosis (and Enderby and Pelmore [1] admit that "the immediate postoperative recovery is a little slower than normal"), then it is difficult to escape the inference that this is due in part to a stagnant anoxia of the cerebral cortex. The second point is the occlusion of a carotid artery by atheroma. This condition was first demonstrated by Egas Moniz et al.[2] who diagnosed 4 cases by cerebral angiography ; since then a definite clinical syndrome has been established,[3] [4] and Denny-Brown [5] says "any severe fall in systolic pressure . . . is likely to provoke a catastrophic necrosis of a large part of the area supplied by the middle cerebral artery." He suggests that this condition is a not uncommon cause of cerebral thrombosis. It is interesting to note that in one of Fisher's patients [4] occlusion followed a fall in blood-pressure after an operation for "radical neck dissection," and one of Ameli and Ashby's patients [3] was a blood donor who had just given a pint of blood. It may be that carotid-artery disease is another hazard sent, like coronary-artery disease, to plague the anæsthetist.

Hillingdon Hospital,
Middlesex.

R. I. BODMAN.

BOOKS INFECTED BY SCARLET-FEVER PATIENTS

SIR,—Although we think it premature to discuss our findings, regarding the recovery of streptococci from library books used by scarlet-fever patients, until our paper is published, it is worth while pointing out in reply to Dr. Glaisher (Nov. 8) that the "control" books from patients with Sonne dysentery were examined for streptococci and not *Shigella sonnei*. This was stated correctly in your report (Oct. 18) of the investigation.

E. H. GILLESPIE
Director, Public Health Laboratory, Sheffield.
Formerly Director, Public Health Laboratory, Leicester.

A. I. ROSS
Deputy Medical Officer of Health, Leicester.

SOCIETY FOR SPASTICS

SIR,—The medical profession is often charged with inertia and complacency ; and, while these charges may sometimes be justified, they are not always so. From your annotation last week on the new National Spastics Society it would appear that this body, set up by parents of cerebral-palsied children, is preferring (very tactfully) just these charges jointly against the medical profession and the education authorities. One must ask whether these charges are justified.

It is certainly true that both medical and education authorities are fully aware of the need for improved facilities for cerebral-palsied children. The Ministry of Health and the Medical Research Council are both involved in research into the problem with the collaboration of the London County Council which, having started the first cerebral-palsy clinic [6] and the first parents' advice clinic in this country, is still taking a lively interest even though the hospitals concerned have now passed under the control of the health service. Invaluable information has been gathered by Craig,[7] Holoran,[8] Dunsdon,[9] and many others. But it is true that action on a large scale has not followed. Is this the result of inertia or of prudence ?

Dunsdon has shown that worth-while results do not necessarily follow the setting up of a special school for cerebral palsy. Yet that good results can be obtained from treatment has been known since the time of Little. The present urgent need seems to be for the training of personnel: these could use, to a large extent, facilities already available. Recognising this, the Chartered Society of Physiotherapy has placed infantile cerebral palsy on its syllabus for students, and I have recently been privileged to arrange for the society two post-graduate weekend courses. Such measures, however, cannot do more than provide an introduction to the subject; more valuable are the 6-week courses open to any personnel concerned with the diagnosis or treatment of cerebral palsy, which have been held three times a year for several years at Queen Mary's Hospital for Children, Carshalton. The deans of the Institutes of Neurology and of Child Health have under consideration arrangements for a jointly organised course for doctors.

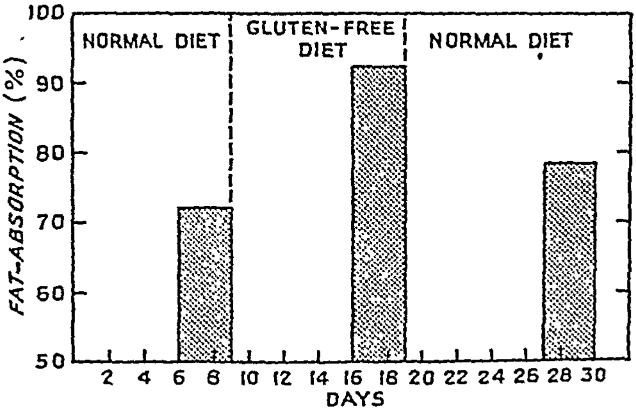
It would appear, then, that much is being done to improve the facilities for the child with cerebral palsy. I hope that the National Spastics Society will see their way to coöperate in measures which should, in a few years, make some of their tasks—e.g., the setting up of a residential special secondary school—unnecessary.

London, W.1. WILLIAM DUNHAM.

MANAGEMENT OF CŒLIAC DISEASE

SIR,—The article by Dr. Sheldon and Dr. Lawson (Nov. 8) poses a query concerning the period for which a gluten-free diet should be continued. The following case suggests that in some instances, if major complications are not to arise later in life, such a diet should be continued for a very long time, or even indefinitely.

A housewife, aged 53, gave a history of attacks of diarrhœa, distended abdomen, and "bowel trouble" in childhood. She was admitted because of severe backache due to a collapsed lumbar vertebra; there was generalised osteomalacia with spontaneous rib fractures. She had also moderate diabetes mellitus of 19 years' duration and hypertrophic hepatic cirrhosis. There was no evidence of hæmochromatosis; the urine could be made acid, and abnormal amino-aciduria was not constantly present. The serum-bilirubin level was 2·6 mg. per 100 ml.; thymol turbidity 8 units; alkaline phosphatase 30 units; serum-albumin 3·6 g. and serum-globulin 3·9 g. per 100 ml; fæcal urobilinogen 55 mg. per 100 g.; serum-calcium 9·0 mg. per 100 ml.; serum-phosphorous 3·4 mg. per 100 ml.; 24-hour urinary calcium output 30·5 mg. The effect of a gluten-free diet on fat absorption is shown in the accompanying figure. There was no evidence of creatorrhœa, and splitting of fat was normal.



Fat absorption on a normal diet and on a gluten-free diet, each containing 70 g. fat per day.

Despite the diabetes and cirrhosis a diagnosis of idiopathic steatorrhœa following cœliac disease is reasonable.

In this case the fact that fat absorption is very much improved on a gluten-free diet, taken in conjunction with the patient's history, suggests that had she been on a gluten-free diet all her life she might not now have osteomalacia. If the cirrhosis is secondary to amino-acid malabsorption she might even have avoided that too.

Manchester Royal Infirmary. R. S. SAVIDGE.

DOWNWARD TREND IN BREAST-CANCER MORTALITY?

SIR,—In his Dorothy Platt lecture, on Progress in the Treatment of Breast Cancer, published in your issue of Sept. 13, Professor Smithers says:

> "There are also difficulties with death certification since the tendency to record death as due to breast cancer in any patient who has once had the disease is so strong. Until 1940 in fact, the Registrar-General's office often changed the recorded cause of death to cancer when this was mentioned as a subsidiary cause by a doctor who had himself attributed the death to something else. It is going to be difficult to judge the effect of treatment by changes in mortality-rates if we are never going to let a patient who has once had breast cancer die of anything else."

If, in females under 60 years of age, any appreciable proportion of deaths from diseases unrelated to breast cancer has been charged to breast cancer, the decline in mortality from these diseases should have caused a decline—though admittedly a small one—in the recorded breast-cancer mortality of that age-group. The lack of any such decline is evidence that deaths charged erroneously to breast cancer in those age-groups were relatively few. This is consistent with general clinical experience. The rates for older ages have been more subject to error. In considering them due allowance for it must be made—and can be made when age-specific rates are used as a basis of comparison.

Professor Smithers then says: "With all these difficulties, however, if correction is made for the growth of the population and its increasingly adverse age composition a slight downward trend in mortality-rate for England and Wales appears." He doubtless refers to a trend line based on age-adjusted "corrected" data of the short and variable period 1930–48, as presented by Smithers et al.[1] In this connection the Registrar-General has cautioned that "the study hitherto made of mortality trends for cancer sites by means of standardised rates at all ages combined was of limited value since it obscured great differences in the behaviour of rates at different periods of life, and these may be important in any attempt to elucidate the causes underlying the trends."[2] In breast cancer the trend based on age-adjusted figures combines the artificially changing trends in older age with the persistently level trends in other age-groups. These significant and reliable level trends are in this way obscured. Hence the basis for comparison used by Smithers et al. is fallacious.

Though changes due to a drastic change in book-keeping in 1940 were also confined largely to the older age-groups, Smithers et al., in an effort to eliminate discontinuity produced by that change in book-keeping, used a "correction factor" for the aggregate of all ages. Like age-adjusting, the use of this correction factor imposes on the aggregate the artificial changes largely confined to older age, and thus gives a distorted impression of the real situation.

There are two other, but minor, objections to the basis they used.

An abrupt decline in the rate for all causes (combined) in the older age-groups about 1940 in England, at variance with the past and with other experience, suggests some artificial factor. Whatever that factor may be, there is no reason to assume that it would not similarly affect breast-cancer mortality. Indeed the nearly 15% drop between the rates of 1936–39 and 1940–44 in the older age-group—a difference quite independent of the change in book-keeping—is fairly confirmatory evidence that such a factor did affect recorded breast-cancer mortality. Further, it is not likely that the full effect of the change in book-keeping in 1940

---

1. Smithers, D. W., Rigby-Jones, P., Galton, D. A. G., Payne, P. M. *Brit. J. Radiol.* 1952, suppl. no. 4; Introduction, p. x.
2. Registrar-General's Statistical Review, 1940–45. Text. Vol. I. Medical. H.M. Stationery Office; p. 142. Registrar-General's Statistical Review, 1946–47. Vol. I; p. 144.

would be evident in the space of 2–3 years: it is more likely that the change would be progressive for some longer time and would thus interfere with even the internal comparability of the rates subsequent to 1940. While the validity and the weight of these two admittedly minor objections can be determined only by later experience, they cannot be disregarded when the rates most involved in them—i.e., those for older age—are included indiscriminately as a basis of comparison, as they are in the age-adjusted corrected rates.

The refutation of Professor Smithers's implication need not rest solely on showing that the basis of his comparison is fallacious, nor yet on analysis of the age-specific rates up to 1939, with the later data excluded.[3]

The Registrar-General himself has applied appropriate age-specific conversion ratios to the age-specific rates of the years preceding the change in book-keeping, so as to allow for that change and thus make the rates of those years fairly comparable with those of subsequent years. These converted rates, in summary form, taken from the Registrar-General's Statistical Reviews [4] are shown in the accompanying table along with the rates up to 1949. While age-specific rates have their weaknesses, they, unlike age-adjusted "corrected" aggregate rates, do not obscure those weaknesses; nor, when due allowance is made for the latter, do they distort the facts of the case. They show the full picture, and in their own characteristics reveal much of their fallacies and their reliability. They allow fair separation of the false and the true so that the true, freed from the false, can be used for comparison.

It is apparent from the table that in the past 20–30 years departures from a level trend are largely confined to the rates of older age. Checking these rates with the rates for all cancer, for other causes, and for all causes combined, demonstrates that such departures from the general level are artificial. On the other hand, the rates in the other age-groups remain fairly constant over the same period. Some small leeway must, of course, be allowed for the effect of possible changes in the age distribution within the specific age-groups, and too much must not be made of small fluctuations.

Interpreted with due regard for their quality, the figures in the table show indubitably that there has been no real decline in breast-cancer mortality in England and Wales. This finding, based on the full picture of age-specific rates converted to reasonable comparability through the use of appropriate age-specific conversion ratios, must take precedence over that of Smithers et al.

Professor Smithers makes two other statements that seem to me to lack support. He says: "Those who are most persistent in telling us that there is no evidence of improvement in survival due to treatment also maintain that early diagnosis makes no difference to the prognosis. This is not so." In examination of highly representative examples of all types of evidence usually supposed to support his dogmatic four-word negation, none was found clear-cut or conclusive; much was based on ambiguous figures and was inconsistent, and some was patently a misinterpretation of data—a failure to distinguish between stage (type) and duration.[5] If he has unequivocal evidence to warrant his statement, it is unfortunate that he did not present it. Secondly, he says: "With the more malignant tumours early treatment is of great importance." But here again he gives no data. In sharp conflict as it is with Bloom's findings,[6] this statement, too, must be set aside until proof is provided. Further, unless we are wrong in supposing that the development of metastases, after their spread, is independent of any specific influence of the primary lesion, there is no logical basis for assuming that treatment achieves material postponement of death.

BREAST CANCER IN FEMALES: ESTIMATED ANNUAL DEA
RATES PER MILLION IN ENGLAND AND WALES

Year	Age (years)					
	0–34	35–	45–	55–	65–	75 a ove
1911–20	6	176	474	696	946	150
1921–30	7	187	508	782	1052	174
1931–35	8	189	529	839	1098	184
1936–39	8	184	516	830	1132	188
1940–44	9	201	533	823	1114	161
1945	9	198	500	784	1067	159
1946	9	211	531	834	1122	162
1947	9	224	520	785	1092	171
1948	9	211	514	804	1082	171
1949	10	206	493	763	1112	175

"In this table the rates for 1936–39 are derived from the d tabulation for those years, and those of earlier periods have b adjusted by the appropriate conversion ratios obtained from t tabulation, making each series of rates comparable with those 1940–44 and 1945" [7] and later.

Professor Smithers himself has eliminated or expos the dubious or fallacious quality of all other eviden (e.g., higher survivals in some series than others) usual advanced to support his contention that changes time and type of treatment over the years have achiev a large increase in survivals. Thus his contention left without any basis of fact, and, in view of the consiste evidence to the contrary, must be rejected.

Certainly it is necessary, as he says, that the clinici warm his facts with compassion when dealing wi patients. That is often thoroughly good medicin But it is just as necessary that he keep them cold wh dealing with himself. Facts must have the same mea ing to the clinician as to that motley group of "path logists, hygienists, biometricians, and statisticians, t pyrrhonists of medicine" for whom presumably special warming of the facts is required.

Public Health

The M.O.H. and the Hospital Service

Dr. E. C. Downer, medical officer of health for Middle brough, says, in his report for 1951, that contact wi the hospital service is still embarrassed by his having connection with any of the three hospital manageme committees in the area or with the committee of a hospital. Dr. Downer suggests that the M.O.H. shou not be a member of any hospital management co mittee, for he cannot have two allegiances: but might attend committee meetings as an observer a have access to agendas and minutes. "The Medic Officer of Health should know what is going on in t Hospital Service and what developments are taking plac just as the Hospital Management Committees, throu their representatives on the Health Committee, ha constant and regular access to what is the mind an policy of the Local Health Authority."

Plantar Warts in School-children

In his report for 1951, Dr. Reginald Leader, medic officer of health for Ipswich, describes an investigatio into the prevalence of plantar warts in school-childre Of 664 girls in secondary schools, 2·1% were affected.

Use of Mass Radiography

In a report to the Liverpool Regional Hospital Boar the senior administrative medical officer suggests th mobile mass-radiography units would be better employe in examining general practitioners' patients than confining their attention entirely to industrial survey "Since 95% of notifications of pulmonary tuberculos

originate with general practitioners, it would only seem right that they should have the facilities of miniature radiography at their disposal at every opportunity. Such a service would not only discover a number of early cases, but also many unrecognised cases, which have been estimated at as many as 4 per 1,000 of the population."

World Statistics of Causes of Death

The World Health Organisation has published the fourth report[1] in the series dealing with the causes of death classified by country, sex, and age-group. It has been possible for the first time to give mortality statistics based on the new *International Abridged List of Diseases and Causes of Death* which was devised in 1948. Of the 54 tables in the report, 20 contain figures classified according to the new list, and other countries have since adopted this classification or will shortly do so.

Births, Marriages, and Deaths

BIRTHS

FATTI.—On Nov. 18, in Johannesburg, to Mavis, wife of Mr. Libero Fatti, F.R.C.S.—a daughter (Elisa Margherita).

SHEPHERD.—On Nov. 21, at the Middlesex Hospital, London, to Audrey (née Arnott), wife of Dr. Peter Shepherd—a son.

MARRIAGES

MACDOUGALL—HANNA.—On Nov. 15, at Las Vegas, Nevada, U.S.A., John Alvah MacDougall, O.B.E., M.D., F.R.C.S., to Beulah Elizabeth Hanna.

DEATHS

ARTHUR.—On Nov. 21, the Rev. John William Arthur, O.B.E., M.D. Glasg., D.D. St. And., late of Kikuyu, Kenya, and Woodburn Terrace, Edinburgh.

WILSON.—On Nov. 18, James Dunlop Octavus Wilson, M.D. Glasg. of Drumsheugh Place, Edinburgh, formerly of Endrick, Alloa.

WILSON CLYNE.—On Nov. 18, James Wilson Clyne, M.B. Aberd.

Appointments

DOUGLAS, MARY, M.D. Edin., D.M.R.T.: radiotherapist (consultant), Royal Infirmary of Edinburgh.

HILL, R. L. T., M.B. Glasg., D.M.R.D.: part-time consultant in radiology, Bradford Royal Infirmary, St. Luke's Hospital and other hospitals in the Bingley, Keighley, Skipton, and Settle H.M.C. group.

ROSIE, J. M., M.D. Glasg., D.P.M.: consultant psychiatrist and deputy medical superintendent, Craig Dunain Hospital, Inverness.

TLUSTY, K. H., M.D., D.C.H. Rome, C.P.H.: asst. M.O., maternity and child-welfare department, Sheffield.

WATSON, J. A. G., M.B. Lond.: asst. M.O., maternity and child-welfare department, Sheffield.

YOUNG, AUSTEN, M.B. Edin., F.R.C.S.: part-time consultant E.N.T surgeon, Royal Infirmary, Sheffield.

Liverpool Regional Hospital Board:

BAUER, FRANCIS, M.D. Prague, F.R.C.S.E., D.L.O.: consultant otorhinolaryngologist, hospitals in the North Liverpool area.

MCFARLAND, J. C., M.D. Lpool, F.R.C.S.E., D.P.H., D.L.O.: part-time consultant otorhinolaryngologist, Southport Promenade Hospital.

MARTIN, DOREEN, M.B. Lpool, M.R.C.O.G.: part-time consultant obstetrician and gynæcologist, Wallasey Hospital for Women.

TURNER, D. P. B., F.R.C.S.: part-time consultant general surgeon, East Liverpool group of hospitals.

South-East Metropolitan Regional Hospital Board:

HAFNER, R. H. V., F.R.C.S.: consultant orthopædic surgeon, Camberwell group of hospitals.

HINDS, S. J., M.R.C.S., D.M.R.: consultant radiologist, Dartford, Medway, Gravesend and Mid-Kent group of hospitals.

MCDOUGALL, BERTHA, M.B. St. And., D.A.: consultant anæsthetist, Brighton and Lewes group of hospitals.

SAMMAN, P. D., M.A., M.D. Camb., M.R.C.P.: consultant dermatologist, Orpington and Sevenoaks group of hospitals.

SAMRAH, M. E., M.B. Lond., D.A.: consultant anæsthetist, Brighton and Lewes group of hospitals.

SPACEK, M. R. W., B.A., M.B. Dubl., D.A.: consultant anæsthetist Brighton and Lewes group of hospitals.

WOOD, P. H., F.R.C.S., D.L.O.: consultant in E.N.T. surgery, Medway and Gravesend group of hospitals.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

Notes and News

STANDSTILL ON PROGRESS

IN their report for 1950–52 the Luton and Hitchin Group Hospital Management Committee record with pleasure considerable progress in upgrading their hospital facilities and accommodation. But they remind us that this general improvement has been bought at a price. All over the country levelling up has been achieved only by enforcing a standstill order on the more progressive hospitals. As the administrative body closest to the hospital, staff, and patients, the committee claim to see at first-hand the effects of this policy. The limited capital resources made available by Parliament have done little more than provide for alterations and improvements to existing buildings, and no large hospital building scheme has been undertaken for the past decade. The committee fear that there is a real danger " that these factors will have the effect of losing in frustration the vitality which has always distinguished the best of our hospitals."

POSTGRADUATE AWARDS

THE association of Universities of the British Commonwealth (5, Gordon Square, London, W.C.1) have published a list of awards for advanced study and research including fellowships, scholarships, and grants. The list is divided into two parts: the first describes awards tenable in the United Kingdom with an indication of whether they are open to *graduates from this country and/or overseas*; the second sets out the more important awards tenable overseas by British graduates but does not claim to be comprehensive. The list will appear as appendices II and III of the *Commonwealth Universities Yearbook 1953.*

EXTRACURRICULAR READING FOR THE D.T.M. & H.

DISASTER came upon Govind, the Indian tailor, in the midst of his modest, contented, and busy life when he realised that he had contracted leprosy. His way of life and his illness are unfamiliar to most of us; but in the *Mask of the Lion*[1] Dr. A. T. W. Simeons succeeds in making them real. By describing Govind supervising his shop, bathing, eating the meals his wife has cooked, and setting out for a railway journey at an hour selected by an astrologer, Dr. Simeons teaches us a set of conventions as rigid and well-mannered as those that governed Cranford. His experience as director of the medical health services of an Indian State enables him to show us equally vividly Govind's life as a leper and the varying standards of medical care offered to him. Guided by Dr. Simeons's sympathy and tolerance we come to understand how the hardships and excitements of the wandering life of a band of beggars may be preferable to the restrictions and monotony of even a well-run leprosarium. It is a pity that the last chapters, describing Govind's cure by an unnamed drug, are the least satisfying part of the book.

In *White People Smile at Me*[2] Mrs. Christine Garnier deals less successfully with another problem and another culture. Doéllé, the missionary-educated African midwife, is not wholly accepted by the white community at Manoho. Nor is she wholly free of the fetishism which rules the life of the village where her mother still takes offerings to the Temple of Pythons. The descriptions of African traditions and ceremonies in this over-intense and uneasy book are effective. But where Dr. Simeons is content to interpret the unfamiliar, Mrs. Garnier seems to prefer to shock with the strange.

PLURAL BIRTHS

Dr. C. F. Mayor, late editor of the *Index Catalogue* of the U.S. Surgeon-General's Library, apparently does not share the intense interest that is usually aroused by the arrival of quads or quins, for he has excluded such events from his engaging paper[3] on plural births. He has made a critical and systematic review of the 95 historically authenticated or legendary cases of births in which the mother has been delivered of six or more children from a single pregnancy. Each instance is described briefly and the original source of the report indicated or assessed. A few hoaxes have been included; indeed, it is unlikely that many of the births were as spectacular as history relates, but this in no way lessens their interest. Barbara

[2] London: Putnam. 1952. Pp. 218. 10s. 6d.

[3] Mayer, C. F. *Acta genet. med. gemellol., Rome*, May, 1952.

Stratzmann of Würtemberg, for example, was an exceptionally fertile woman. Among her 53 children born in the 15th century, were five sets of twins, four of triplets, one of sextuplets, and one of septuplets. A 16th-century woodcut portrays the whole family grown up and apparently healthy, although only 34 were born alive. A more convincing lady is the Roman mother who in 1811 gave birth to thirteen children, six boys and seven girls, within an hour. The attending midwife, not unnaturally, obtained the help of an obstetrician. All the children were born alive and well-formed, but none of them survived for long. The incident caused some stir and was reported in print within the month. Then there is the story of a serving-maid who gave birth to triplets. She was accused of promiscuity by her mistress, who held that it was impossible to conceive three children from the semen of one man, twins being the maximum, one from each testis. The lady herself then became pregnant and gave birth to nine children! The interesting illustrations to Dr. Mayer's paper include a reproduction of a bas relief on the house where the Römer septuplets of Hamelin were born in 1600. The two boys and five girls lived long enough to be baptised, but none survived longer than a fortnight. The carving was made in the same century and local opinion has no doubts about the truth of its story.

BIBLICAL FLORA

AN up-to-date flora of Palestine would be far more welcome to botanists than a new attempt,[1] by Mr. Harold Moldenke, PH.D., curator of the herbarium at the New York Botanical Garden, to identify the flora (including bacteria and *Treponema pallidum*) either mentioned or indirectly alluded to in the Bible, in an age when scientific botany was totally unknown. A few choice errors in other matters in the Bible are listed in the initial historical sketch, thus emphasising the fact that the translators were apt to slip up badly in naming plants which they did not know (witness the muddle over the bulrush). In fact nearly every item in the present work is, as an identification, a sheer guess or a bundle of suppositions. Under each heading are grouped all the conceivable plants that have been, or might be, suggested as the correct translation of the original Hebrew. Nevertheless the contents are extremely interesting both to botanists and to Biblical students. For instance, the burning bush is identified with a crimson-flowered mistletoe; the antiquity of favism is possibly to be deduced from the information given under *Faba vulgaris*; and a host of Biblical references are adduced to support the claim that syphilis goes back not to Columban America but to Sinai about 1490 B.C. (according to Archbishop Ussher's long-obsolete chronology, which is followed by the authors). The illustrations are, on the whole, lavish and excellent except for the inclusion of worn-out Victorian woodcuts (from C. W. Wilson's *Picturesque Palestine* published in 1883) used to illustrate trees which can barely be recognised.

University of Birmingham

Dr. A. B. MacGregor has been appointed to the chair of dental surgery, which has been given the title of the John Humphreys chair of dental surgery.

Dr. MacGregor, who is 43 years of age, was educated at Marlborough College and Trinity Hall, Cambridge. He entered St. Mary's Hospital with the senior scholarship of the year, and after graduating M.B. Camb. in 1933 he held house-appointments there in the E.N.T. department and as house-physician and obstetric officer. He entered the Royal Dental Hospital, and while working on dental research for the Medical Research Council took the L.D.S. in 1936. At the Royal Dental Hospital he won the Saunders and Woodhouse scholarships and the Storer-Bennett research prize. During the late war he served for six years in the R.A.F.V.R. Medical Service as a maxillofacial specialist. In 1944 he took his M.D. and four years later was elected F.D.S. R.C.S. For his work in dental surgery he was awarded the Colyer prize of the Royal Society of Medicine in 1937 and the Howard Mummery prize, British Dental Association, in 1948. He holds appointments as dental consultant to the Royal Navy, St. Bartholomew's Hospital, Royal Dental Hospital of London, Plastic and Jaw Centre, Hill End Hospital, St. Albans, and as maxillofacial consultant at Amersham Hospital. He is an examiner for the L.D.S. R.C.S. and a member of the board of the Faculty of Dental Surgery of the Royal College of Surgeons. He has published papers on research in oral and dental surgery and the treatment of jaw injuries.

Dr. J. L. Hardwick is to be acting head of the department of dental surgery for the current session.

University of London

At recent examinations the following were successful:

Final examination for M.B., B.S.—Vincent Ainsworth, A. J. Bowdler (university medal), J. J. Brown, John Ernsting, Kathleen M. Huntington, W. J. Jones, Violet H. Meyerstein, Doreen M. Nutbourne, J. I. S. Robertson, R. J. Shephard, R. P. Wise (with honours); Lilian E. Ackermann, E. D. B. Allen, L. G. Andrews, J. M. Armitt, J. A. Armstrong, K. M. Backhouse, A. H. W. Bain, D. T. C. Barber, Joyce L. Barber, N. H. Barley, D. W. Barnes, I. R. Beale, Anthony Betts, J. F. Bird, Joan M. Bishop, S. W. Bissell, Joy S. Blight, Richard Blight, Maurice Bloch, E. A. Boulter, Stanford Bourne, J. G. Bradford, R. F. Braithwaite, Louise A. Brandram, J. H. Breed, E. W. Brentnall, C. P. B. Brook, M. D. Brydson, Mavis Buck, Jeffery Caplan, Margaret S. Cavendish, E. J. Chalker, P. J. C. Chapman, H. P. Williamson, J. B. Williamson, Roy Wilton, Mary A. Winser, Sylvia H. Wollner, A. R. Worters, A. P. Wright, D. A. Wright, D. E. Wright, F. A. Yates.

D.P.M.—E. F. Carr.

University of Leeds

Dr. R. G. Paley has been appointed research fellow in medicine for 1952–54.

Royal College of Surgeons of England

Prof. George Perkins will deliver the Robert Jones lecture at 5 P.M. on Thursday, Dec. 11, at the college, Lincoln's Inn Fields, London, W.C.2. His subject will be Rest and Movement.

Royal College of Surgeons in Ireland

On Nov. 21 the fellowship was conferred on the following:

J. T. Carroll, D. L. T. G. Finn, S. J. Heffernan, I. C. Modebe, J. P. McMullin, O. M. O'Malley, R. D. H. Parker.

Kettle Lecture

Dr. C. V. Harrison will deliver this lecture on Thursday, Dec. 4, at 5 P.M., at the Wright-Fleming Institute of Microbiology, St. Mary's Hospital Medical School, London, W.2. He will speak on Pulmonary Vessels in Mitral Stenosis.

Harben Lectures

Lord Horder will deliver the Harben lectures at the Royal Institute of Public Health and Hygiene, 28 Portland Place, London, W.1, on Tuesday, Wednesday, and Thursday, Dec. 9, 10, and 11, at 4.30 P.M. His subject is to be Fifty Years of Medicine.

---

[1] Plants of the Bible. Waltham, Mass.: Chronica Botanica. Pp. xx + 364. $7.50. Obtainable in Great Britain from Messrs. Wm. Dawson & Sons Ltd. 60s.

The International Hæmophilia Society

A meeting of this society will be held at the Seymour Hall, Seymour Place, London, W.1, on Sunday, Nov. 30, at 2 P.M.

Illuminating Engineering Society

At a meeting of this society to be held on Tuesday, Dec. 9, at the Lighting Service Bureau, 2, Savoy Hill, London, W.C.2, at 6 P.M., Mr. H. C. Weston, F.I.E.S., will present a paper on Visual Fatigue with Special Reference to Lighting.

Health Education in the Secondary School

The Ling Physical Education Association is holding a course on this subject at the Victoria Hall, Bloomsbury Square, London, W.C.1, from Jan. 5 to 7. Sir John Charles will give the opening address and speakers will include Dr. Melville Mackenzie and Dr. A. G. Mearns. Further particulars may be had from the secretary of the association, Hamilton House, Bidborough Street, W.C.1.

Hearing-aids

The number of patients waiting for National Health Service hearing-aids at the end of last August stood at 66,000 compared with 110,000 in August, 1951. In the six months ending in August, each week 1800 patients were supplied with aids and nearly 800 new patients were added to the lists. Since the beginning of the National Health Service up to the end of last August, over 230,000 patients have been fitted with hearing-aids.

Manchester Bequest

Dr. Catherine Chisholm has left half the residue of he estate to establish a trust fund for the promotion of researc into the health and diseases of infants to be known as "Th Alice Chisholm Fund," and the other half to the Victori University of Manchester to be applied in, or towards, th endowment of the school of child health.

Kingston and Malden Victoria Medical Foundation

This foundation was formed last year by a group of doctors and laymen who plan to start a new voluntary hospital to take the place of the former Victoria Hospital, Kingston, which was taken over as a gynæcological unit by the South-west Metropolitan Regional Hospital Board (see *Lancet*, 1951, ii, 644). In an appeal to general practitioners for subscriptions Dr. F. B. Lake, the foundation's chairman, says that the aim is to acquire a large house and convert it into a small hospital; and "we are about half way to the minimum sum we think it prudent to collect before we can acquire property and start conversion." "We believe," says Dr. Lake, "that in creating a new independent local hospital we will do much to demonstrate the value of such institutions and eventually help to establish the just place of the general practitioner in the Service." Cheques, payable to the Kingston Victoria Fund, should be sent to the hon. treasurer, 9, Coombe Rise, Kingston Hill, Surrey.

EMERGENCY BED SERVICE.—In the week ended last Monday, applications for general acute cases numbered 1108. The proportion admitted was 91·24%.

Diary of the Week

NOV. 30 TO DEC. 6

Monday, 1st

INSTITUTE OF CHILD HEALTH, The Hospital for Sick Children, Great Ormond Street, W.C.1
5.30 P.M. Dr. H. Grüneberg: Animal Genetics and Diseases in Children.

BRITISH PSYCHO-ANALYTICAL SOCIETY
8.15 P.M. (1, Wimpole Street, W.1.) Prof. R. W. Russell, PH.D.: Behaviour Under Stress. (Ernest Jones lecture.)

Tuesday, 2nd

BRITISH POSTGRADUATE MEDICAL FEDERATION
5.30 P.M. (London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1.) Dr. P. R. Peacock: Carcinogenesis.

INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2
5.30 P.M. Dr. S. C. Gold: Lupus Erythematosus.

UNIVERSITY OF BRISTOL, Bristol, 8
8.30 P.M. Prof. Geoffrey Hadfield: Bacterial Hypersensitivity and Rheumatic Carditis. (Carey Coombs lecture.)

Wednesday, 3rd

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5 P.M. *Section of History of Medicine.* Mr. R. C. Brock: Sir Astley Cooper.
5 P.M. *Section of Surgery.* Dr. E. E. Pochin, Dr. F. T. Farmer, Mr. D. M. Wallace, Mr. Selwyn Taylor, Mr. T. P. Morley: Use of Radio-isotopes in Surgery.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, W.1
3.30 P.M. Mr. A. Dickson Wright: A Historical Review—Royal Illnesses.

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. J. O. Oliver: Hargraves Cell and L. E. Phenomenon.

INSTITUTE OF LARYNGOLOGY AND OTOLOGY, 330, Gray's Inn Road, W.C.1
5.30 P.M. Dr. Ettore Bocca (Milan): Laryngectomy with Block Dissection of the Neck—Unilateral and Bilateral.

INSTITUTE OF UROLOGY, St. Paul's Hospital, Endell Street, W.C.2
5 P.M. Mr. J. F. Barrington: Indications for Treatment in Enlarged Prostate.

HARVEIAN SOCIETY OF LONDON, 11, Chandos Street, W.1
8.15 P.M. Dr. C. H. Andrewes, F.R.S.: Recent Work on the Common Cold.

LONDON ASSOCIATION OF THE MEDICAL WOMEN'S FEDERATION
8.15 P.M. (Royal Free Hospital School of Medicine, 8, Hunter Street, W.C.1.) Mr. Charles Evans: Explorations in Solu Khumbu, Nepal.

MANCHESTER MEDICAL SOCIETY
4.30 P.M. (University of Manchester.) *Section of Medicine.* Sir Geoffrey Jefferson, F.R.S.: Varying Behaviour of Pituitary Adenomas.

MEDICO-CHIRURGICAL SOCIETY OF EDINBURGH
8.30 P.M. (Royal College of Surgeons of Edinburgh, 18, Nicolson Street.) Dr. Douglas Kerr: Health, Physical Standards and Training of Motor Drivers, in Relation to Road Accidents.

Thursday, 4th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5.30 P.M. Dr. C. H. Andrewes, F.R.S.: Common Cold.

BRITISH POSTGRADUATE MEDICAL FEDERATION
5.30 P.M. (London School of Hygiene and Tropical Medicine.) Prof. Wilson Smith, F.R.S.: Virus Adaptability in Relation to Human Disease.

ROYAL SOCIETY OF MEDICINE
5 P.M. *Section of United Services.* Surgeon Lieut.-Commander W. H. B. Ellis: Human Factor in Naval Aviation, with Particular Reference to Deck Landings.
8.15 P.M. *Section of Neurology.* Dr. F. M. R. Walshe, F.R.S.: Thoughts on the Equation of Mind with Brain. (Hughlings Jackson lecture.)

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, S.W.1
5 P.M. Dr. J. Hamilton Paterson: Neurological lecture-demonstration.

ST. MARY'S HOSPITAL MEDICAL SCHOOL, W.2
5 P.M. Dr. C. V. Harrison: Pulmonary Vessels in Mitral Stenosis. (Kettle lecture.)

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. H. Haber: Cellular Nævi and Melanomas.

INSTITUTE OF PSYCHIATRY, Maudsley Hospital, Denmark Hill, S.E.5
3 P.M. Dr. Graham Weddell: Cutaneous Sensibility.

HONYMAN GILLESPIE LECTURE
5 P.M. (University New Buildings, Teviot Place, Edinburgh.) Mr. W. Selby Tulloch: Surgery of the Prostate.

UNIVERSITY OF ST. ANDREWS
5 P.M. (Medical School, Small's Wynd, Dundee.) Prof. F. A. E. Crew, F.R.S.: Medicine as an Instrument of Social Policy.

Friday, 5th

ROYAL SOCIETY OF MEDICINE
10.30 A.M. *Section of Otology.* Mr. J. Angell James, Mr. Gavin Livingstone, M[illegible] [illegible] nic Otitis Media.
2.30 P.M. *Section of* [illegible] Collins, Mr. D. S. Middleton, Mr. [illegible] of Nose and Upper Jaw.
5.30 P.M. *Section of Anæsthetics.* Dr. E. H. Rink, Dr. A. M. Hutton, Dr. D. M. Carnegie: Anæsthesia in Cardiac Disease.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark Hill, S.E.5
4.30 P.M. Sir Ernest Finch: Romance of Surgery. (*Lees* lecture.)

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. Gold: Lupus Erythematosus.

WHIPPS CROSS HOSPITAL MEDICAL SOCIETY, Whipps Cross Hospital, E.11
8.30 P.M. Dr. W. J. O'Donovan, Mr. A. E. Mortimer Woolf: Should the Doctor Tell?

Saturday, 6th

MIDLAND TUBERCULOSIS SOCIETY
3 P.M. (Chest Clinic, 151, Great Charles Street, Birmingham, 3.) Dr. V. H. Springett: Fates of Some Minimal Lesions.

ŒSOPHAGEAL CONTRACTION AND CARDIAC PAIN*

WILLIAM EVANS
M.D., D.Sc. Lond., F.R.C.P.
PHYSICIAN TO THE CARDIAC DEPARTMENT OF THE LONDON OSPITAL AND TO THE NATIONAL HEART HOSPITAL; CONSULTING CARDIOLOGIST TO THE ROYAL NAVY

DURING twenty-five years when the clinical recognition f cardiac infarction has become commonplace, and nowledge of its cardiographic design has grown, our wareness of the frequency with which coronary disease rovides the cause of chest pain has increased. The elation of cardiac-like pain to disease of the coronary rteries when the electrocardiogram is strictly normal ontinues to be ill-understood. It was while searching or a solution to this problem that I found help from vatching during cardioscopy the progress of a barium neal along the œsophagus.

A moderately thick paste, when swallowed, quickly eaches the level of the aortic arch, whence it progresses nore slowly, with an awl-like head, over the arch, and in urn over the left bronchus, the left auricle, and the lescending aorta, until it passes through the diaphragmatic opening into the stomach. In some cases the propulsion of the meal is very rapid and in others it is tardy. Such progress depends on œsophageal contraction more than on gravity, because the barium reaches the stomach just as quickly when it is swallowed while the subject is in the inverted position. Allison (1942) has pointed out that the act of swallowing increases the intra-œsophageal pressure, causing food to enter the stomach irrespective of peristalsis and of gravity.

The Abnormal Radiological Sign

At times the customary rhythmical progression of the meal along the œsophagus gives way to irregular movements. In this event the first portion of the meal halts, often momentarily, at the diaphragmatic opening, and some or much of it may pass into the stomach. When the next portion of the meal arrives, it is again held up, and each additional supply of barium distends the lower end of the œsophagus. As the act of swallowing proceeds, the air above presses on the column of barium below and causes the tube to swell still more, but the œsophageal trap holds firm, and the bulk of the meal fails to enter the stomach. The next notable event is a sharp recoil of the meal so that it is suddenly jettisoned upwards in the gullet, whose lumen resumes its customary narrow-calibre for a brief period. This sequence of events may be re-enacted several times before the barium is ultimately discharged piecemeal into the stomach. If the trap at the diaphragmatic opening remains closed, the œsophagus may hold a tall column of barium and may not display its spectacular movements until it is partly emptied; this phase differs from the naturally sluggish œsophagus where the meal passes slowly but without noticeable impediment and without recoil.

Since these irregular movements represent a departure from the normal rhythmical progression of the barium swallow, I have named the condition *œsophageal arrhythmia.* It is not to be confused with cardiospasm or achalasia, nor with the effects of carcinomatous obstruction at the lower end of the œsophagus, where the barium might be held at the seat of the block, causing the gullet above to widen as it fills and the meal to recoil; this more ominous lesion is told by inspecting the head and particularly the neck of the column, for its outline is never smooth and is irregular on one or both sides.

Although œsophageal arrhythmia is easily recognised during cardioscopy and best when the patient is in the right oblique position, its graphic registration is difficult. A kymographic examination of the barium swallow can demonstrate a change in the direction of the meal, and McLaren (1943) has devised a method which traces graphically the progress of the œsophageal movements, but the analysis is confined to the brief period during which the kymogram is recorded (fig. 1). Cineradiography, too, cannot display satisfactorily the sequence of events, because of the short duration of the observation period. A diagrammatic representation is not wholly satisfactory either (fig. 2). Nonetheless, once œsophageal arrhythmia has become familiar to the observer, no examination beyond cardioscopy is necessary to discover it.

The Investigation Described

When œsophageal arrhythmia first came to my notice in a patient with cardiac-like pain in whom the electrocardiogram had proved to be physiological, I decided to seek this radiological sign in other patients in like circumstances. Although this investigation was started casually some fifteen years ago, when the importance of the sign was less clearly appreciated, the majority of the patients in the series have been assembled during the last ten years. This has supplied the opportunity to observe the subsequent progress of the patients, and especially of those in whom œsophageal arrhythmia was the only abnormal sign.

A detailed history was taken in each case and a routine physical examination made. An electrocardiogram included the three orthodox limb leads, lead IIIR (III during deep inspiration), and the three chest leads, CR_1, CR_4, and CR_7; occasionally other leads were recorded as well. The cardiogram was often repeated after strenuous physical exercise. The progress of a barium swallow was watched during cardioscopy in every instance.

Results

The patients were allocated to two main groups, one consisting of control cases and the other, which comprises the test series, of patients in whom cardiac-like pain was associated with a normal electrocardiogram.

CONTROL SERIES

To test the specificity of the œsophageal sign the results have been controlled by seeking it in 700 healthy

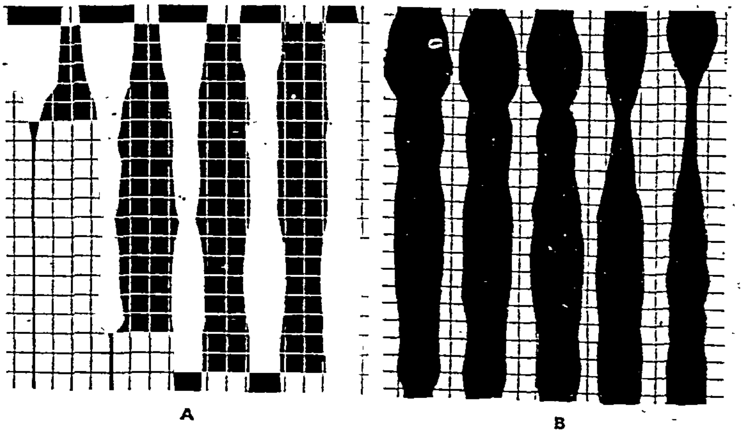

Fig. 1—Kymographic appearances of progress of œsophageal contraction in a patient with œsophageal arrhythmia. Black columns depict outline of œsophagus at intervals of two-fifths of a second. In A the band of contraction is progressing downwards; in B, recorded soon afterwards, it is moving upwards.

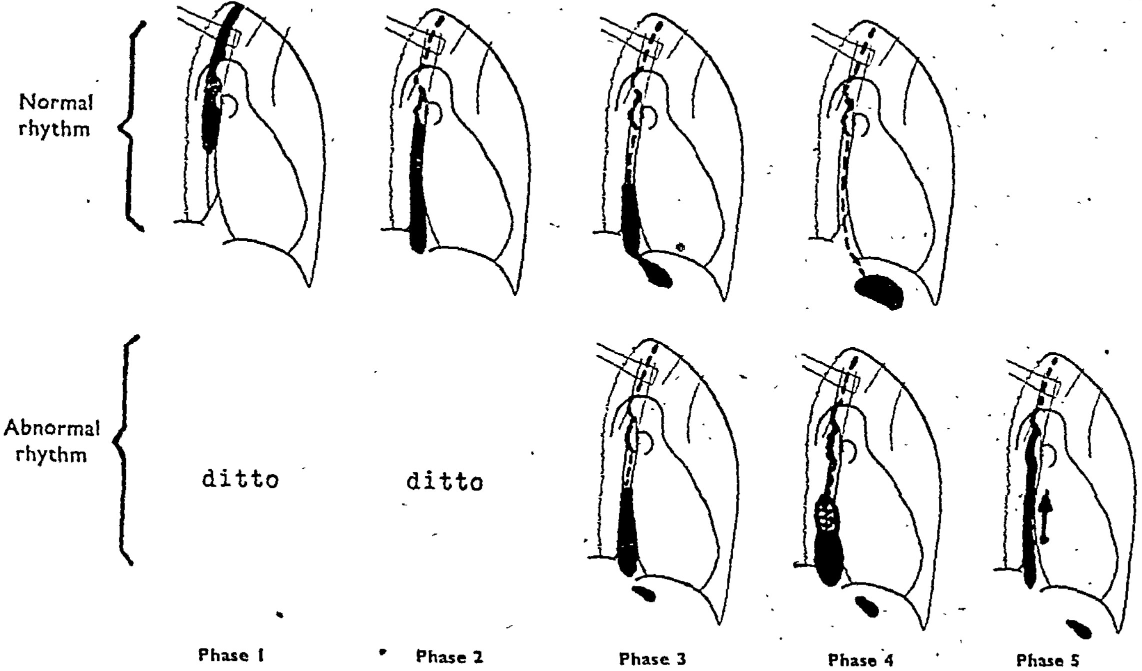

Fig. 2—Normal and abnormal movements of œsophagus observed in right oblique position during progress of barium swallow.

subjects, in 200 patients with painless heart disease, and in 500 patients with cardiac infarction. Thus, in 1400 cases œsophageal arrhythmia, if present, would have been a fortuitous finding and not part of any painful syndrome, for pain of any kind was absent in 900 and had a cardiac source in 500 where the electrocardiogram had shown the presence of cardiac infarction. The results will now be considered for each of the three groups.

Healthy subjects.—In order to annul the age factor from the analysis of the comparative results, 200 of the 700 healthy subjects were young people (average age 27), and 500 were adults over 45 (average age 57). Care was taken to exclude organic heart disease in all, and in none was there chest pain. Œsophageal arrhythmia was found once in the younger and smaller group and six times in the older and larger group.

Patients with painless heart disease.—In this group 200 patients were examined and their age was 45 or more. They included 137 patients with hypertensive heart disease, 49 with valvular heart disease, 9 with thyrogenic auricular fibrillation, and 5 with heart block and failure. Their symptoms, if any, consisted of palpitation and breathlessness for the most part. None had chest pain. Clinical examination elicited physical signs characteristic of the heart condition which happened to be present. Similarly the electrocardiogram varied in accordance with the nature of the heart condition and sometimes it did not deviate greatly from the normal. Cardioscopy usually revealed some cardiac enlargement. The impression was sometimes gained that, when there was great enlargement of the heart, the progress of the barium swallow was sluggish, but there were too many exceptions to regard this as a significant finding. Œsophageal arrhythmia was observed in 5 (2·5%) of the 200 patients.

Patients with cardiac pain.—This third control group was made up of 500 patients with an abnormal electrocardiogram from cardiac infarction. In 409 the pain had appeared at one time or another while they were at rest, or had lasted a long time and for periods exceeding half an hour, so that a clinical diagnosis of cardiac infarction was likely on this account. In 91 (18%) the pain had been caused by exertion only and had quickly yielded to rest, suggesting the syndrome of cardiac ischæmia or angina pectoris of effort, but in thes patients as in the former ones the electrocardiogram ha proved the presence of cardiac infarction. Althoug patients of every age were admitted into this group, there were only 31 under the age of 45 years. The number showing œsophageal arrhythmia was 25 (5%). The slightly higher incidence of the radiological sign in this group might be explained by dyspepsia causing a share of the pain in that this was more frequent and more severe at rest in 5 patients than was expected from coronary arterial disease alone, although this was known to be present in each and the cause of the pain at the start of the illness if not subsequently.

All three groups.—When these three groups were considered together, œsophageal arrhythmia was present in 37 out of 1400 cases (2·6%). The sign occurred in 12 (1·3%) of the 900 cases without chest pain, and in 25 (5%) of the 500 cases of cardiac infarction whose pain presumably was the direct outcome of coronary arterial disease. From these data it will be seen that although œsophageal arrhythmia is found in health *it is uncommon*, and when met with it can have little significance in a person free from symptoms. In only 3 subjects in the control series was the sign prominent, and these were patients with cardiac infarction who were subject to frequent painful attacks at rest. It has not yet happened that one of the 7 healthy subjects showing this radiological sign has returned with chest pain, but the number is small, and no attempt has been made to recall these cases for re-examination lest they should develop unjustifiable invalidism from such medical inquisitiveness.

TEST SERIES

The patients in this class complained of chest pain which subjectively was characteristic of cardiac pain, but the electrocardiogram had failed to confirm the presence of coronary arterial disease. The clinical history had suggested this ætiology in each instance because the pain, usually in the centre of the chest, was described as gripping, constricting, a tightness, a sense of pressure, a dull ache, or like indigestion; never once was it lancing. It often radiated to the jaw, the shoulder, or the left arm, and sometimes it spread into the right arm as well. There were 332 patients in this group, and in 114 the pain was brought on by exertion only and quickly yielded to rest. In the remaining 218 cases the pain had occasionally set in at rest, and/or had lasted an hour or more, suggesting cardiac infarction. Very often episodes of pain had been severe while the patient was at rest and had awakened him from sleep, necessitating the urgent attendance of a doctor, who had invariably diagnosed coronary thrombosis and administered morphine for the relief of the pain. In none was there pain on swallowing, for this symptom would have excluded them from the series. Thus, the history of the illness in each patient differed in no particular way from that obtained in a patient where a subsequent electrocardiogram had proved the presence of cardiac infarction, except in the higher incidence of pain precipitated by effort alone. Indeed, a diagnosis of cardiac pain had been made by a general practitioner, and often by more than one, in every instance; often a consulting physician had added his opinion. Long periods of rest in bed had been enforced in some cases, and for the relief of short painful attacks glyceryl trinitrate had been prescribed, often with benefit. Clinical examination had discovered no abnormal physical signs in this group: the blood-pressure was natural, cardiac enlargement was absent even on radiological examination, and there was neither triple heart rhythm nor evidence of valvular disease.

The electrocardiogram was carefully examined to discover any signs which might suggest coronary arterial disease. After such scrutiny the tracing was judged to be normal in all the cases. When the patients were recalled for examination after two years, the same competent electrocardiogram was repeated and the test of induced cardiac anoxæmia was often added. The incidence of œsophageal arrhythmia in this group was impressive, for the sign was present in 133 (40%) of the 332 cases (table I).

TABLE I—ŒSOPHAGEAL CONTRACTION IN PATIENTS WITH CARDIAC-LIKE PAIN IN WHOM THE ELECTROCARDIOGRAM WAS NORMAL AND IN PATIENTS ASSEMBLED FOR CONTROL

Description	No. of cases	Initial electrocardiogram		Œsophageal contraction	
		Normal	Abnormal	Normal	Abnormal
Patients with cardiac-like pain ..	332	332*	0	199	133 (*40*%)
Control series:					
Healthy subjects under 45 ..	200	200	0	199	1 } (*1*%)
Healthy subjects over 45 ..	500	500	0	494	6 }
Patients with painless heart disease	200	Variable		195	5 (*2·5*%)
Patients with cardiac pain..	500	0	500	475	25 (*5*%)

* In 5 patients the electrocardiogram later showed changes (see text).

I have accepted this finding as meaning that, when a patient with cardiac-like pain presents a physiological electrocardiogram, even after exercise, and at the same time shows œsophageal arrhythmia, the pain has a dyspeptic source. Even in those without this radiological sign it is likely that dyspepsia is the commonest cause of the pain, though occasionally other external influences, such as excessive smoking, play a part.

Naturally, this assumption demands that the electrocardiogram is strictly normal, and it also tests the view that a normal electrocardiogram excludes the presence of coronary arterial disease as the source of the chest pain. Decision on this cannot come easily, and the contribution which the sign of œsophageal arrhythmia makes to this problem had to be examined. It meant, therefore, that the patients with cardiac-like pain and a physiological electrocardiogram had to be watched for years lest in time any should give the abnormal tracing belonging to coronary arterial disease or unexpectedly die from cardiac infarction without any cardiographic warning. The patients belonged to a precarious age-group in that cardiac infarction might happen fortuitously in them, and this would delay final opinion on this issue. Such incidental deaths, if they took place, must necessarily be few if it is possible to predict an absence of a special susceptibility to the effects of coronary arterial disease in this class of patients. on the other hand, should the casualties prove light, we may conclude that in such patients the source of the chest pain is unlikely to reside in coronary arteries affected by an unusual degree of atheroma. The progress of these patients was therefore watched. Their ages varied from 37 to 85 and the average age was 55 years. The period of observation has been less than two years in 93, over two years in 239, over four years in 158, over six years in 87, and over ten years in 15 (table II).

TABLE II—LENGTH OF OBSERVATION PERIOD IN 332 PATIENTS WITH CARDIAC-LIKE PAIN COMPARED WITH THAT IN 332 WITH TRUE CARDIAC PAIN

Description	Period of observation in years since start of pain.				
	Less than 2	More than 2	More than 4	More than 6	More than 10
True cardiac pain ..	143	189	111	52	10
Cardiac-like pain ..	93	239	158	87	15

It was not easy to keep in touch with so many patients and to observe their progress three times in six years. There were delinquents, but special care was taken in such instances to ascertain the cause of absenteeism and in this way to avoid upsetting the statistical analysis.

The subsequent progress of these patients with cardiac-like pain will now be considered in relation to the persistence and the severity of the painful attacks, to any change in the erstwhile normal electrocardiogram, and to the incidence of death from cardiac infarction.

Change in Character or Incidence of Pain

Mention has already been made of the higher incidence in this group of pain which was induced by exertion alone and which quickly disappeared when the effort causing it was discontinued. This was true of 34% of the patients; but when the same information was sought in a like number of patients with true cardiac pain it was found in only 18%. When patients in the first group, however, were re-examined, many of them in the meantime had experienced occasional attacks while at rest, and/or these had lasted a longer time. It also came to light that in some instances the pain had left them after a time, and this applied particularly to those cases where the painful attacks had been long ones or had appeared at rest. This remission from pain was a feature in 83 patients; in 34 the pain had been absent for periods up to two years, in 49 for two years or more, and in 16 for more than four years. This freedom from pain was in obvious contrast with the findings in the same number of patients with true cardiac pain. In this second group such remission from pain was present in only 22 patients (table III).

TABLE III—INCIDENCE OF REMISSION FROM PAIN IN 332 PATIENTS WITH CARDIAC-LIKE PAIN COMPARED WITH THAT IN 332 WITH TRUE CARDIAC PAIN

Description	Remission from pain			
	Total	Less than 2 years	More than 2 years	More than 4 years
True cardiac pain	22	4	18	2
Cardiac-like pain..	83	34	49	16

This knowledge cannot prove useful in diagnosis nor help to allocate a patient to either group when he first presents for examination, but it does emphasise the difference in prognosis between the two groups, and in turn it suggests for each a different ætiology.

Subsequent Electrocardiogram

The initial physiological electrocardiogram in 5 of the 332 patients gave way to an abnormal tracing. In one, however, it was because of the development of aortic stenosis; later the changes suggested a myocardial injury from coronary arterial disease, and at necropsy there was considerable coronary atheroma, although frank cardiac infarction was absent. This is the only instance in the series where death resulted from heart disease, and the case is described in greater detail below.

In the remaining 4 patients the electrocardiogram recorded at their first attendance was judged to be faultless. These cases could not be regarded as examples of cardiac infarction taking place fortuitously in an ageing patient, because each complained of chest pain at the time when the normal tracing was obtained; and, in view of the subsequent abnormal electrocardiogram, the pain must have been the outcome of coronary arterial disease at the start.

During this investigation 4 other patients came to my notice whose chest pain was caused by coronary arterial disease and whose electrocardiogram for that reason showed changes due to cardiac infarction, but whose tracing on a subsequent occasion proved to be normal. It is necessary to include these 4 along with the other 4 patients in any discussion on the infallibility of the electrocardiogram to tell true cardiac pain; for, had they been seen for the first time when the electrocardiogram had recovered, they would have been regarded as cases of cardiac-like pain. None of the patients had symptoms or signs which suggested auricular tachycardia or pericarditis as causes of temporary cardiographic changes, and none showed œsophageal arrhythmia. Thus in only 8 patients out of 332 would a wrong diagnosis have been made if it had rested on the premise that chest pain arising from coronary arterial disease is associated with changes in the electrocardiogram. Of these 8, 4 were the only exceptions among the 332 patients considered to have cardiac-like pain, and the other 4 were the only exceptions among 1000 consecutive patients with true cardiac pain in that their abnormal cardiogram appeared to have recovered. It needs emphasis, however, that in none of the 8 patients was the electrocardiogram repeated after exercise, and critical re-examination of the tracing accepted as physiological in the first place either showed suspicious changes or found it to be an inadequate electrocardiogram in 6 out of the 8.

Incidence of Deaths

The mortality-rate among the 332 patients with cardiac-like pain was compared with that in 1000 patients with true cardiac pain examined during the same observation period. In the first group there were only 14 deaths compared with 190 in the second group, a mortality-rate of 4·4% against 19%. Of greater significance, however, is the result of an analysis of the cause of death in the two series. Among the 190 patients with true cardiac pain death was due to cardiac infarction in 184, renal failure in 3, carcinomatosis in 2, and rupture of the abdominal aorta in 1. In 13 of the 14 patients with cardiac-like pain and a normal resting electrocardiogram death was due to causes outside the heart (table IV). In 3 death followed an operation for gastric ulcer, in 2 it resulted from carcinoma of stomach, in 2 from carcinoma of pancreas, in 2 from carcinoma of lung, in 1 from carcinoma of uterus, in 1 from carcinomatosis, in 1 from pulmonary embolism following systemic venous thrombosis, and in 1 with scleroderma from pulmonary hypertension. Of these patients who died, 7 belonged to the group showing œsophageal arrhythmia and 7 to the group where this radiological sign was absent. In 6 out of 7 cases examined at necropsy, there was no excessive coronary atheroma nor an unhealthy myocardium. The remaining patient was aged 72 when she died.

TABLE IV—CAUSES OF DEATH IN 190 PATIENTS FROM AMONG 1000 WITH TRUE CARDIAC PAIN AND IN 14 FROM AMONG 332 WITH CARDIAC-LIKE PAIN OBSERVED DURING THE SAME PERIOD

True cardiac pain		Cardiac-like pain	
Cause of death	No. of cases	Cause of death	No. of cases
Cardiac infarction ..	184	Heart failure; aortic stenosis	1
Renal failure.. ..	3	Gastrectomy for ulceration..	3
Carcinomatosis ..	2	Carcinoma of stomach ..	2
Rupture of abdominal aorta	1	Carcinoma of pancreas ..	2
		Carcinoma of lung	2
		Carcinoma of uterus	1
		Carcinomatosis	1
		Pulmonary embolism ..	1
		Pulmonary hypertension and scleroderma	1

She was first examined because of cardiac-like pain at the age of 50. The pain had started twelve years before, when she was 38. It was described as 'gripping' and as a tightness in the chest, with pain spreading into both arms. Exertion, especially walking in cold weather immediately after a meal readily brought on the pain, which quickly subsided on resting. She continued to attend the cardiac department of the London Hospital for twenty-two years, and in all she had been subject to painful attacks for thirty-three years, apart from a period of a year, when she had been free from them. During the last few years the pain had set in when at rest.

Clinical examination found no abnormal signs, and during the earlier years the limb-lead electrocardiogram was normal, and so also were the chest-lead tracings when these were added. At the age of 62 signs of aortic stenosis appeared, and in time this affected the cardiogram. In her last year the tracing showed signs of coronary arterial disease as well. Œsophageal arrhythmia was always a prominent sign. Through the years she had obtained great benefit from glyceryl trinitrate, and had ingested some 45,000 tablets; but latterly they had proved less effective. Subjectively the severe paroxysms of pain resembled those from coronary arterial disease, but I always regarded them as arising from a dyspeptic source. An œsophageal mercurial bougie introduced three times a day for a week had no effect on the œsophageal arrhythmia, nor had the removal of the myenteric plexus at the lower end of the œsophagus.

In further support of the thesis that the pain had a dyspeptic rather than a cardiac source were the following facts: in spite of daily attacks of strong chest pain over twenty-four years the electrocardiogram had remained strictly normal, and only when aortic stenosis set in did it show left ventricular preponderance and, in the last year of life, the effects of coronary arterial disease.

Constipation was a life-long complaint, and so also was flatulence; hence a carminative mixture gave relief always comparable with glyceryl trinitrate, and latterly it gave greater relief. During her stay in hospital on one occasion the surgeon considered that air-swallowing caused the painful attacks, and instructed that a cork should be kept between her teeth, but this procedure did not abate the attacks; belladonna improved her symptom for a time.

At her last admission to hospital she was found to have heart failure with bilateral hydrothorax and she died. At necropsy there was severe aortic stenosis and atheroma of the coronary arteries, which had caused narrowing without occlusion, and subendocardial ischæmic fibrosis; frank or salient infarction was absent. There was no obvious abnormality of the œsophagus.

It is likely that this patient's painful attacks during at least twenty-three years were unrelated to the heart. The onset of aortic stenosis and the presence of severe coronary atheroma could have induced cardiac pain latterly, but the absence of cardiac infarction at the last was a notable finding.

Lerche (1950) has described the case of a woman, aged 26 who had experienced cardiac-like pain for ten years. Repeated radiological examination of a barium swallow had shown œsophageal spasm at its lower end. She was taken ill with pneumonia and died. No gross abnormality of the œsophagus was found at necropsy; the coronary arteries were not examined.

Discussion

MECHANISM OF ŒSOPHAGEAL ARRHYTHMIA

The *first phase* of œsophageal arrhythmia is characterised by a spasm which affects the lower third of the gullet as a rule and usually its lower end. This spasm may come into being as the meal reaches the affected part, with the result that nothing proceeds beyond the impasse at the start, but it is commoner for this sphincter-like action to begin after part of the meal has entered the stomach unimpeded, and then only the last part of the meal is halted abruptly.

Moersch and Camp (1934) described three kinds of spasm at the lower end of the œsophagus: (1) the diffuse irregular spasm which was the commonest form; (2) diffuse narrowing which suggests tetanic spasm; and (3) segmental spasm producing concentric narrowing at different levels.

A study of the myenteric nerve plexus at the lower end of the gullet allowed Lendrum (1937) to say that there was loss of ganglia cells with advancing years, and from the examination of 12 cases of achalasia, where spasm is associated with failure to relax, he concluded that a fault in the myenteric plexus had caused the spasm.

My series of healthy subjects, made up of a younger and an older group, did not show decisively that age influenced the incidence of œsophageal arrhythmia, while the patients with both the radiological sign and chest pain belonged only to a slightly older age-group. Thus, the average age of 199 patients with cardiac-like pain and no œsophageal arrhythmia was 53 compared with 60 years for 133 patients with œsophageal arrhythmia. Removal of the myenteric plexus round the lower end of the œsophagus in one patient did not, however, affect the radiological sign, which was seen after the operation as clearly as before.

There is no general agreement on the presence of a sphincter muscle at the lower end of the œsophagus. Those who have asserted that an anatomical sphincter exists at the cardia include Cannon (1911), Todd (1915), Thieding (1921), Bennett (1925), Hurst (1925), and Lerche (1950), while Fleiner (1900), Zaaijer (1923), Jackson (1927), Abel (1929), and Lendrum (1937) have stated that there is no sphincter. Whether there is an anatomical sphincter or not, there is no denying that this localised purse-string appearance of the barium-filled œsophagus is an affair of the gullet, which is not merely pinched at the diaphragmatic opening, because the constriction is often situated above this.

The *second phase*, characterised by a sharp recoil of the meal up the gullet, is more difficult to explain. Is it a relaxation of the œsophagus after the downward peristaltic wave has ended, allowing the compressed meal below to regurgitate and the gullet to collapse and assume its customary size with a narrow lumen, or is the action caused by an active retroperistaltic movement? The latter appears to be the explanation, for in some cases the spasm appears to be a minimal effect, and repeated recoil of the meal a spectacular feature.

Moersch and Camp (1934) considered that with the spasm of the lower end of the œsophagus the barium moved up and down with peristaltic activity, and that such rapid changes in the size of the lumen distinguished the deformity from the fixed defect of cardiospasm. Dahm (1931) used the kymograph to record these antiperistaltic movements which take place in œsophageal stenosis from various causes. Even such methods of recording, however, can hardly distinguish unerringly between the two mechanisms which might be causing the recoil of the meal. If the spasm is situated high in the œsophagus and then usually associated with an œsophageal pouch, recoil of the meal is not seen.

SIGNIFICANCE OF ŒSOPHAGEAL ARRHYTHMIA

The association of chest pain and œsophageal spasm has been reported by others.

Moersch and Camp (1934), describing 8 cases of diffuse spasm of the lower part of the œsophagus, found that the pain in some of them was experienced during swallowing, but in 2 the pain was characteristic of angina pectoris, and this clinical diagnosis had been applied to them in the past.

Wolferth and Edeiken (1942) regarded œsophageal spasm as the most important of all extracardiac causes of angina pectoris, although they had often observed spasm without symptoms. They said they had excellent reasons for believing that many of the seizures thought to be angina pectoris among highly strung nervous people, heavy smokers, and patients with gall-bladder disease, were really due to œsophageal spasm; the electrocardiogram in such cases remained normal even during the painful attack.

Harrison (1945) reported 35 cases with chest pain which in respect of its location and severity resembled angina pectoris, where œsophageal disease was responsible for the pain in 11 and gastric disorders in the remaining 24. In 8 of the 11 cases with an œsophageal fault there was spasm. Harrison opined, however, that neither in œsophageal nor in gastric disorders was the pain ordinarily related to physical exertion. His patients, therefore, showed pain which resembled cardiac pain from infarction rather than one readily induced by exertion and quickly yielding to rest.

MECHANISM OF THE PAIN

It has been held for some time (Schrager and Ivy 1928) that reflexes arising from diaphragm, œsophagus, stomach, or gall-bladder, in health or in disease, may affect the coronary circulation and produce cardiac symptoms. The thoracic, phrenic, vagus, and spinal nerve pathways are much the same for the diaphragm, lower end of the œsophagus, and the stomach, and Miller (1939, 1942) has described these nerve pathways and explained the radiation of the pain to the sternum, præcordium, and left arm in hiatus hernia as well as in other thoracic and abdominal visceral disease. Afferent pathways from the stomach, diaphragm, and œsophagus may enter practically all the dorsal spinal roots and even overflow into the brachial and cervical plexuses.

Gilbert et al. (1940) observed diminution of the coronary blood-flow in dogs when the stomach was distended, a vagal reflex which could not be abolished by vagotomy or by injection of atropine. These experiments confirmed earlier ones made by Anrep and Segall (1926) on the regulation of the coronary circulation which allowed them to conclude that it was possible for stimuli in the vagal or sympathetic nerve-endings in the lower end of the œsophagus or stomach to produce vasomotor changes in the coronary arteries initiating cardiac ischæmia or its equivalent effect and giving rise to the characteristic pain of angina pectoris.

From these physiological experiments some clinicians have assumed, perhaps too readily, that hiatus hernia can produce pain in the chest through reflex vasoconstriction of the coronary arteries. Indeed, many workers have held that hiatus hernia can produce pain in the chest identical with angina pectoris from coronary arterial disease (Jackson and Jackson 1936, Jones 1941, Herman and Singer 1946), and Jones and Chapman (1942) reported disappearance of the pain after successful surgical treatment of the hernia. Master et al. (1949), however, from their experience with the anoxæmia test in 57 cases of hiatus hernia, stated that this condition, with few exceptions, did not produce typical angina of effort unless it was associated with coronary arterial disease; they added that the œsophageal lesion might act as a trigger mechanism in precipitating angina pectoris when the coronary arteries are sclerotic.

Paul White (1937) pointed out that in Liddell and Scotts' Greek Lexicon καρδία was translated as heart or stomach and καρδιακος as pertaining to the heart or stomach; dyspeptic. It was no wonder, he added, that we had remained confused on differential diagnosis!

RESPONSE TO TREATMENT

Now that emphasis has been given to the dyspeptic origin of this cardiac-like pain, we may examine its response to treatment.

Morrison and Swalm (1940) stated that several of their patients with angina pectoris responded indifferently to glyceryl trinitrate, and that therapy directed to the gastro-intestinal tract gave much better results and reduced the number of the painful attacks.

Wolferth and Edeiken (1942) also found that in such patients the pain as a rule was not relieved by glyceryl trinitrate in a degree comparable with the effect gained in patients with cardiac pain from coronary arterial disease, and that the pain yielded in time to treatment with antispasmodics, sedatives, and psychotherapy.

Douthwaite (1943) found that belladonna and 'Eumydrin' had no effect on achalasia, but that amyl nitrite produced full, though temporary, relaxation; glyceryl trinitrate had the same action, more lasting though less complete.

In 4 children with achalasia Field (1944) found that octyl nitrite relaxed the cardia and produced clinical improvement greater than amyl nitrite or glyceryl trinitrate.

The painful attacks which physical exercise produced in my patients have yielded to chewing tablets of glyceryl trinitrate, and as readily as in those of cardiac origin, but not with the same success when used as a preventive, nor in the attacks which set in spontaneously at rest and which last some time in the face of all remedies other than morphine.

It was difficult to tell whether glyceryl trinitrate relieved the pain in virtue of its action on the coronary circulation or on the intestinal tract. Breaking wind was a common sequel, but this follows ingestion of trinitrin both in patients with cardiac-like pain and in those with true cardiac pain.

Reassurance on the more innocent nature of the pain, together with sedation for a time, has given the most consistent benefit. In those with obstinate constipation needing the habitual and daily use of a saline laxative, a tablet containing nux vomica, belladonna, and aloes has often reduced the susceptibility to pain; so also has a weight-reducing diet in the obese. Discontinuance of smoking has reduced or even annulled the painful paroxysms in a few cases. Cajaput oil and brandy are two carminatives that have sometimes helped.

It will be seen, therefore, that response to a particular form of treatment does not tell the nature of the pain, but on the whole the patients in this group have responded to remedies intended to relieve gastro-intestinal rather than cardiac symptoms.

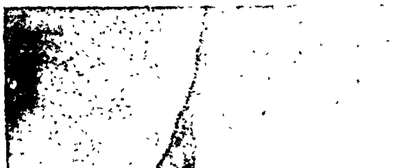

Fig. 3—Right oblique teleradiogram of intrathoracic stomach showing deviation of œsophagus to right (1) by stomach (2) which has herniated through diaphragm on left side, in a woman, aged 57, with cardiac-like pain.

THE SPASM AND PAIN

I cannot agree with the view that chest pain is the direct outcome of œsophageal spasm, except in the case of segmental spasm. Œsophageal spasm was met with in people who did not complain of symptoms, and, even when it was a prominent feature in a patient with cardiac-like pain, the pain never set in during radiological examination, which showed the presence of both œsophageal spasm and recoil of the meal.

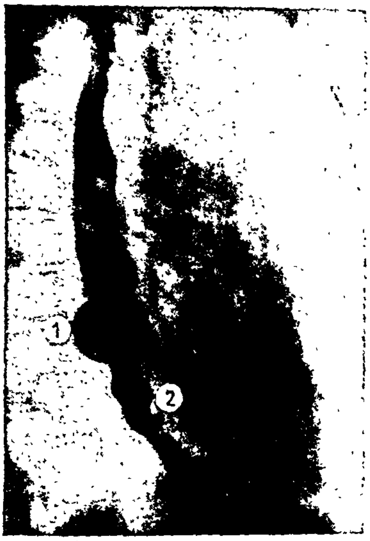

Fig. 4—Right oblique œsophogram showing œsophageal pouch (1) in middle third of gullet and segmentation (2) of its lower third, in a woman, aged 56, with cardiac-like pain. In a search for this condition patient should be examined in both oblique positions.

The protean symptoms identified with achalasia, œsophageal ulceration, pouch or hernia, gall-bladder disease, and gastro-intestinal upsets provide a common playground for the sport of many departmental specialists, but to be drawn into a discussion of the differential diagnosis of these several ailments is unprofitable, and I am concerned here only to find whether any of these conditions came to light in those patients with cardiac-like pain in whom the electrocardiogram proved to be strictly normal during the time they were being watched.

In the patients forming my series, however, gastro-intestinal lesions were not deliberately sought by special tests unless symptoms and signs pointed suspiciously to their presence, and this did not happen in any of the cases when they first presented with cardiac-like pain. The presence of hiatus hernia, for instance, was never tested by special radiological investigation unless it was seen while watching the progress of a barium swallow.

Not once did achalasia or œsophageal ulceration explain the pain, but a definite lesion of the intestinal tract apart from œsophageal arrhythmia appeared during a period of observation in 18 patients. Thus, gastro-duodenal ulceration was eventually found in 4, intrathoracic stomach (fig. 3) in 4, œsophageal pouch (fig. 4) in 3, cholecystitis in 3, carcinoma of stomach in 2, carcinoma of pancreas in 2, and segmental spasm of the œsophagus in 2; the last 2 patients are not included among the 133 cases which showed œsophageal arrhythmia.

Alongside the symptom of cardiac-like pain, others which appeared included flatulence, abdominal pain or discomfort, and obstinate constipation needing a daily aperient. Although such symptoms were also present in patients with true cardiac pain they were far more common in the series with cardiac-like pain, but they have not been regarded here as giving proof by themselves that the chest pain had a dyspeptic source.

* * *

At the turn of the century windy dyspepsia was a common bedside diagnosis in a patient bent by chest pain and trying to break wind, assisted by a host of carminative mixtures which remain in our pharmacopœia to remind us of the determined attempts once made to ease this symptom which was thought to be caused by gastro-intestinal ballooning. When it was shown that cardiac infarction could be the cause of such painful episodes, its recognition soon became commonplace, and windy dyspepsia was henceforth to recede as an inelegant diagnosis. In this the older clinicians have been shown to be wrong. It is likely that they were wrong many times, but were they wrong all the time, and today are we not wrong sometimes? It is my thesis that we are.

If we rely on a characteristic history for the positive diagnosis of cardiac pain there is a 3 to 1 chance that we are right, but it would be well to express this differently and to emphasise that there is 1 chance in 3 that we are wrong.

Enforced unwarranted invalidism is a cruel imposition at any age. It is most cruel when the autumn of life is clouded by unjustified restrictions which not only deny hobbies anticipated pleasurably during years of hard work but also indelibly remind the sufferer that he harbours a mortal illness within his breast. For the doctor to miss a step here is to commit a mistake from which there is no clear retreat; even when the diagnosis is eventually withdrawn, harm has been done and the mental injury lasts. Failure to recognise the marks of coronary arterial disease is of equal moment; hence at this cross-roads the doctor must read the signs clearly when the patient awaits to know which road he is to take and in what manner he must travel.

Osler once reminded us that the diagnosis of pain was made from a regard of the patient's statement, that its severity was judged by observation, and that the recognition of its cause demanded a thorough study. This applies specially to cardiac pain, where the scarcity of physical signs has driven us to rely on the electrocardiogram. It is the theme of this communication that, when the electrocardiogram is strictly normal in a patient with cardiac-like pain, as it often is, we shall gain help in our search for the cause of the pain if we look for the radiological sign of œsophageal arrhythmia.

I wish to thank Dr. Russell Reynolds for recording the œsophageal movements by cineradiography in five, and Dr. J. W. McLaren by kymography in two, of my patients.

A TEASPOONFUL OF BAKING-SODA

A. J. GLAZEBROOK
M.D. Lond., M.R.C.P.E.

FRED WRIGLEY
M.R.C.S., D.I.H., M.P.S.

From the Ministry of Pensions Hospital, Chapel Allerton, Leeds

> "Once I had a pain when my stomach was empty. Now I get a pain when it's full."
>
> (A patient, after his partial gastrectomy.)

IN these days of gels and resins it is unfashionable to prescribe sodium bicarbonate for dyspepsia. We point to its undesirable property of stimulating acid secretion in the stomach and to the dangers of alkalosis. Yet some patients remain irritatingly unconvinced by these disadvantages and may even assert that baking-soda gives them more relief than does anything else. Perhaps more of it is used in medical wards than we know of or suspect.

There seems to be some doubt about whether either rebound or direct stimulation of gastric secretion takes place after the administration of bicarbonate, and the dangers of alkalosis have possibly been overemphasised, but a whittling down of the side-effects does not fully explain a dyspeptic's preferences.

The ability of sodium bicarbonate to neutralise hydrochloric acid is not outstanding, being only about a quarter of that of magnesium oxide weight for weight, and little more than half of that of magnesium carbonate or of calcium carbonate. It has been tacitly assumed that it relieves pain so well because of the rapidity with which it buffers gastric acidity. This explanation may serve for patients with hyperchlorhydria but hardly for those who have little or no acid in their stomachs, some of whom dislike acid hydrochlor. dil. and flourish on sodii bic. Latterly the numbers of this group have been increased by the accession of those with post-gastrectomy syndromes.

There is a further class of patients who perform, as it were, a physiological gastrectomy on themselves. They present with symptoms of a duodenal ulcer, and a test-meal may show hyperacidity. A deformed duodenal cap is seen on X-ray examination, and it is assumed that the diagnosis of duodenal ulcer has been established. The years roll on, the episodes of dyspepsia persist, but the gastric acidity diminishes and may eventually disappear; and yet they continue to gain relief from alkalis, particularly sodium bicarbonate, and it is as easy to explain to them why this should be as it is to dissuade them from demanding to undergo partial gastrectomy.

A colleague, challenged by the unwillingness of some patients with "dumping" syndromes to continue taking the acid hydrochlor dil. he had prescribed for them, after they had submitted to partial gastrectomy operations designed to reduce their gastric acidity, advanced an ingenious hypothesis. He thought that a sort of conditioned reflex had become established after many years of food→pain→alkali relief, and that alkali had become part of a ritual and an essential support for the psyche during digestion. It seemed to us, however, that, since sodium bicarbonate is a major constituent of both bile and pancreatic secretions, adequate amounts of it were probably essential for the proper functioning of the digestive mechanisms of the small bowel. We therefore thought it more likely that the therapeutic efficacy of bicarbonate lay in its power to make good a deficiency when taken by mouth. An attempt was made to test this idea.

METHODS

Eighteen patients who had been admitted to hospital for the treatment of post-gastrectomy syndrome were examined by the dextrose-barium-meal technique (Glazebrook 1952, Glazebrook and Welbourn 1952). In this examination 230 ml. of a 50% solution of dextrose in water is added to 230 g. of barium, and the patient is asked to swallow the mixture, the motility of the small gut being observed by screening, and the appearances being recorded by fifteen-minute and hour films.

Nine of the cases were thought to be motility disturbances, as judged from the clinical history and examination and the results of radiography and balloon kymography. Three were diagnosed as afferent-loop-distension syndrome because pure bile unmixed with food was vomited after meals. In two cases stomal ulcers had been seen on gastroscopy.

The examination was also done with the same dextrose-barium mixture combined with 4 g. of sodium bicarbonate.

Six patients were given the unmodified dextrose-barium mixture soon after admission to hospital, and the bicarbonate-modified mixture seven days later. Afterwards, to minimise influences due to the hospital régime of rest and dietary control, the remaining twelve patients were given the bicarbonate-dextrose mixture first and the unmodified dextrose-barium meal a week later.

The X-ray appearances, particularly within the first fifteen minutes of the examination, and the symptoms produced by the dextrose were compared in each case on the two occasions. Some had a third examination in which the effects of atropine and of a synthetic spasmolytic, 'Ro 2-3773,' given by injection, were compared with those produced by bicarbonate.

RESULTS

The results are given in the accompanying table.

The sodium bicarbonate quietened the rush and spasm of the small gut produced by the sugar of the barium meal in each of the twelve cases of motility disturbances and, in addition, abolished or ameliorated the unpleasant symptoms brought on by the examination.

The bicarbonate relaxed the small bowel in each of the three cases of afferent-loop-distension syndrome but did not relieve the symptoms in one of them in spite of the X-ray appearances, which suggested an easement of the tension.

Not one of the three patients with stomal ulceration noticed any change in their sensations as between the two barium meals; in one some relaxation of the small bowel was seen on X-ray screening. In these three cases very little barium entered the small bowel during the first fifteen minutes, in contradistinction to the fifteen cases mentioned above, owing to stomal spasm, and this spasm was not much affected by bicarbonate.

ILLUSTRATIVE CASES

Intestinal Hurry

Case 1.—A man, aged 45, had undergone partial gastrectomy for chronic duodenal ulcer in 1950. Severe postprandial symptoms led to a second laparotomy in 1951, but nothing abnormal was found, and the abdomen was closed after appendicectomy. When the patient came under our observation his symptoms were characteristic of intestinal hurry—weakness, distension, and sweating after meals, with loose light-coloured bulky motions, and an inability to maintain his weight. The fifteen-minute film after a dextrose-barium meal shows the rapid rate of travel of the meal through the small bowel (fig. 1); the man had all of his postprandial symptoms during this time. A second dextrose meal, with sodium bicarbonate 4 g. mixed with it, showed quite different appearances at fifteen minutes (fig. 2), and the man had no symptoms save slight distension.

EFFECTS OF BICARBONATE

Syndrome	No. of cases	Effect on symptoms	Effect on radiograph
Postprandial "dumping": Intestinal hurry	2	Relieved in both cases	Rate of passage of meal slowed in both cases
Intestinal spasm	3	Relieved in all cases	Spasm relaxed in all cases
Mixed types	4	Relieved in all cases	Spasm relaxed in all cases; rate of passage slowed in 1 as well
Afferent-loop distension	3	Relieved in 2 cases; unchanged in 1	Bowel relaxed in all cases
Stomal ulcer	3	No change in symptoms	No change in 2 cases; bowel relaxed in 1

Intestinal Spasm

Case 2.—A man, aged 31, had a duodenal ulcer which perforated twice before he underwent partial gastrectomy in 1950. After this operation he never felt well. He had exactly the same sort of epigastric pain after meals, its severity being equal to that of the original ulcer pain at its worst just before his second perforation, and he still had to diet himself and take alkalis for its relief. His bowels were very costive and his motions small and dark; he felt generally weak but had not lost any weight. Although he felt like lying down after meals, there were no vasomotor symptoms, such as sweating, palpitations, and pallor. The pain had changed its time of onset in relation to meals, coming on fifteen minutes after eating instead of two to three hours, and an intense feeling of distension was prominent. A dextrose-barium meal brought on all of his symptoms, with severe pain and feeling of distension, and severe spasm was seen at fifteen minutes (fig. 3). The patient's conception of being "blown out with the wind" should be compared with the radiograph of his small bowel, which appears to be tied up into knots. The same examination, repeated with sodium bicarbonate 4 g., led to less spasm at fifteen minutes (fig. 4) and less intense symptoms, although he still had a good deal of discomfort.

Afferent-loop-distension Syndrome

Case 3.—A man, aged 27, had a bad family history, his father having died of a perforated gastric ulcer and two of his brothers having had peptic ulcers. The patient had undergone partial gastrectomy in 1950, after a radiological report of a deformed duodenal cap. During the operation he had severe laryngospasm. No definite evidence of either gastric or duodenal ulcer was obtained, but nevertheless four-fifths of his stomach was amputated. Severe post-

prandial distress, relieved by vomiting large amounts of pure bile, was noticed as soon as he had got over the immediate postoperative phase. The bile was unmixed with food, even although he had just eaten. Once the bile had come up, he might be free from distress for some hours and get through the next meal without trouble. Certain foods —e.g., eggs—invariably brought on the symptoms, and he had got into the habit of refusing most things offered to him, preferring to live on a diet of dry bread and 'Bovril.' On this régime he lost weight slowly, became too weak for his employment, and was troubled with obstinate constipation. Fig. 6 is the fifteen-minute film after a dextrose-barium meal, and fig. 7 the fifteen-minute film when 4 g. of bicarbonate had been added to the dextrose-barium mixture. On both occasions the patient felt nausea and distension, but the symptoms were milder when bicarbonate was used. The degree of relaxation seen in fig. 7 is remarkable, but a similar degree of relaxation was seen in four other patients.

Flatulent Distension

This common symptom of the dyspeptic, which is so amenable to sodium bicarbonate, is associated, in our experience, more often with bowel spasm than with gaseous distension, although it is difficult to convince the patients of this fact, so certain are they that they are being blown out with wind.

Case 4.—A man, aged 40, underwent partial gastrectomy in 1950, an active duodenal ulcer being found. Afterwards he had one main symptom—flatulent distension ten minutes after food. He had maintained his weight but, like so many patients after partial gastrectomy, he never felt as strong as he did before operation. A dextrose-barium meal showed most of the meal at fifteen minutes to be in the small gut (fig. 9), which responded by initial localised spasm followed by hurry, the barium being evacuated within one and a half hours. Intense flatulent distension with nausea was complained of for the first twenty minutes after the meal. When the examination was repeated with the addition of sodium bicarbonate 4 g., the bowel relaxed and became full of gas at fifteen minutes (fig. 10), yet the symptom of "flatulent distension" was relieved.

Gas was noticed in the bowel of one other patient after the bicarbonate-dextrose-barium mixture.

COMPARISON OF SPASMOLYTIC EFFECTS OF SODIUM BICARBONATE AND OF VAGUS-BLOCKING COMPOUNDS

Atropine gr. $^1/_{100}$, injected subcutaneously just before the barium meal was swallowed, led to similar changes, relieving spasm and slowing hurry, the effects observed being comparable to those seen after giving sodium bicarbonate by mouth. In some cases atropine seemed

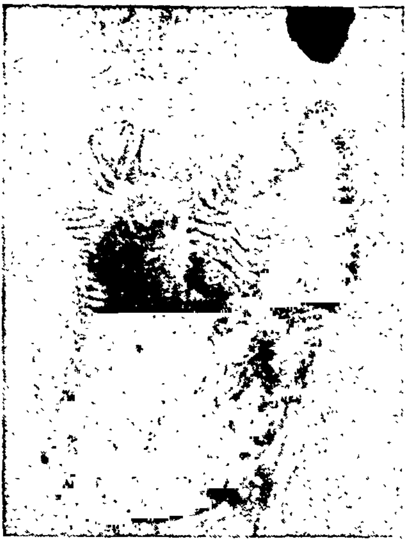

Fig. 10—Fifteen minutes after bicarbonate-dextrose-barium meal in case 4 (cf. fig. 9).

to have a relaxant action rather superior to that of bicarbonate ; in others it was not quite so effective.

Ro 2-3773 is a vagus-blocking agent which also has about the same activity as tetraethylammonium bromide as a ganglion-blocking agent (Randall et al. 1952) Balloon kymography had shown in man that its action on the small bowel, and the nature and extent of its side-effects, were similar to those of atropine.

Fig. 5 shows the fifteen-minute film of case 2. Ro 2-3773 10 mg. had been given immediately before he took the dextrose-barium meal. More relaxation was obtained, compared with the bicarbonate picture (fig. 4), and the patient felt even less distressed during the X-ray examination after Ro 2-3773 than after the two other barium meals.

In case 3, however, 10 mg. of Ro 2-3773 did not relax the bowel to the same extent that bicarbonate did at fifteen minutes (fig. 8). On the other hand, although most relaxation was seen with the bicarbonate, Ro 2-3773 afforded greater relief from symptoms.

DISCUSSION

One of the attractions of gastro-enterology is that the commonplace so often stimulates. One sometimes wonders, for instance, whence cometh the wind that distresses our chronic dyspeptics so woefully, and it certainly seems odd that a man should find he still has to take his alkali and his spasmolytic after partial gastrectomy.

The experimental work described here and elsewhere (Glazebrook 1952, Glazebrook and Welbourn 1952) suggests that small-gut spasm and hurry play their part in the production of post-gastrectomy syndromes. It must be admitted that the mixing of dextrose with barium is an artificial way of inducing disorders of motility, and other workers (Frazer et al. 1949, Ardran et al. 1950) state that the appearance of clumping of the barium, which we believe is largely due to spasm, is caused by the flocculating action of mucus. However, we are satisfied that both vagus-blocking agents and sodium bicarbonate can modify the X-ray appearances and the symptoms induced by the sugar.

The action of atropine and related compounds is expected ; that of bicarbonate is interesting, and the results encourage thought and speculation.

So far as the problems of partial gastrectomy are concerned, perhaps motility disorders of the small bowel are in some cases due to minor forms of the afferent-loop-distension syndrome, the bile following the meal down the alimentary canal instead of being mixed with it. In other cases possibly the food is dumped into the small gut so rapidly that it is denied the buffering actions and digestive ferments of the pancreatic juice.

There may be a type of dyspepsia related to deficiencies in the production of bile and pancreatic juice rather than to excess production of acid ; in some people the risks of alkalosis may prove a lesser evil than the long-term effects of diminishing pancreatic output by powerful vagus-blocking agents. Certainly after partial gastrectomy, where so much of the glandular apparatus of digestion has been abolished, further loss of digestive power by pancreatic depression should be avoided if possible.

Some of the most severe cases of post-gastrectomy syndromes are met with in patients who, so far as can be made out, have never had a duodenal ulcer at all, the X-ray sign of a deformed duodenal cap being taken as sufficient evidence to justify partial gastrectomy. Perhaps a primary disorder of intestinal motility, due to instability of the neuromuscular apparatus of the gut which makes it more sensitive to pH changes, is at fault. The man quoted at the head of this paper underwent partial gastrectomy at the age of 22. No evidence of a peptic ulcer, or of the scar of one, was seen either at operation or by the pathologist who reported on the removed tissues. The man, who found his pain was relieved by bicarbonate after the operation just as well as before, misinterpreted his visceral sensations. His gastric stump was empty at the time that he had his pain.

SUMMARY

Peristaltic rushes and spasms caused by giving sugar to eighteen patients with post-gastrectomy syndromes were, in fourteen cases, quietened by a teaspoonful of baking-soda.

The spasmolytic effect of the baking-soda was similar to that obtained by injecting either 0·6 mg. of atropine or 10 mg. of the spasmolytic substance Ro 2-3773 (1-methyl-3-benziloyloxy-quinuclidinium bromide).

We are grateful to Prof. J. le F. C. Burrow and Mr. George Armitage for their help and encouragement. We wish to thank the Director-General of Medical Services, Ministry of Pensions, for permission to publish, and Messrs. Roche Products Ltd. for supplies of Ro 2-3773.

PROGRESSIVE ORAL GANGRENE ROBABLY DUE TO LACK OF CATALASE IN THE BLOOD (ACATALASÆMIA)

REPORT OF NINE CASES

SHIGEO TAKAHARA
M.D.
PROFESSOR OF OTORHINOLARYNGOLOGY, OKAYAMA UNIVERSITY MEDICAL SCHOOL, JAPAN

An enzyme which generates oxygen in all animal nd plant cells by decomposing hydrogen peroxide has ong been known. Loew in 1901 named it catalase, nd it has been the subject of considerable biological nd chemical research; its rôle has hitherto remained bscure because of the difficulty of excluding catalase xperimentally from the tissues.

About five years ago I found a girl who had no atalase in her blood. She presented at hospital with painful mouth, and oral gangrene was found which had started at the margin of her gums. It was not until after considerable investigation that I found she had no catalase in her blood, and then I suspected a close connection between her lack of catalase and her symptoms.

After that I found five more cases of this rare condition, four of them being in siblings (see figure). These cases have already been published (Takahara and Miyamoto 1949); but I am still studying this subject and have discovered several new facts (Takahara 1951).

CASE-RECORDS

Case 1—On Dec. 25, 1946, a girl, aged 11 years, complained of pain in her mouth. Small ulcers had begun to appear on her gums when she was 8 years old. Some of them disappeared spontaneously, but were very soon succeeded by others which encroached upon the gums and dental alveoli, thus loosening the teeth. When these teeth dropped out spontaneously or were pulled out, the affected parts healed. After a tooth had been extracted in November, 1946, a sequestrum appeared at the site of the tooth, and gangrene followed. Various medical treatments were given unsuccessfully; in fact, the condition became worse. About Dec. 15, 1946, the right cheek began to swell, causing keen pain, and the patient's temperature rose to 101°F.

On examination her cheeks were greatly swollen and slightly reddened, and she was pale. She had lost several teeth, and almost all the remaining teeth were affected by gangrene. The most conspicuous symptom was caries in the right maxilla, extending as far as the maxillary sinus and nasal cavity and giving forth a nauseating smell. The patient's temperature was 99·5°F, and pulse-rate 85. Her liver and spleen could not be felt. Examination of her blood showed erythrocyte-sedimentation rate 35 mm. in one hour, 54 mm. in two hours; red cells 3,450,000 per c.mm.; leucocytes 9400 per c.mm.; Hb 65%; bleeding-time and coagulation time normal; and serum negative for syphilis. Nothing abnormal was detected in the fæces and urine. On rhinoscopy I found, in the right nasal cavity, a tumour covered with putrid granulations, which bled easily on being touched. A biopsy specimen revealed chronic inflammation.

Operation.—The tumour was radically removed and the area curetted. I washed the operation wound with hydrogen peroxide as usual, whereupon the cavity in the maxilla and the blood oozing from the wound immediately became brownish black, just as if silver nitrate had been applied by mistake. Thinking this was so, I frantically poured on saline solution to neutralise the silver nitrate. Next, I washed the wound with hydrogen peroxide from a new bottle, and the same thing happened again. Finally I noticed that the black colour was caused by the blood oozing out of the wound, and that there were very few bubbles.

Postoperative Course.—The diseased part in the upper right jaw took a turn for the worse three times after the operation. Sequestra formed three times, necessitating curettage each time; but the affected part was completely cured in about two months. In January, 1948, the site of the extracted teeth became ulcerated; so it was curetted, and sulphanilamide was given. In spite of this, gangrene developed spread rapidly toward the root of the tongue. So I made a small opening from the diseased part to the submental part and inserted a drainage tube. By repeatedly washing out with 'Rivanol' solution through the opening for about a month the pus was cleared away and the disease checked. In October, 1948, another tooth was pulled out. Gangrene rapidly developed from the site of the tooth, and the cheek became much swollen, causing great pain. The patient's temperature rose to 101·3°F, and other constitutional symptoms developed. After a course of intramuscular penicillin G 400,000 units, a sequestrum came away spontaneously, and the part was cured. After that, teeth were pulled out one after the other whenever ulcers appeared in her gums. Now, at the age of 15, she is in full development and in good health but has not a tooth left. She recently had her first menses.

Her mother told me she had five children besides this girl, and that two of them, a boy and a girl, had the same disease. I got them to come to the hospital for a blood examination. I dropped hydrogen peroxide into the blood taken from their ear lobes. As I expected, the blood turned brownish black instantly and no bubbles were generated. By the same method I found that another sister, aged 8 years, had the same kind of blood. In other words, four children out of six born of the same parents (see figure) had no catalase; and only these four children showed similar symptoms in their gums.

Case 2.—A boy, aged 13, older brother of case 1, also had sporadic ulcers of the gums from the age of 8 years, and the diseased teeth dropped or were pulled out. When he was aged 12, a tooth became loose and was extracted by a dentist. Later an ulcer formed at the site. It did not heal readily and part of the jaw became very painful, swollen, and slightly inflamed. The diseased part of the lower jaw was resected, and the disease was checked. A year later the defect in the jaw was made good with part of one of his ribs. Half a year or so later another tooth in the maxilla was extracted, and afterwards an ulcer developed from the socket of the extracted tooth and advanced to the maxillary sinus. I curetted the affected part by Luc's method, and it soon healed.

In June, 1949, when he was 14, a boil appeared on his right cheek and suppurated. Two or three days later the right submaxillary gland became swollen, causing a dull pain, and was massaged at home. Next, his neck began to swell and the pain became unbearable; his temperature rose to 101°F. At midnight he complained of a difficulty in breathing and appeared to have Ludwig's angina. As soon as day broke he was brought to our hospital. Tracheotomy was done immediately, and the swollen part was incised just below the right jaw. A drainage tube was inserted to enable the incised wound to be washed out every day with rivanol solution, and intramuscular penicillin G 1,000,000 units was given. The boy recovered and was completely healed within ten days.

Case 3.—A girl, aged 4 years, sister of cases 1 and 2, was attacked by the disease at an earlier age than her sister and her brother. When she was aged only 2 years, gangrene started at the gums of her lower front teeth. After five teeth had been pulled out, the ulcers healed. When she was aged 4 years, her upper teeth became affected likewise.

On examination she was a little pale but she was otherwise in good health, and her liver and spleen were impalpable. A blood-count showed red cells 5,030,000 per c.mm; leucocytes 8500 per c.mm., Hb 74%.

Treatment and Progress.—By pulling out all the affected teeth, the patient was soon cured. Two or three new permanent teeth have begun to appear since then, and nothing unusual is noticeable about them.

Case 4.—A girl, aged 9, sister of cases 1–3, showed nothing abnormal in her mouth when I first examined her with the other siblings of case 1 and found that her blood was blackened by hydrogen peroxide. Later, however, she began to complain of dull pains round some of her upper teeth at night. Next, the gums between the teeth became slightly shrunken and a small ulcer appeared there. The same happened to other upper teeth in the next two months; but the disease disappeared spontaneously without any medical treatment.

Case 5.—A boy, aged 13, had had similar trouble for ten years. When he was aged about 3 ye a small ulcer w far as the buccal mucosa and an œdematous swelling appeared on the cheek, resembling noma. This was checked by medical treatment, but ulcers recurred in other parts of the gum. Although various treatments had little effect, the disease did not progress rapidly. The boy's teeth were removed only after the alveoli had been destroyed and the teeth became loose. When he was aged 11 years, he was sent to hospital with ulcers over a wider area of the gums. That is when I first saw him. The condition improved temporarily, but by the next year gangrene developed, reaching the left maxilla. A sequestrum was removed, and a fistula appeared on the site, extending as far as the left maxillary sinus. The pus had a very bad smell, severe pain was felt at the diseased part, and the boy's temperature rose to 101·4°F. Temporary improvement was brought about by curettage of the diseased part followed by penicillin injections.

Towards the end of 1948 ulcers reappeared at the same place and his cheek was swollen. From that time on he began to complain of a dull pain in the right lower jaw and the *fetor ex ore* became more intense. So in February, 1949, he called at our clinic. When I added hydrogen peroxide to his blood, it blackened immediately, just as in cases 1–4. After a while it began to fade, finally becoming completely discoloured. This colourless liquid showed the pentdyopent reaction (see below). The fact that catalase was completely lacking in his blood was also shown by quantitative examination. The diseased part in the upper left jaw was removed by Luc's method, and the wound was washed with rivanol solution. At the same time intramuscular penicillin 600,000 units was given. By these treatments the diseased part was completely healed.

Later, in April, 1949, a deep ulcer, which was similar to Vincent's angina, appeared (having no connection with the teeth) on the left tonsil. Although such an ulcer was not seen in cases 1–4, I think it must be an important symptom of this same disease. Since many organisms usually live in the crypts of the tonsils, hydrogen peroxide is produced continuously by bacteria (see below). Consequently necrosis begins in the crypts of the tonsils as it does in the gums. In April, 1950, the patient had necrosis of the tongue on the left side, caused by extension of an ulcer connected with one of his lower teeth.

Besides cases 1–5 four others were found in ten siblings of the Abe family (see *figure*) in a different prefecture. They showed a lack of catalase in the blood and two of them also had the same symptoms, though slight, at the gums in their childhood.

EXPERIMENTAL STUDIES

If hydrogen peroxide solution is dropped into normal human blood, gas is evolved and the colour of the blood remains unchanged. This is because the H_2O_2 is decomposed by the action of the catalase in the blood:

$$2\,H_2O_2 \xrightarrow[\text{(catalase)}]{} 2\,H_2O + \underset{\text{(bubbles)}}{O_2}$$

TABLE I—QCAT OF BLOOD AND ORAL AND NASAL TISSUE I ACATALASÆMIC AND IN NORMAL PERSONS. ESTIMATED B WARBURG'S MANOMETRIC METHOD (FUJITA AND KODAM 1931)

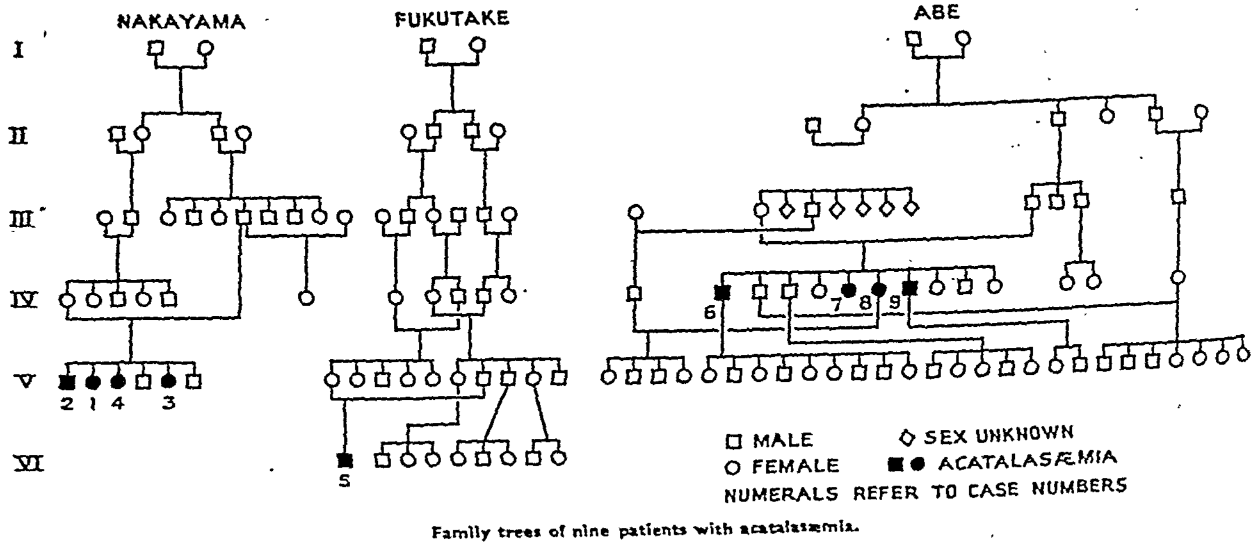
Acatalasæmia					Normal persons
Case no.	Sex	Age (yr.)	Material examined	Qcat	Qcat
1	♀	16	Blood from earlobe	7	4500
2	♂	18	Venous blood	5	About 4500
			Blood from earlobe	6	4500
3	♀	8	Blood from earlobe	10	4500
			Normal oral tissue	0	250
4	♀	14	Blood from earlobe	10	4500
5	♂	17	Venous blood	9	About 4500
			Erythrocytes of venous blood	8	12,000
			Normal oral tissue	0	250
			Marginal tissue of oral ulcer	0	..
			Tissue of oral ulcer	0	..
			Tissue of ethmoidal sinus	0	450
			Nasal polyp	0	200

Qcat (quotient of catalase) is calculated according to the following formula:

$$\text{Qcat} = \frac{\text{Quantity of } O_2 \text{ generated in 30 min. at 38°C (c.mm.)}}{\text{Weight of dried substance of examined material (mg.)}}$$

When, however, hydrogen peroxide was dropped into the blood of cases 1–5, the blood blackened immediately and gas did not appear; after a while only a few little bubbles were seen. I therefore estimated the amount of catalase in their blood (table I).

From table I it will be seen that the Qcat of every tissue taken from the nose and mouth in acatalasæmia was 0 and the Qcat of the blood of these patients was 5–10. Since this number for the Qcat of blood was a little more than that of an average observational error, it seemed that the acatalasæmic patients might have an extremely small amount of catalase in their *blood*. The Qcat of a normal person's blood is about *4500*, and the ratio between the Qcat for normal and acatalasæmic blood is about 450/1 to 900/1. Since the Qcat of the tissues of the acatalasæmic patients was always 0, it seemed possible that the number (5–10) for the Qcat of their blood had almost no meaning, in so far as it



Family trees of nine patients with acatalasæmia.

concerned the function of catalase. Such conclusions were further justified by the results, obtained during the past five years, of catalase estimations made by Inoue's permanganate method. Catalase in the blood of healthy persons and of inpatients of our clinic has been estimated by this method, and the results are shown in table II.

Table II shows that most persons whose blood was normal as regards catalase had an index number of about 5·0–10·0 (3·3–10·9). It is also clear that, except in acatalasæmia, the index numbers had no relation to disease. The index numbers of the blood in acatalasæmia were 0·0–0·1, and I have not noticed any significant change in the quantity of blood-catalase in five years.

I have thus confirmed that the quantity of catalase in the blood in acatalasæmia was about $^1/_{1000}$ of normal. If our acatalasæmic patients had had any catalase in their blood, it must have been an extremely small amount in comparison with that of normal persons. Peroxidase was found in normal amounts in the blood of all our patients.

The reason why the acatalasæmic blood was blackened by adding hydrogen peroxide may be as follows. Hydrogen peroxide poured into acatalasæmic blood is not decomposed as usual by catalase. As a result, the hydrogen peroxide changes the oxyhæmoglobin into methæmoglobin by oxidation; accordingly the blood is blackened in an instant.

TABLE II—QCAT OF BLOOD IN ACATALASÆMIC AND IN NORMAL PERSONS ESTIMATED BY METHOD OF INOUE 1920 AND INOUE ET AL. 1925 (STERN 1927, 1932)

Cases	No. of persons	Catalase index		
		Average	Min.	Max.
From families with acatalasæmia :				
With acatalasæmia	9	0·0	0·0	0·1
Without acatalasæmia	45	5·5	3·4	7·2
Normal healthy persons	20	7·4	4·3	9·5
100 inpatients of the clinic :				
Maxillary sinusitis	19	7·6	5·2	10·2
Tonsillitis	17	7·8	5·5	9·5
Suppurative otitis media ..	12	7·7	6·9	9·2
Carcinoma of larynx	12	8·9	6·8	10·9
Carcinoma of maxillary sinus ..	10	7·4	3·3	10·5
Tumour of nasopharynx ..	3	7·7	7·5	7·9
Carcinoma of œsophagus ..	3	6·9	4·9	8·0
Epistaxis	3	6·2	4·1	7·3
Diphtheria..	2	7·5	7·3	7·7
Carcinoma of tongue	2	7·6	7·1	8·1

Miscellaneous diseases :
Brain abscess, 10·9; glioma of temporal lobe, 8·6; cyst of cerebellum, 9·2; Ménière's disease, 6·3; tumour of cheek, 8·8; perforation of nasal septum, 6·2; spontaneous gangrene of nose, 7·6; sarcoma of maxillary sinus, 7·2; cystoma of dental root, 9·6; ranula, 8·9; lymphosarcoma of tonsil, 7·5; carcinoma of pharynx, 8·7; paralysis of larynx, 7·8; Mikulicz's disease, 6·9; nocturnal laryngeal dyspnœa, 4·4; carcinoma of thyroid gland, 8·2; struma cystica, 8·7.

This oxidation can be observed in a test-tube. When a small quantity of hydrogen peroxide is poured into acatalasæmic blood in a test-tube, the blood remains black for a long time. However, if an excess of hydrogen peroxide is added, oxidation continues and the blood begins to lose its dark colour within about 20–30 minutes and becomes light-reddish brown, then lemon-yellow, and finally colourless and transparent. This liquid contains propentdyopent, a final decomposition product of hæmoglobin (see below).

Previous research concerning this chemical process was carried out by Bingold (1935, 1936), Fischer and Müller (1937) and Fischer and von Dobeneck (1940). Bingold, studying the destruction of hæmoglobin by hydrogen peroxide, noticed the formation of a colourless substance, the final breakdown product of hæmoglobin. If a small amount of a solution of potassium hydroxide is added to this colourless substance, and the mixture is heated for a little while and then reduced with sodium dithionite ($Na_2S_2O_4$), a beautiful rose colour is seen. Bingold (1935) named this rose-coloured substance "pentdyopent," and the reaction the "pentdyopent reaction." The name "propentdyopent" was given by Fischer et. al. to the substance which is the foundation of the "pentdyopent reaction"—i.e., the precursor of pentdyopent. This reaction was positive with the blood of all my acatalasæmia cases.

The question arises why a particular oral disease is caused when catalase is lacking in the blood. To study this question, I made a blood-agar plate with blood from one patient and another plate with blood from a normal person. I then planted hæmolytic streptococci or pneumococci type I, taken from the affected parts of the oral cavity of patients, on to these blood-agar plates. Since hæmolytic streptococci or pneumococci type I were the predominating organisms in the affected parts, we can suppose that these bacteria were the main organisms causing the ulceration. On the blood-agar plates there was no conspicuous difference between the development of the colonies; but on the plate made from the acatalasæmic blood wide transparent rings instead of hæmolytic rings appeared round the colony after 24 hours' incubation, whether it was aerobic or anaerobic. After 48 hours these discoloured rings became wider. My explanation of this is as follows.

It is well known that hydrogen peroxide is generated when hæmolytic streptococci or pneumococci grow. When the hydrogen peroxide generated from the colony on the acatalasæmic blood-agar plate reaches the surrounding medium it oxidises the oxyhæmoglobin to methæmoglobin. As the oxidation goes on, the media round the colony gradually fades and is finally turned into transparent propentdyopent. Needless to say, the ring-shaped colourless zone round the colony showed the pentdyopent reaction.

In this rare disease, thought to be due to a lack of catalase in the blood, one would expect special histological features of the affected parts. In preliminary histological examinations I have observed the following special features: despite a striking tendency to necrosis, inflammation was only rarely seen; the capillary vascular wall was much destroyed, and it seemed that an affected part had formed round the destroyed blood-vessel.

DISCUSSION AND CONCLUSIONS

From the above-mentioned experimental research I conclude as follows. Gums are apt to be injured by mastication. Wounds in gums are suitable media for oral and other bacteria. Hæmolytic streptococci are most commonly found among oral bacteria. As already mentioned, the hæmolytic streptococcus generates hydrogen peroxide. In normal persons hydrogen peroxide thus generated is easily neutralised by the catalase, and no trouble is caused. But in people who lack catalase in their blood the consequences would be serious. In them the hydrogen peroxide produced by the bacteria would oxidise blood reaching the lesion, thus depriving the infected area of oxygen and causing necrosis. This would favour multiplication of the bacteria and thus increase the amount of hydrogen peroxide being generated and lead to further oxidation of oxyhæmoglobin. In this way a small ulcer might gradually develop into a very large one with much necrosis but not much inflammation.

The acatalasæmia in at least two of these three families is probably hereditary. The family relationships are shown in the accompanying figure. In the Nakayama family four out of six children have acatalasæmia, and their parents are consanguineous, being second cousins. In the Fukutake family the patient has no brothers or sisters; but not only are his parents first cousins but also both his father and his mother are the children of two pairs of cousins. In the Abe family four out of ten children have acatalasæmia, and their parents are also first cousins. It therefore looks as if acatalasæmia is hereditary and facilitated by consanguineous marriages.

As regards the dental disease, in the Nakayama family the father, two aunts, and a grandfather all have severe alveolar pyorrhœa. The father's teeth were all gone before he was 30, owing to alveolar pyorrhœa. In the Fukutake family the patient's father also had this disease. Thus, although the main cause of the oral gangrene described above is the lack of catalase in the blood, it is also probable that its occurrence might be promoted by factors transmitted from the paternal side.

SUMMARY

Nine cases, in three families, of complete lack of catalase in the blood (acatalasæmia) are reported.

Seven of the nine patients had progressive oral gangrene which was probably due to the lack of catalase.

The most prominent characteristic is that the blood blackens instantly when hydrogen peroxide is added to it.

The condition is probably inherited.

I wish to thank my colleagues Dr. H. Miyamoto, Dr. H. Sato, Dr. H. Matsumura, Dr. S. Inoue, Dr. K. Tsugawa, Dr. M. Doi, Dr. S. Mihara, and Dr. Y. Ogura, whose coöperation was a great help to me in this research.

CONGENITAL VACCINIA AND VACCINIA GRAVIDARUM

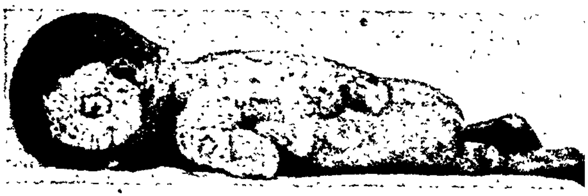
PATRICK MACARTHUR
M.D. Glasg., F.R.F.P.S., D.C.H.
CONSULTING PÆDIATRICIAN, LANARKSHIRE COUNTY COUNCIL

IN 1950 there was an outbreak of smallpox in the West of Scotland (Laidlaw and Horne 1950) and many people came for vaccination in the first week of April that year. Among them was a young woman about three months pregnant who had never before been vaccinated. She developed a severe primary reaction, and three months later she was spontaneously delivered of a feeble hydropic premature infant covered with a very severe generalised vaccinia (see figure). The child died 18 hours after birth and necropsy was performed. The detailed clinical and pathological features on which the diagnosis of fœtal vaccinia was established, including nuclear inclusion bodies similar to those described in vaccinia, have been recorded elsewhere (Macdonald and MacArthur 1952).

Considering the countless millions of vaccinations that have been done, it is remarkable that congenital vaccinia has been described only once before (Lynch 1932). The recognition of this case prompted further investigations to determine the frequency with which vaccination during pregnancy has a harmful effect on the fœtus.

PRESENT INQUIRY

As a very large number of persons had been vaccinated during the West of Scotland outbreak of smallpox it was thought that valuable information might be obtained from a follow-up of a series of women who were pregnant at the time of vaccination.



Premature infant with severe generalised vaccinia.

A sheet of paper bore on one side a letter from th Medical Officer of Health reminding the recipient of h interest in her health and welfare, and exhorting her t answer the list of questions on the other-side of th paper and to return it to him. The questions wer designed to discover whether the woman had bee successfully vaccinated, whether she was pregnant a the time of vaccination and, if so, the result of he pregnancy, with dates, birth weight, place of confinement and other information. In only 3 cases was it necessar to correspond further with a woman to clarify he statements.

In all, 5059 of these questionnaires were posted t women under the age of 45 years who had given the titl "Mrs." before their name at the time of vaccination No other selection was made, and the names were take consecutively from the vaccination returns until about 5000 had been obtained. The Post Office delivered 482 of these 5059 questionnaires, and 3408 (71%) replies were received. At any given time there will be an approximately equal number of women in each trimester of pregnancy ; and therefore, if chance alone determined the incidence of reply, we should expect about an equal number of returns in each trimester. Table I shows that similar numbers were in fact received. The first trimester has, however, been extended by two weeks to include women who became pregnant within two weeks of vaccination ; and therefore this group should have been somewhat larger than the other two. Since this expectation is not fulfilled, it is possible that a somewhat larger proportion of the women who did not reply may have been in this group. This hypothesis is further supported by the fact that a woman is less likely to remember the exact date of an early abortion than the date of her child's birth, and if she receives an inquiry more than a year later she may not remember whether she aborted shortly before or shortly after her vaccination. If she aborted during the second month she may not even be sure that she was pregnant. Being in doubt she would probably leave the inquiry unanswered.

It is believed, therefore, that the 29% of women who did not reply may have had no influence on the results obtained ; or, if they did influence the figures, it is most probable that they did so by diminishing the number of abortions in early pregnancy. If these women had replied they would thus have been more likely to reinforce the argument than to weaken it.

Of the replies, 259 were from women who had been pregnant about the time of vaccination, but 45 of these women did not develop a vaccination reaction leaving a scar, and a further 11 became pregnant more than tw weeks after the day of vaccination. When these 56 ar eliminated, there remain 203 women who developed vaccination reaction and were pregnant at the time o vaccination or became pregnant within two weeks of the day of vaccination.

These 203 pregnancies were classified according to the stage of pregnancy at the time of vaccination (table I). There were 67 in the first trimester, 69 in the second, and 67 in the third. The first trimester was further subdivided into (1) women who were pregnant for less than four weeks before vaccination or became pregnant within two weeks after vaccination, and (2) women whose pregnancy lasted from four to twelve weeks when they were vaccinated.

The results of each of these 203 pregnancies has been determined (table I), and it is at once obvious that only in the first trimester, particularly in the second and third months of pregnancy, could there be any question of vaccination having a harmful influence on the pregnancy. No less than 47% of women vaccinated in the second or third month of pregnancy failed to give birth to a healthy child; or, if the whole of the first trimester is taken together, the proportion is 24%.

It was impossible to devise a suitable local control series with which to compare the results obtained in this inquiry; so a review of recent literature on the incidence of unintentional abortion was undertaken to obtain a basis for comparison. The senior consultant obstetrician in the area in which the inquiry was made (Dr. R. A. Tennant) is confident that the incidence of unintentional abortion in the area is comparable to modern experience in other centres and is far less than was encountered in this inquiry. The incidence of stillbirths is known to be less than 3% of all births. There is a considerable measure of agreement among recent workers on the frequency of unintentional abortion, and Randall et al. (1950), after reviewing the subject and presenting their own series of 2050 women with 5·5% abortions, conclude that "recent literature indicates that the overall incidence of abortion in any sizeable series of cases should approximate 5–7 per cent and should never exceed 10 per cent." For statistical comparison, if these estimates are correct and the mortality has been the worst possible—i.e., 10% abortions and 3% stillbirths—the total fœtal loss would be 13%. In the vaccinated series only women in the first trimester have been included, because the great majority of abortions occur during this stage of pregnancy, and almost all the women who became pregnant at the same time as those in the second and third trimesters (table I) but aborted did so before they were vaccinated and therefore do not appear in this inquiry at all. A statistical test shows that there is a significant increased mortality (on the 5% level of significance) among the fœtuses of women who were vaccinated during the first trimester of pregnancy (table II).

TABLE I—ANALYSIS OF REPLIES TO QUESTIONNAIRE

Stage of pregnancy	No. of women	Result of pregnancy	Percentage of abnormals	
Less than 4 weeks ÷ Women who became pregnant within 2 weeks after vaccination	33	32 Normals 1 Miscarriage	3	24
4–12 weeks	34	17 Normals 1 Normal premature 10 Miscarriages 5 Stillborn 1 Congenital abnormality	47	
2nd trimester ..	69	66 Normals 1 Normal premature 1 Stillborn 1 Neonatal death	3	
3rd trimester ..	67	63 Normals 3 Normal prematures 1 Cerebral birth trauma	2	

TABLE II—FŒTAL LOSSES

Series	Fœtal deaths	Total number of pregnancies	Fœtal loss (%)
Randall et al. (1950) (with highest possible mortality)	267	2050	13
Present vaccinated series (1st trimester)	16	67	24

DISCUSSION

Since the introduction of vaccination by Jenner in the 18th century there have been many reports that vaccination has no harmful effect on a pregnant woman or on the fœtus within her. Sometimes the statement has been copied word for word from one publication to another. Most of these reports come from workers who vaccinated pregnant women in a maternity hospital. Sometimes no information is given about the duration of pregnancy at the time of vaccination, but it is obvious from most reports that most of the women were at or near term when vaccinated. One example of a report that has been copied by other authors is that of Urner (1927). He vaccinated 129 pregnant women and stated that there was not a single case of threatened abortion, miscarriage, or premature labour. He concluded that vaccination in pregnancy had no deleterious effects on mothers or their infants. But he did record the stage of pregnancy at which the vaccinations were done, and we find that of the 129 women 107 were in the last trimester: indeed only 1 woman was vaccinated in the twelfth week of pregnancy, and 128 in the fourth month or later.

It is obvious that investigations of this scope do not justify the sweeping conclusions that have been drawn from them. Nearly all these studies were made before the work of Gregg (1941) and Swan et al. (1943), in Australia, established the importance of virus infection in the second and third months of pregnancy as a cause of fœtal abnormality. What they do show is that vaccination in the later months of pregnancy has no harmful effect, at any rate in the great majority of cases. On the grounds of analogy it seems probable that, even in the last weeks of pregnancy, vaccinial infection in the mother could be transmitted occasionally to the fœtus, since it is fully established that the related virus infections of variola and of chickenpox are capable of transplacental transmission (Marsden and Greenfield 1934, Shuman 1939).

There has been one study of the effect of vaccination in the first trimester. In 1947 there was an outbreak of smallpox in New York, and about five million people were vaccinated. Greenberg et al. (1949) found no significant increase in the number of malformed children, premature births, or stillbirths born to 4172 women vaccinated in the first trimester of pregnancy. But there is much to criticise in this investigation of such enormous numbers. These workers studied reports on children admitted to child-welfare centres at the appropriate time and the notifications of stillbirths and the number of babies born prematurely in the city's maternity hospitals, and then set out to discover whether or not the mothers had been vaccinated in pregnancy. The 4172 women classified as "vaccinated during the first trimester" were examined by doctors and were retained in this group although it is stated that almost half of them bore no vaccination scar. Greenberg et al. had no information about abortions. There are opportunities for cumulative statistical errors in this inquiry, and, further, this retrospective method of study has inherent fallacies which have been clearly described by Logan (1951), who asserts that the only satisfactory approach to the problem of the effects of virus infection in pregnancy is the prospective type of inquiry which begins with a series of pregnancies and studies their results. The inquiry conducted by us was of this prospective type.

It is regrettable that no suitable control series of unvaccinated women could be arranged to run concurrently with the vaccinated series, and the lack of a comparable control certainly diminishes the reliability of the findings. There is, however, so large a measure of agreement among recent investigations into the frequency of abortion that this deficiency should not invalidate my conclusions. The control that has been used is theoretical and not factual; it represents the highest incidence of fœtal loss that Randall et al. (1950) considered could occur in a series of normal pregnancies—not an average figure but nearly twice the rate of fœtal loss that Randall et al. (1950) encountered in their own practice. The figure of 2050 pregnancies is the number in Randall's own series. Although there is no control series with which to compare the pregnant and vaccinated women, some internal comparisons in the group of vaccinated women are of value.

It is very striking that only one fœtus was lost by the 33 women vaccinated within four weeks of conception, when the fœtus is much more completely separated from the mother than in the later months, when intimate placental contact between the two circulations exists. It was during the next two months that the fœtal loss was greatest, though the potential duration of exposure to damage from the virus was similar in these two groups. This virus seems to be particularly lethal to the fœtus during the second and third months of pregnancy.

Of the 24 pregnancies going to term, or nearly to term, in the second group (table I) 5 produced stillbirths, but only 1 of the 169 other such pregnancies produced a stillbirth.

We have no knowledge of the pathological changes in the fœtus which lead to death, though it would be very valuable to know what these are. Nor have we any detailed clinical information about the health of the survivors, but it is intended to pursue this later. In the absence of this information no useful statement can yet be made about vaccination as a cause of congenital abnormality in children.

CONCLUSIONS

The conclusions reached from this study are as follows:

(1) Vaccination of a pregnant woman may, though very rarely and perhaps only in special circumstances, lead to fatal generalised vaccinia of the fœtus.

(2) Vaccination of a pregnant woman during the first trimester of pregnancy, and especially during the second and third months of pregnancy, significantly increases fœtal mortality.

If these findings are confirmed by others, it will be clear that vaccination should never be done during the first trimester of pregnancy as part of routine public protection, and that it should be done at this stage of pregnancy only in women who have been in contact with smallpox. Damage to the fœtus is done, however, only during the first trimester of pregnancy, and there is virtually no risk from vaccination during the later months.

SUMMARY

A case of congenital vaccinia following vaccination of a pregnant woman at the end of the third, or beginning of the fourth, month of pregnancy is recorded.

An inquiry was made into the frequency with which vaccination during pregnancy is harmful to the fœtus. Analysis of the results in 203 pregnancies in which the woman was vaccinated immediately before or during pregnancy showed a highly significant increase in mortality among the fœtuses of women vaccinated during the first trimester of pregnancy.

I am greatly indebted to Dr. Andrew G. Reekie, medical officer of health for Lanarkshire, for generous facilities and assistance in this inquiry, and also to Mr. David Reid, of the department of public health, Lanarkshire County Council, and his assistants, who did so much extra clerical work. I am also grateful to Dr. R. A. Robb, lecturer in statistics in the University of Glasgow, for the statistical analysis; to Dr. A. M. Macdonald for the photograph; and to Prof. Stanley Graham and Dr. J. H. Hutchison for advice on the preparation of this report.

TERRAMYCIN IN THE TREATMENT OF INFECTIVE DIARRHŒA IN INFANTS

I. J. Carré
M.R.C.P.

K. B. Rogers
M.D. Lond.

S. M. Saddington
M.B. Birm.

W. C. Smallwood
F.R.C.P.

From the Children's Hospital, Birmingham

Terramycin, isolated from *Streptomyces rimosus* by Finlay et al. (1950), has been shown to combine low toxicity with a wide range of antibacterial action. It is effective against many gram-positive and gram-negative bacteria and against spirochætes, rickettsiæ, and some viruses. Except for the one case of Neter and Shumway (1950) we have found no reference to the use of terramycin in the treatment of non-specific diarrhœa in infants. By non-specific diarrhœa we mean cases of infective diarrhœa other than those due to infection with organisms of the salmonella or shigella groups or with *Giardia lamblia*. The small clinical trial here described was undertaken to determine the possible value of terramycin in this condition.

FORM OF TRIAL

The trial was confined to 21 infants admitted to one floor of the Leonard Parsons infants' block of the Birmingham Children's Hospital between March 31 and June 20, 1952. The ages of the infants varied from 2 weeks to 8 months; the average age of those receiving terramycin was 4½ months and of the controls 5 months. The criterion for inclusion in the trial was the presence of diarrhœa severe enough to require a period of feeding with clear fluid. Infants with gross parenteral infection were excluded, as well as any whose diarrhœa could be ascribed to overfeeding. At the time of their selection for the trial cases were classified into two groups, mild and severe; those requiring parenteral fluid was classed as severe. No reclassification was made later, whatever the course of the illness. Alternate infants in each group were given terramycin, the others serving as controls. The number and form of the stools passed each day were recorded. Fæces or rectal swabs were cultured at the time of selection for the trial and then daily for at least two weeks. The results of these bacteriological studies were not made known to those responsible for the ward work during the trial.

The first specimens were examined fully for salmonellæ, shigellæ and, when possible, *Giardia lamblia*. Specimens were plated on to desoxycholate citrate agar and into selenite F, the latter being subcultured after 1 and 5 days on to desoxycholate plates. Every specimen was plated on MacConkey's medium, and the colonies were examined by slide agglutination for the presence of 6 of the specific strains of *Bact. coli* that have been found to be associated with infantile gastro-enteritis. Positive cultures were confirmed by biochemical study and by tube agglutination against O and K specific antisera.

All the infants, terramycin-treated and controls, were fed alike. For the first twenty-four hours feeds were restricted to 5% dextrose in $N/5$ saline solution, and this was followed by the gradual reintroduction of milk feeding, the aim being to achieve full-strength feeds by the tenth day of treatment. The infants with severe diarrhœa received intravenous fluids for various lengths of time. An elixir of terramycin was given six-hourly by mouth for 7 days in a total dosage of 75 mg. per lb. of body-weight a day to infants in the treated group. No other antibiotic or chemotherapeutic agent was administered to any infant, unless there was evidence of parenteral infection, and in these only intramuscular penicillin or streptomycin was used. One terramycin-treated baby and 2 controls were so treated. For the purposes of assessment all infants receiving full-strength feeds whose diarrhœa had ceased by the tenth day of entry into the trial were regarded as having made a "satisfactory recovery." Any return or increase in severity of diarrhœa within the next three weeks requiring treatment with clear fluids orally was termed a "relapse."

RESULTS

Mild Group

Of the 8 infants *treated with terramycin* all still had diarrhœa at the end of seven days' treatment, with 5–10 loose green stools a day. When terramycin was discontinued, the stools diminished in number and became of normal consistence and colour within 3–5 days. 6 of the 8 terramycin-treated babies in this group were regarded as having made a "satisfactory recovery." Of these 6, 1 later "relapsed." Of the 2 infants whose clinical course was unsatisfactory 1 continued to pass frequent loose stools and later "relapsed," whereas the progress of the other was apparently retarded by a complicating parenteral infection. 7 out of these 8 infants had *Bact. coli* type 0·111 B.4 (Kauffmann and Dupont 1950) cultured from rectal swabs taken at the time of entry into the trial. At the end of the seven-day treatment with terramycin this organism could no longer be isolated from the fæces, but in 4 infants the organism had reappeared within five days of stopping treatment with terramycin. Only 1 of these 8 babies showed evidence of parenteral infection. This infant had an upper respiratory-tract infection which rapidly cleared on treatment with terramycin, but the character and frequency of the stools remained unaltered.

In the 7 *control cases* the diarrhœa seemed to abate rather more rapidly, but full recovery from diarrhœa in both treated infants and controls was achieved in about the same number of days. 4 infants were deemed to have made a "satisfactory recovery," and none of these 4 relapsed. 1 of the others continued to have diarrhœa and showed evidence of a parenteral infection. The clinical course was prolonged in the second. The third infant had persistence of loose stools and eventually a "relapse."

On entry to the trial 6 of the 7 control infants had *Bact. coli* type 0·111 B.4 in the fæces, and these organisms were still present in 5 at the end of a week.

Since the object of the trial was the treatment of diarrhœa, the numbers of stools passed by the terramycin-treated and control infants are shown in the accompanying table.

COMPARISON OF NUMBERS OF STOOLS OF TREATED INFANTS AND CONTROLS

Group	Average no. of stools passed daily during first 7 days' treatment	Average no. of stools passed daily during 8th to 12th days of treatment
Terramycin-treated (8 cases)	5·5	4·2
Control (7 cases)	3·8	4·0

Severe Cases

Of 6 babies with severe diarrhœa 3 were treated with terramycin. Of these 1 made a "satisfactory recovery." A second had persistent diarrhœa but was later shown to have pancreatic fibrosis. The third infant died thirty-two hours after admission to the trial with bilateral suprarenal hæmorrhages. This was the only death in the whole series. In the first and third infants *Bact. coli* type 0·111 B.4 were isolated from rectal swabs.

Among the 3 controls 2 recovered within two weeks; the third ran a more prolonged course but eventually recovered. *Bact. coli* type 0·111 B.4 were isolated from the stools of all 3 infants.

In none of the 11 terramycin-treated cases did any evidence of moniliasis appear. There was no vomiting or anorexia which could be attributed to terramycin; nor was there any increased tendency to sore buttocks.

DISCUSSION

As most of the cases included in the trial had their origin in a small institutional outbreak of infantile gastro-enteritis, probably the majority in each group were affected by the same ætiological agent. Every effort was made to ensure that both terramycin-treated and control groups were comparable. Though the results of so small a clinical trial must be examined with caution they suggest that terramycin in the dosage used is without effect in controlling diarrhœa or in preventing relapse. Terramycin produced a rapid disappearance of *Bact. coli* type 0·111 B.4 from the stools, but in many of those treated the organism reappeared within five days of stopping treatment with terramycin. These results differ from that of Neter and Shumway (1950), whose 1 infant infected with *Bact. coli* 0·111 was later treated successfully with terramycin. These workers also tested in vitro nine strains of the same organism against different antibiotics. Their results suggested that, though sensitive to terramycin, the strains studied were more sensitive to chloromycetin and polymyxin.

No definitely toxic reactions were noted. The terramycin-treated babies tended to have a greater number of loose green stools while receiving terramycin than did the controls; this may have been an effect of the terramycin, although this symptom has been reported only occasionally and was not noted by Wooding and Scott (1951) who gave doses larger than those used in the present trial.

SUMMARY AND CONCLUSIONS

A small clinical trial to assess the possible value of terramycin in the treatment of infective diarrhœa in infants is described.

No evidence is adduced to suggest that this antibiotic used alone is of any real value in this condition.

We are indebted to Dr. W. H. P. Cant for allowing us to include in the trial patients under his care; to the antibiotics trials committee of the Medical Research Council for supplying the terramycin; and to Dr. J. M. Webb, Sister E. Tanner, and Sister J. Bradley for their generous coöperation.

ANTIDIURETIC SUBSTANCE IN HUMAN SERUM

Ross Wilson Hawker
M.B. Sydney
LECTURER IN PHYSIOLOGY IN THE UNIVERSITY OF QUEENSLAND

Birnie et al. (1949b) found an antidiuretic substance (A.D.S.) in the serum of rats, and Lloyd and Lobotsky (1950) detected A.D.S. in human serum by the same method.

Birnie et al. (1949a) consider that the A.D.S. found in rat serum is probably made in the posterior lobe of the pituitary gland. Biologically it resembles the anti-diuretic hormone (A.D.H.) in that it is antidiuretic and stimulates the renal excretion of chlorides; it is inactivated on standing and by neutralised thioglycollic acid; it is not present in the blood of hypophysectomised rats; it exerts its antidiuretic action by increasing the resorption of water through the renal tubule cells; its level alternates in rats subjected to hydration and dehydration; and "in all respects tested its actions are like those of posterior pituitary extract."

It is well known that during human pregnancy there is retention of water; in fact excessive retention of water, shown by increase in weight of the patient, is used as a sign of pre-eclampsia. I thought that the serum-A.D.S. level might throw some light on this retention and therefore determined this level in women during the normal menstrual cycle, normal pregnancy, and the early postpartum period. The results have already been reported briefly (Hawker 1952).

METHOD

The method of Birnie et al. (1949a) was followed closely.

Venous blood was collected not more than 45 minutes, and generally less than 30 minutes, before the assay. The blood was centrifuged for 10 minutes, and 1 ml. of the serum was injected intraperitoneally into virgin female Wistar rats weighing 130–200 g. each. At least three rats were included in each group of controls and of serum-injected test rats.

Two doses of distilled water, 3 ml. per 100 sq. cm. of body-surface (calculated from the formula $6{\cdot}27 \times \text{weight}^{0{\cdot}73}$), warmed to body-temperature, were administered by stomach-tube hourly to rats placed in funnels draining into 25 ml. measuring cylinders. The urine excreted was measured an hour after the second dose of water. Any rat which, during this hydration period, excreted 50% more or less urine than the mean volume excreted by the other rats was not used for the experiment.

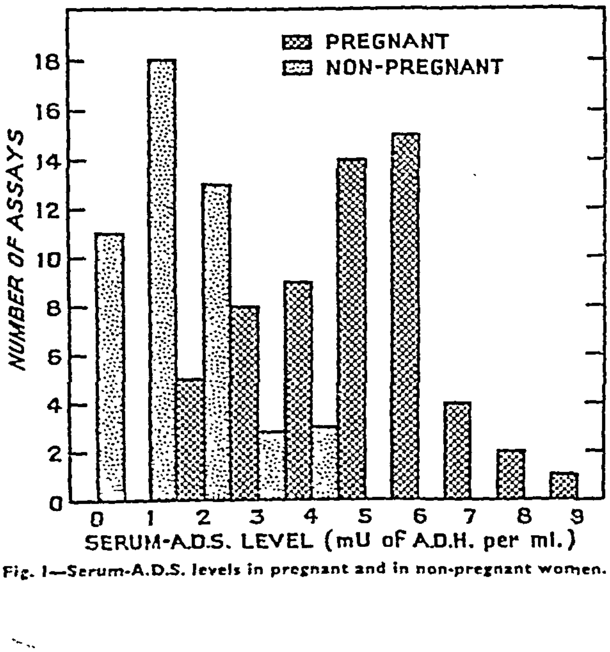

Fig. 1—Serum-A.D.S. levels in pregnant and in non-pregnant women.

A third dose of water was next administered, and serum was injected into the peritoneal cavity of the test rats. The urine excreted was measured 1½ hours after injection of the serum. Control rats were not given an intraperitoneal injection of isotonic saline (NaCl) solution, because it was previously found that this precaution had no effect on excretion values.

The serum-A.D.S. level was calculated as follows. The difference between the volume of all the water given in the three doses and the volume of urine excreted at the end of the two hours' hydration was called the "water load." The percentage of the "water load" excreted at 90 minutes after the injection of the serum was calculated. The anti-diuretic effect was expressed in units derived from the difference between the percentages of the "water load" excreted by the serum-injected rats and the controls. Rats which had received serum once were not used again, because of the possibility of protein sensitisation.

A graph was constructed correlating the A.D.S. units with concentrations of freshly prepared 'Pitressin' (Parke, Davis & Co.) 20 U per ml. by using other rats.

People coming for assay were instructed to abstain from fluids for four hours before venepuncture.

Serum-A.D.S. levels were assayed in healthy females, mostly medical students aged 17–22. Altogether 48 assays were done on 17 women at different times during the menstrual cycle. Assays were also done monthly on healthy pregnant women, usually from about the 10th or 12th week after the last menstrual period. In this group 58 assays were done on 14 women; and in 11 healthy women who had successfully passed through normal pregnancies and had been selected at random after parturition 50 assays were done in the first four or five postpartum days.

TABLE I—SERUM-A.D.S. LEVELS DURING NORMAL PREGNANCY AND FIRST DAY POST PARTUM

Time	Mean serum-A.D.S. level (mU of A.D.H. per ml.)
2nd trimester	4·27 (10 assays)
3rd trimester	4·40 (17 assays)
Last month of pregnancy ..	4·55 (8 assays)
1st day post partum	5·50 (11 assays)

RESULTS

This work shows that A.D.S. is present in the serum of the healthy cyclically menstruating female. Fig. 1 shows clearly that during the menstrual cycle the serum-A.D.S. level is most commonly 1–2 mU of A.D.H. per ml. of serum, with a fairly even distribution about the mode—i.e., between 0–1 and 2–3 mU of A.D.H. The arithmetic mean of the averages of the 17 cases examined was 1·91 mU of A.D.H. per ml. of serum.

It is impossible at this stage to show convincingly whether there are any real differences in the serum-A.D.S. level during successive weeks of the menstrual cycle, but the available figures suggest that the serum-A.D.S. level rises during the week preceding menstruation and falls during menstruation; the means of 8 assays made during the premenstrual week and of 7 menstrual assays were 2·85 and 1·60 mU of A.D.H. per ml. respectively.

During pregnancy the serum-A.D.S. level is higher than during the menstrual cycle, and the distribution is wider. Thus fig. 1 shows that the serum-A.D.S. level is most commonly 5–6 mU of A.D.H. per ml. The mean of the average serum-A.D.S. level of each of the 14 women examined was 4·53 mU of A.D.H. per ml. In about 78% of the 58 assays made on pregnant women the serum contained 3 or more mU of A.D.H. per ml., whereas during menstruation about 94% of the assays showed 3 or less mU of A.D.H. per ml. of serum.

The serum-A.D.S. level rises early in pregnancy; just how soon after conception has not been determined, but in one assay made eight weeks after the last menstrual period the serum-A.D.S. level was 4·2 mU of A.D.H. per ml. This was the earliest measurement made during the first trimester of pregnancy, and only a few have been made during this period. The level appears to remain comparatively steady throughout pregnancy, showing only slight fluctuations and perhaps a slight upward trend as pregnancy advances (see table I).

It has not been determined exactly when the serum-A.D.S. level rises during the last month of pregnancy, but it is suspected that it rises immediately before or during labour. This notion is supported by figures derived from two cases followed closely during the last week of pregnancy (table II).

During and immediately after parturition the serum-A.D.S. level is higher than in non-pregnant women. I therefore thought that this high titre might be related to some physiological phenomenon peculiar to the female after parturition and not to the cyclically menstruating female. Since lactation is a distinguishing feature between the two groups, it seemed reasonable that some relationship might exist between the high post-partum serum-A.D.S. levels and the onset of lactation.

TABLE II—SERUM-A.D.S. LEVELS BEFORE AND AFTER PARTURITION

Case no.	Time before delivery	Serum-A.D.S. level (mU of A.D.H. per ml.)
1	48 hours 2 hours	4·40 5·65
2	8 days 1st day post partum	3·25 5·95

Reference to table III will show that such a correlation appears to exist. Here there occurred an initial post-partum fall in the serum-A.D.S. level, and lactation began within a few hours after the serum-A.D.S. approached or reached its lowest recorded initial level. This was quickly followed by a rise in serum-A.D.S. level (except in case 2 in which it was not estimated), which subsequently began to fluctuate unpredictably. In no instance did lactation begin before the *initial* fall in serum-A.D.S. level. This correlation is shown in four typical cases in fig. 2.

The patients were placed on a strict fluid-balance régime. By the term "onset of lactation" is meant the subjective sensation by the mother of "milk let-down" and the clinical observation of the change from colostrum to milk.

The mean serum-A.D.S. levels in the 11 women (table III) on the first postpartum day and at the onset of lactation were 5·50 (SD ± 1·29) and 3·11 (SD ± 1·39) mU of A.D.H. per ml. respectively (first postpartum reading for case 4 excluded because lactation had already begun).

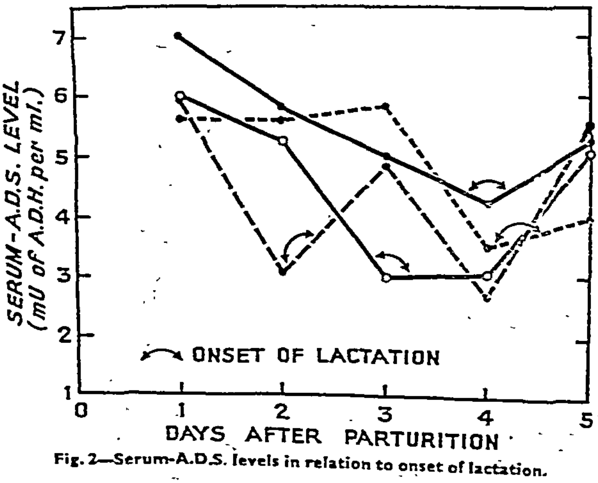

Fig. 2—Serum-A.D.S. levels in relation to onset of lactation.

TABLE III—SERUM-A.D.S. LEVELS AND ONSET OF LACTATION

Case no.	Days after parturition				
	1	2	3	4	5
	Serum-A.D.S. level (mU of A.D.H. per ml.)				
1	7·00	5·85	5·00	4·15	5·20
2	4·90	4·45	*4·00*	..	..
3	3·45	4·85	*2·35*	6·15	..
4	*2·50*	3·15	3·35	5·10	..
5	5·95	5·20	*2·90*	3·00	5·10
6	4·45	4·30	*3·35*	7·10	2·30
7	4·40	3·85	*0·00*	7·20	3·90
8	7·85	*3·30*	5·30	..	..
9	5·50	*5·15*	7·20	2·95	4·10
10	5·60	5·60	5·85	3·45	3·90
11	5·90	*3·10*	4·90	2·75	5·45

Italic figures mean that lactation began within a few hours of this point.

The results show that A.D.S. is present in the serum of women during the normal menstrual cycle, normal pregnancy, and the early postpartum period. These results are recapitulated in table IV.

DISCUSSION

Serum-A.D.S. during Pregnancy and Possible Relation to Water Retention

Water is retained during pregnancy, but evidence of this is quantitatively incomplete. Chesley (1944) has reviewed this subject and assessed the average gain in extracellular fluids as follows:

TABLE IV—SUMMARY OF SERUM-A.D.S. LEVELS DURING MENSTRUAL CYCLE, NORMAL PREGNANCY, AND POST PARTUM

—	Mean serum-A.D.S. level (mU of A.D.H. per ml.)	Remarks
Menstrual cycle:		
Whole cycle ..	1·91	Mean of all levels observed during menstrual cycle
Last week ..	2·85	Mean of all levels observed during week before menstruation
First week ..	1·60	Mean of all levels observed during week following 1st day of bleeding
Pregnancy:		
13–24 weeks ..	4·27	Mean of all observations
25–36 weeks ..	4·40	" " " "
37–40 weeks ..	4·55	" " " "
Post partum:		
First day ..	5·50	" " " "
Onset of lactation	3·11	" " " "

	Litres
Products of conception	1·5–2·0
Uterus and breasts	0·7
Blood-plasma	1·3
Extragenital interstitial fluid	2·5
	6·0–6·5

The extracellular compartment of the total body-water increases from 12 litres to 18·5 litres during pregnancy (this accounts for most of the water retained). There is a 60% increase in the plasma (1·3 litres extra) and 33% increase in the interstitial compartment (3·2 litres extra). Huggett (1950) states:

> "The mechanism of this water retention (in pregnancy) is unknown. There is an enlargement of the suprarenal cortex but no change in the size of the posterior pituitary. The rôle of desoxycorticosterone in this condition has got to be assessed accurately. Further, nothing is known of the effect of the salt changes in the diluted blood or the production of the antidiuretic hormone of the blood."

It is a universal clinical observation that the diuresis after drinking water is smaller in the pregnant than in the non-pregnant woman, and there is a pronounced post-partum diuresis accompanied by a rapid loss of weight.

A positive salt balance obtains throughout the greater part of pregnancy. About 3 g. is retained per week, and this retention would lead to a raised osmotic pressure in the extracellular fluid unless water were retained at the same time. It is not clear, however, whether the retention of salt precedes that of water or vice versa.

The total increase of blood volume is approximately 25–30% during pregnancy, and this increase is due mainly to an increase in plasma volume. The plasma-protein level is lower, despite an increase in quantity of the plasma-proteins, the plasma-albumin level being lower than the plasma-globulin level. Hence the colloid osmotic pressure is lower (by about 20%) than in the non-pregnant woman. The plasma-electrolytes level is lower, and the viscosity of the blood decreased. Calcium, potassium, magnesium, sulphur, and phosphorus are all retained in excess of the requirements of the developing fœtus.

Verney (1946) considers that changes in the osmotic pressure of the arterial blood stimulate, or inhibit, osmoreceptors in the hypothalamus (supra-optic nuclei), which in turn stimulate, or inhibit, the release of antidiuretic hormone by the pituicytes in the posterior lobe of the pituitary.

It is now becoming increasingly clear that some of the adrenal cortical steroids exert a reciprocal action on the excretion of water and salt by the kidney. Under their influence the retention of sodium and chloride is increased and the excretion of water is enhanced. Silvette and Britton (1938) suggested that there might be a reciprocal relationship between the antidiuretic hormone of the posterior lobe of the pituitary gland and the adrenal steroids regarding the excretion of water and salt by the kidney. Lloyd and Lobotsky (1950) have strengthened this hypothesis by their report of three patients with diabetes insipidus in whom the serum-A.D.S. level was low and urinary corticosteroid values ranged from normal to very high levels. They also observed in the untreated human with Addison's disease a very low excretion of corticosteroids and a very high serum-A.D.S. level.

It is felt that the antidiuretic activity of human serum (assessed by the biologic assay method described here) represents the algebraic sum of substances producing water retention and of substances causing diuresis. The former substance is assumed to be A.D.H., and the latter may be adrenal corticosteroids. If this notion proves to be correct, it becomes obvious that an increased antidiuretic effect can be due either to increased output of A.D.H. or to decreased output of adrenal steroids. Since it has been shown by many workers that the production of adrenal steroids is increased in pregnancy, there must be an absolute increase in the amount of A.D.S. present in the serum during pregnancy.

McLennan (1943) showed that pressure changes in the veins of the lower extremities during pregnancy could lead to the retention of water. On the hormonal side it has been reported that the water retention might be related to the concentration of œstrogens, progestogens, or adrenal steroids, all of which are normally increased in pregnancy.

In view of the finding that during pregnancy the serum-A.D.S. level rises roughly by 230%, it is postulated that this substance is responsible for some of the water retained during pregnancy. It may follow the retention of salt or be due to the influence of those hormones which are known to be increased during pregnancy: œstrogens, progestogens, chorionic gonadotrophin, adrenal steroids (which may account for salt retention), and thyroxine. Because of the salt retention that is known to take place in pregnancy one can perhaps reasonably postulate that, in accordance with Verney's concept, this is responsible for the raised level of serum-A.D.S. and hence for the water retention. So far as I am aware, there is no evidence that the ionic osmotic pressure is increased during pregnancy, and there is well-substantiated evidence which shows that in this state the colloid osmotic pressure is in fact lowered. It is almost certain that a complex pattern of physiological factors underlies the mechanism by which the serum-A.D.S. level is raised during pregnancy. In a preliminary attempt to elucidate this problem chorionic gonadotrophin was given to seven healthy cyclically menstruating women, and in each case the serum-A.D.S. level rose above 200%. The serum-A.D.S. level in 6 œstrogen-treated females did not alter significantly. It would be premature to draw any conclusions, however, from this aspect of the work, because it has not been carried on long enough.

Serum-A.D.S. Level after Parturition and its Possible Relation to Onset of Lactation

The hormonal background to lactation is not clearly understood. Petersen (1948) states:

> "It is well known that a completely developed mammary gland may not lactate; thus. factors other than those necessary for mammary growth must be present to stimulate and maintain milk secretion. Although the field is still far from being free from controversy and in need of more work before it is completely understood, there is sufficient evidence to show that several endocrine factors are essential for maintenance of milk secretion. A rather complex interaction of secretions from the hypophysis, thyroid, parathyroid, adrenals and pancreas is indicated."

In normal circumstances the mammary glands develop during pregnancy, and lactation (as is usually understood) starts soon after parturition. Much evidence has been presented that the production of the lactogenic hormone increases at the onset of lactation. The reasons for this are unknown, but it is thought that the release of the lactogenic hormone may be influenced by hormones from the ovary and placenta.

Extracts from the posterior lobe of the pituitary exert a rapid but fleeting effect on the mammary gland. The general consensus of opinion is that posterior-pituitary extract has no effect on the secretion of milk—i.e., the synthesis of milk and its passage into the alveolar lumen from the cytoplasm of the epithelial cells—but influences the discharge of already preformed milk from the mammary gland. This is possibly brought about by stimulation of the myo-epithelial cells in mammary tissue (however, it has not yet been shown that these cells possess contractile properties). In this respect it seems that the oxytocic principle is more effective than the vasopressor factor, which is probably the antidiuretic factor (A.D.H.) in posterior-pituitary extract.

In a limited number of cases it is here reported that lactation always began soon after the serum-A.D.S. level reached or approached its lowest initial level. The assays were made at 24-hour intervals, and so it is entirely possible that fluctuations in serum-A.D.S. level were missed, and that larger falls than were recorded may have preceded the onset of lactation. This difficulty is being overcome by making more frequent assays. It is tempting at this stage to suggest that a lack of onset of lactation may be associated with a steady serum-A.D.S. level—i.e., where this level does not fall—and that the onset of lactation could be inhibited by any procedure preventing a fall in this level. A time-honoured method of stimulating lacation is by hydration. Verney (1946) has shown that hydration, by lowering the osmotic pressure in the serum, inhibits the production of A.D.H. This then may be the mechanism by which water can stimulate lactation.

The results of the present work suggest that a fall in the serum-A.D.S. level is associated with the onset of lactation, and not with the continuance of lactation, because this, once started, continues, despite wide variations in the serum-A.D.S. level, provided the stimulus of suckling is present. Although it can be shown experimentally that pitressin will stimulate the discharge of already formed milk from the lactating gland, it is not likely that this procedure would provoke lactation in the non-lactating gland immediately after parturition. To my knowledge it has not been shown that it possesses this property. This conjecture is supported by the finding that the serum-A.D.S. level is high during the period when lactation is either inhibited or unstimulated.

Stilbœstrol and œstrogens are freely used to suppress lactation; but, although the production of milk is generally stopped, it is doubtful whether these hormones alone are responsible. Stilbœstrol given by me to normally menstruating women in this department, and by Cross (1951) to female rats, caused no demonstrable difference in serum-A.D.S. levels.

SUMMARY AND CONCLUSIONS

A substance possessing antidiuretic properties (A.D.S) is present in the freshly drawn serum of women during the normal menstrual cycle, normal pregnancy, and early postpartum period.

The serum-A.D.S. level is higher during pregnancy than during the menstrual cycle.

It is postulated that this high level during pregnancy accounts for some of the water retention of pregnancy.

A correlation appears to exist between the level of serum-A.D.S. after parturition and the onset of lactation. In each of eleven cases examined lactation always began after an initial fall in the serum-A.D.S. level.

I wish to thank the National Health and Medical Research Council (Australia) for the grant that enabled this work to be undertaken; Prof. W. V. Macfarlane, Prof. H. J. G. Hines, and Dr. P. Hagen for their many helpful suggestions; Dr. Roger Salter, medical superintendent, Dr. K. G. Cockburn, registrar in obstetrics, and the nurses at the Brisbane Women's Hospital; and Mr. Alex Tuffley, of the physiology department in the University of Queensland, for the illustrations.

POLYCYTHÆMIA IN ASSOCIATION WITH HYDROCEPHALUS

DAVID A. PRIMROSE
B.L., M.B. Glasg.
LATE HOUSE-PHYSICIAN,
UNIVERSITY MEDICAL CLINIC, STOBHILL GENERAL HOSPITAL, GLASGOW

THE association of polycythæmia with lesions of the central nervous system is well known, especially in pituitary basophilism (Cushing 1932), encephalitis lethargica, and Huntington's chorea (Schulhof and Matthies 1927), narcolepsy (Gunther 1930), and lesions of the hypothalamus and pituitary gland (Guillain et al. 1932, Moehlig and Bates 1933, Haynal et al. 1949). Polycythæmia is common in carbon monoxide poisoning and may then be associated with damage to the basal ganglia (Dittmar 1939). It has been reported in concussion (Hecht and Weil 1929), and Drew and Grant (1945) collected ten published cases in which an expanding intracranial lesion other than of the diencephalic area was associated with polycythæmia; these cases included such diverse lesions as a subdural hæmatoma with papillœdema, and cerebellar tumours. Polycythæmia hypertonica has been attributed by Castex (1929) to a diencephalic lesion.

No case, however, of polycythæmia in association with hydrocephalus seems to have been published in the last thirty years.

CASE-RECORD

Mrs. A. is a childless widow, aged 49, who was working as a waitress until the onset of her present illness. In September, 1949, while in a general hospital in Glasgow for the removal of gall-stones, she had a blood-pressure of 180/110 mm. Hg and hæmoglobin 70%. A month later the hæmoglobin had fallen to 52%, probably because of post-operative complications and infection. She made a good recovery from the cholecystostomy, returned to work, and remained in good health until Nov. 6, 1951, when the present illness began.

Onset of Illness

The first symptoms were headache and vomiting accompanied by moderate pyrexia and mental confusion. Her condition deteriorated, and on Nov. 18 she was admitted to the neurosurgical unit of Killearn Hospital with delirium, nuchal rigidity, a positive Kernig's sign, papillœdema, left hemiparesis, and inverted respiratory rhythm. Her temperature was 101·6°F and pulse-rate 90. Her blood-pressure was 130/80 mm. Hg. Next day radiography of the chest showed no abnormality other than prominence of the aortic knuckle.

Treatment and Investigation

Penicillin 500,000 units six-hourly was given from Nov. 18 to Dec. 2. The patient became afebrile by Nov. 28, and her general condition steadily improved. On Dec. 4 she was eating well and spoke occasionally. Within the following two weeks, however, her condition again deteriorated and paralysis developed in all four limbs. There was incontinence of urine and fæces. She rarely spoke.

Ventriculography was performed on several occasions. On Nov. 21 it showed a mild hydrocephalus involving the lateral and third ventricles, the fourth ventricle being normal. On Dec. 10 the hydrocephalus began to increase rapidly until by Jan. 5, 1952, it was gross, involving the fourth ventricle, the cisterna magna, and the basal cisterns. As no air entered the subarachnoid space, it was suggested that meningeal adhesions were the cause of the hydrocephalus.

Examination of the optic fundi on Dec. 12 showed hæmorrhages but no papillœdema, and gave the general appearance of a sudden rise of intracranial pressure, which was subsiding. Ocular movements and ocular reflexes were normal.

The cerebrospinal fluid was normal throughout. For example, on Nov. 23 it was clear and under normal pressure, and contained 4 lymphocytes per c.mm., protein 20 mg. per 100 ml., chlorides 724 mg., and sugar 80 mg. The Wassermann reaction was negative and the colloidal gold curve 0,000,000,000.

Further Observations

In this state of hydrocephalus, quadriplegia, aphasia, and incontinence the patient was transferred to a general medical ward in Stobhill General Hospital on March 5.

On admission her complexion was pale and her tongue clean and moist: she had no œdema and no palpable lymph-nodes. Her radial pulse was regular, her heart sounds pure and of good quality, and her heart not enlarged. Cheyne-Stokes breathing was present from time to time, and other respiratory irregularities also occurred. Nothing abnormal was detected in chest or abdomen. The spleen was not palpable. There was arteriosclerosis of the retinal vessels, but no papillœdema or retinal hæmorrhage. The urine was infected with *Bacterium coli* and proteus, but after treatment to clear the infection it contained no albumin, sugar, blood, or casts. The blood-pressure varied from 180/135 to 215/160 mm. Hg. The erythrocyte-sedimentation rate was 6 mm. in 1 hour (Westergren).

Until June 3 there was quadriplegia in flexion with cog-wheel rigidity of all four limbs. On that day a jacksonian fit started in the right hand, and generalised convulsions shortly supervened and continued for three hours until morphine gr. $^{1}/_{4}$ was given. They then gradually diminished, but limb and facial twitchings persisted until June 12. Since June 4 the left arm and lower limbs have been flaccid, but the right arm, after being flaccid during the convulsions, is again rigid. The deep tendon-reflexes, including the jaw-jerk, have remained normal. The plantar reflexes were flexor until June 4, when they became extensor. Clonus was not present. Apart from the convulsion and subsequent flaccidity the general condition has remained similar to what it was on admission.

The hæmatological findings are shown in the accompanying table.

Date (1952)	Hb (g. per 100 ml.)	R.B.C. (million per c.mm.)	W.B.C. (per c.mm.)	P.C.V. (ml. per 100 ml.)	Eosinophils (per c.mm.)	Platelets (per c.mm.)
March 5	15·1	5·83	11,200	—	—	—
March 17	18·1	6·82	16,000	64·0	—	—
March 20	18·1	6·91	9600	63·0	50	272,000
March 31	16·1	5·57	9200	52·0	50	110,000
May 26	13·9	4·94	10,000	48·5	300	267,000
June 3*	15·2	5·40	23,600	53·0	0	—
June 12	13·2	4·82	8200	46·0	110	244,000

* 15 mins. after start of convulsions. Plasma chloride 126 m.eq. per litre (444 mg. per 100 ml.); alkali reserve 60 vol. CO_2%. *Blood films and differential white counts were normal.*

DISCUSSION

The nature of the original neurological lesion is obscure, but it seems to have caused meningeal adhesions at the base of the brain, leading to hydrocephalus. Either the original lesion or the subsequent gross hydrocephalus has produced both pyramidal and extrapyramidal lesions, and there has been a temporary erythrocytosis.

The diagnosis of polycythæmia hypertonica was suggested by the blood picture, the presence of arterial hypertension, and the absence of splenomegaly. This diagnosis proved to be untenable, however, when the blood picture reverted to normal. The same objection applies to a diagnosis of erythræmia, and in addition the blood-platelet count was normal on repeated examinations.

It has been reported in several cases of polycythæmia that, after removal of an associated intracranial lesion, the blood-count returned to normal values (Dittmar 1939, Drew and Grant 1945). In the present case the reduced eosinophil-count at the time of the maximum red-cell count may suggest that there was intracranial stress causing both phenomena, and that adjustment to it had taken place when the counts became normal. The return to normal blood values, and the disappearance of circulating eosinophils during the fit, make it unlikely that the polycythæmia was due to a destructive lesion of the basal ganglia or of the pituitary-hypothalamic system.

SUMMARY

Polycythæmia is sometimes associated with various lesions of the central nervous system.

No case of polycythæmia in association with hydrocephalus seems to have been published in the last thirty years.

Such a case, in which the polycythæmia was transient, is described. The patient also had hypertension.

ADDENDUM

The patient has since died from intercurrent infection. Gross pathology confirmed the hydrocephalus and absence of splenomegaly, but showed no obvious cause for the hydrocephalus. Histological examination has not yet been completed.

I am indebted to Prof. Stanley Alstead and other members of the visiting staff of Stobhill General Hospital for helpful criticism.

GLUTEN-FREE DIET IN IDIOPATHIC STEATORRHŒA

REPORT OF A CASE

Cecil McIver
M.B. Camb., M.R.C.P.
FELLOW IN CLINICAL INVESTIGATION, THE METABOLIC UNIT, VANCOUVER GENERAL HOSPITAL, VANCOUVER, B.C.

The case reported here is one of a series under observation in a long-term study of the pathogenesis of idiopathic steatorrhœa. It is presented separately because of the remarkable remission induced by gluten-free diet. The work of Weijers and van de Kamer (1950), Dicke (1950), and Anderson et al. (1952) on the dietary control of cœliac disease raised hopes that gluten-free diet might also succeed in sprue. In the present case the results have been most encouraging.

CASE-RECORD

Mrs. A. was born in 1907. Her only child was born in 1926. In 1927 she was jaundiced and some weeks later developed diarrhœa, which has persisted since. Her weight fell from 120 to 110 lb., and she complained of malaise, weakness, flatulence, abdominal distension, and attacks of carpal spasm, which were controlled by calcium injections. Her stools were loose, pale, bulky, and offensive, but she normally passed only one or two daily. Two further pregnancies in 1929 and 1932 miscarried between the 12th and 16th weeks.

Idiopathic steatorrhœa was first diagnosed in 1940, when the dried fæces were found to contain from 17 to 40% of fat, which was normally split. Cholecystography showed a normal gall-bladder, and no gall-stones or pancreatic calculi were seen. Barium-meal radiography showed that the small intestine was abnormal. The hæmoglobin was 9 g. per 100 ml. In 1941 thyroidectomy was performed, because the basal metabolic rate (B.M.R.) was + 27%, and a fœtal adenoma was removed. Subsequent treatment with a low-fat diet, vitamin and calcium supplements, dilute hydrochloric acid, and pancreatic extracts did not prevent gradual but progressive deterioration in the patient's condition.

In 1950 she weighed 95 lb., and balance tests showed only 40–60% absorption of fat. Her prothrombin-time was low, and she bruised easily. The hæmoglobin was 12·5 g. per 100 ml., and macrocytosis (+ 2) was reported. The serum-calcium level was 8·1–8·5 mg. per 100 ml.

In September, 1951, she was admitted to hospital for eight weeks' treatment with oral cortisone, which produced great improvement. She remained well without further treatment until January, 1952, when she had recurrence of diarrhœa (from two to four pale loose offensive stools daily), malaise, lassitude, œdema, and tetany.

She was readmitted on Feb. 25, 1952, when examination showed pallor, œdema, hypotension, generalised brownish skin pigmentation, pathological bruising, and a positive Trousseau's sign. Her body was thin and her abdomen distended by flatus.

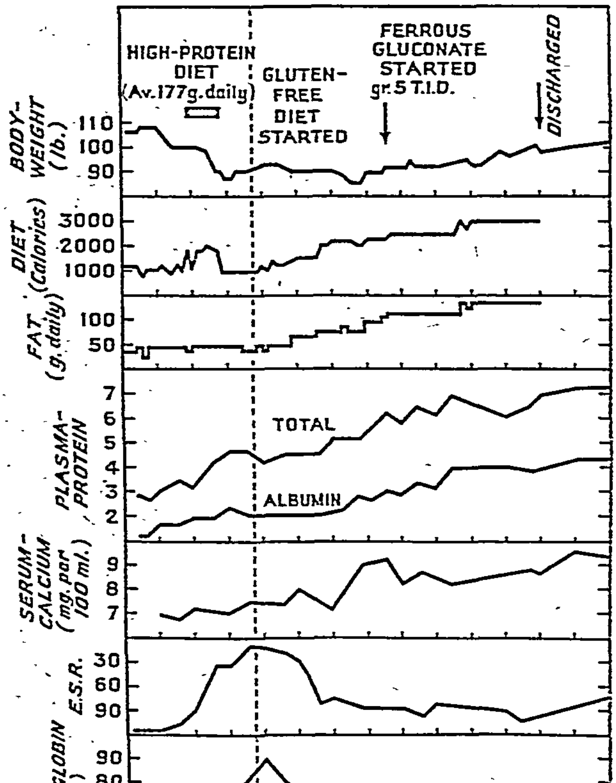
Laboratory examinations showed Hb 11 g. per 100 ml., colour-index 1·1, macrocytosis (+ 2), serum-calcium level 7·2 mg. per 100 ml., plasma-protein level 3·6 g. per 100 ml. (albumin 1·6 g.), and prothrombin-time 40% of normal. Fæcal fats were 95% split, but fat-absorption was only 60% of the 70 g. daily intake. Radiography of the small intestine showed an abnormal pattern and flocculation of barium.

Hypoprothrombinæmia was corrected by the parenteral administration of vitamin K, but no other specific treatment was given. The patient was offered a normal diet containing 70 g. fat daily, with supplements of 100 mg. of ascorbic acid, 1 tablet of 'Multivite,' and gr. 10 of calcium lactate t.i.d. She was not anxious to have adrenocorticotropic hormone (A.C.T.H.) or more cortisone, but on March 7, 1952, A.C.T.H. therapy was begun because she was now seriously ill. Her appetite was poor and her food intake inadequate; she had developed gross dependent œdema, ascites, and small bilateral pleural effusions.

A.C.T.H. 10 mg. given daily by slow intravenous infusion in 5% dextrose between March 7 and 23, produced rapid symptomatic and clinical improvement. Treatment with folic acid 15 mg. t.i.d. was started on March 24, but within two weeks diarrhœa recurred, and within four weeks the patient's condition was as bad as it had been before A.C.T.H. treatment, and diarrhœa was more troublesome.

She refused further A.C.T.H. or cortisone, and her condition rapidly worsened. Between May 12 and 15, 1680 ml. of dextran was infused intravenously to relieve œdema. With much persuasion the protein intake was raised to an average of 177 g. daily between May 29 and June 5, but although this raised the plasma-protein level and reduced the body-weight by 10 lb. it was stopped because of increasing diarrhœa, flatulence, and abdominal cramps. On June 6, there was pulmonary embolism, with evidence of phlebothrombosis in the left calf. The leg was supported by a crêpe bandage, and the patient was encouraged to walk. No further embolism took place.

On June 11 gluten-free diet was started. Bread and all foods containing wheat and rye flour were omitted, muffins made from corn and soya flour being substituted for bread.



Significant changes since the start of gluten-free diet on June 11, 1952 (indicated by vertical line). There has been gradual rise of weight representing a proportionately greater gain of tissue owing to simultaneous loss of œdema. Calorie and fat intake has risen. Plasma-protein and serum-calcium levels have risen to normal. Hb has decreased. Colour-index has fallen from 1·1 to 1·0, and progressive decrease in macrocytosis is reported on examination of blood films. E.S.R. is high at start of chart because dextran had been given intravenously a few days previously; it was a month before E.S.R. returned to normal. It rose sharply after diet was started, as it had done in previous remissions induced by A.C.T.H. and cortisone.

At this time the patient was in severe relapse. There was pronounced anorexia, malaise, weakness, œdema, and profuse diarrhœa. Within a week there was obvious improvement: appetite increased after a few days, the patient began to take more interest in her surroundings and looked better, and diarrhœa was succeeded by obstinate constipation requiring digital evacuation on three consecutive days. Since then the bowels have been open once daily, and the stools, although not normal, have become more formed, coloured, and less malodorous. 'Neptal' 1·5 ml. given intravenously on June 16, produced a good diuresis, and œdema and ascites have continued to clear as the plasma-protein level has risen, but there is still slight pitting at the ankle. Her weight has varied, but there is a net increase of 10 lb. If the loss of fluid is taken into consideration, this probably represents a substantial gain of tissue. The plasma-protein and serum-calcium levels are now normal. The amount of hæmoglobin has decreased, and the erythrocyte-sedimentation rate (E.S.R.) has risen (see figure).

The patient left hospital on Aug. 9. She says that she feels better than she has done for years. She does her own housework, has plenty of energy, and a large appetite, and enjoys her food. Although still pale and thin she looks vastly improved and is still making progress.

DISCUSSION

During the period of observation the E.S.R. has shown an unexpected pattern of change: in relapse it is normal but in remission it rises sharply to about 100 mm. in 1 hour (Westergren), only to fall to normal again when relapse sets in following arrest of A.C.T.H. or cortisone therapy. With the diet-induced remission the rate has risen again to high levels. The plasma-fibrinogen level is normal (two estimations) and it is possible that this change is associated with abnormality of the blood-globulin fraction. Facilities for electrophoretic study of the plasma to confirm this point are not available.

The hæmoglobin, which had been maintained at 10·5–13·0 g. per 100 ml. without iron therapy, decreased to 8·5 g. soon after the diet was started, and the morphology of the red cells changed. Macrocytosis decreased, and anisocytosis and hypochromia increased. The colour-index decreased from 1·1 or more to 1·0. Treatment with ferrous gluconate gr. 5 t.i.d. was started on July 8, 1952, but has not produced any change in the blood picture. It seems that the diet corrected the deficiency responsible for macrocytosis, which had not been affected by folic acid, but at the same time caused iron deficiency. Blood-loss is unlikely to be a factor in the development of this anæmia, because repeated tests for fæcal occult blood have been negative and amenorrhœa has persisted since 1943.

Although the patient's clinical condition has improved very greatly, tests of intestinal function other than fat-balance have shown little change. The blood-sugar curve after ingestion of dextrose 100 g. is flat. The small-intestinal pattern is still abnormal, the ileum particularly showing areas of hypotonicity and flocculation of barium. The volume of urine is still greater by night (6 P.M.–6 A.M.) than by day, although there has been some reduction in the ratio towards unity. The results of six fat-balance tests between May 11 and August 6, 1952, have been surprising. In three periods before the start of the diet the fæcal fat has been reported to be 17–21% greater than the intake (35 g.), and in three periods after the start of the diet there has been reported a progressive increase in absorption from 28 to 67% of the intake (50–130 g.). These figures, which have been checked and re-checked, are abnormally low and lower than any found in previous estimations in the present case. The only inference to be drawn from them is that fat-absorption has improved and may improve further.

Increasing appetite after the diet was started allowed the calorie intake to be progressively raised from 1000 to 3000, and the fat-intake from 35 to 130 g. daily. The patient, who had been indifferent to fat, now developed a liking for it.

Six weeks after starting the diet the patient drew attention to the regrowth of hair on her legs, which she said had been hairless for at least fifteen years. This was probably a non-specific expression of improvement in general nutrition, but it may also have been due to a change in adrenocortical function.

SUMMARY

A case of long-established steatorrhœa which has improved on gluten-free diet is reported.

Clinical and biochemical return towards normal has not been matched by improvement in tests of intestinal function.

The hæmoglobin has decreased, but macrocytosis has diminished.

The *erythrocyte-sedimentation rate* has shown an unusual rise.

I am grateful to Dr. R. A. Palmer, chairman of the Metabolic Unit, and to Dr. A. M. Johnson and the members of *the Metabolic Unit of the Vancouver General Hospital* for permission to publish.

ADDENDUM

The patient was last seen on Nov. 13, 1952. She remains much improved symptomatically, and the serum-protein and calcium levels are normal. Her weight is 105 lb. and all evidence of œdema has cleared. The E.S.R. has returned to 30 mm. in the first hour; and, following a course of intravenous iron between Oct. 6 and 13, the Hb has risen to 13·5 g. per 100 ml.

New Inventions

A URINAL FOR THE RECUMBENT FEMALE

MOST hospital patients are embarrassed by the usual methods of collecting excreta, and the nursing of women in plaster beds presents peculiar problems. Owing to the strict recumbency of the patients and the limited abduction of the legs it is impossible for ordinary appliances to be used by the patients themselves. The usual method is to place a bedpan or a tin tray under the plaster bed. Usually, at the end of micturition the urine tends to trickle down the perineum into the seat of the plaster bed, with consequent softening and offensiveness of the plaster. This soiling often becomes troublesome, especially in warm weather.

At the suggestion of Mr. A. T. Fripp an appliance has been designed which can be manipulated by the patient and overcomes these difficulties.

Both the ‘Nylon’ receptacle (perineal cup) and ‘Polythene’ bag (capacity about $2^1/_2$ pints) can be sterilised by boiling but should be wrapped in a piece of gauze to prevent the polythene from coming into contact with the bottom of the steriliser. The appliance is light *in weight. Nylon has been used for the cup because it is a poor conductor of heat and therefore is not cold to the* touch. It is virtually unbreakable and is unaffected by urine. The rigidity of the lip of the cup ensures a satisfactory seal without discomfort.

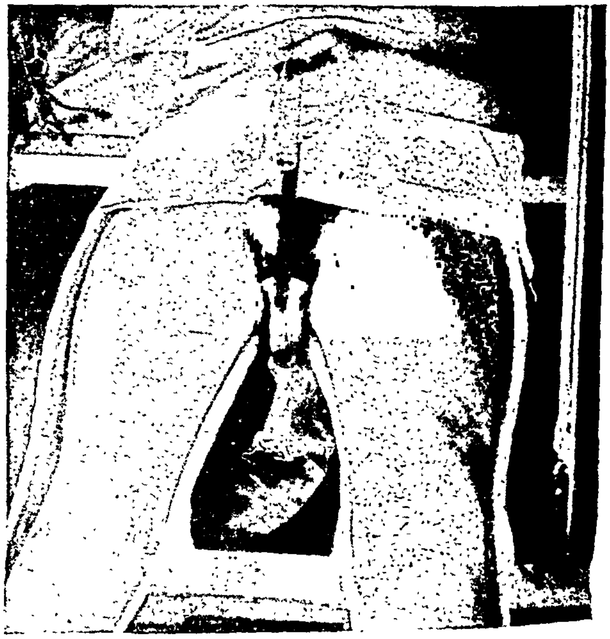

Fig. 3.

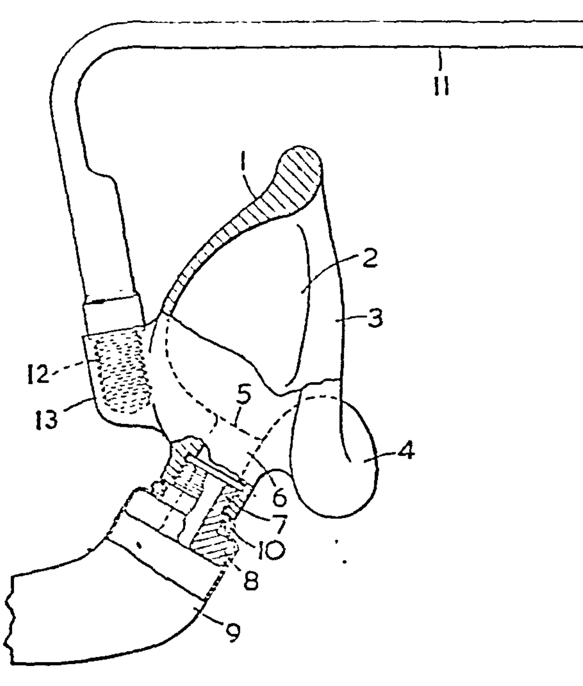

Fig. 1

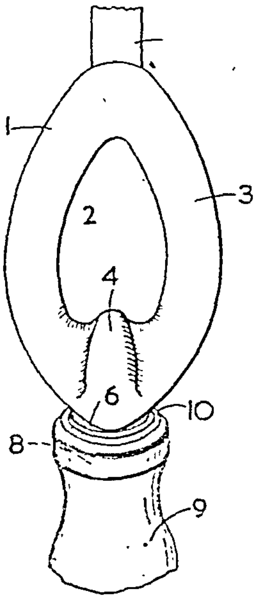

Fig. 2.

Fig. 1 shows the side elevation and fig. 2 the end elevation.

The receptacle (1) is shaped to fit between the patient's thighs. The mouth (3) of the cavity (2) is of such size as to enclose the appropriate part of the perineum. A crest (4), integral with the lower portion of the receptacle, fits between the labial lips above the posterior commissure to provide a fluid seal and prevent urine from trickling down between the receptacle and the perineum. The cavity (2) has an outlet (5) opening into a short conduit (6). This conduit is threaded to take a bush (7) having a cap or flange-like end (8) over which can be gathered the mouth of the polythene bag (9), which is retained in place with an elastic band (10). A swan-neck handle (11) is provided with a screw-threaded portion (12) which is screwed into a boss (13) moulded in the cup (1).

Although expressly designed for patients in plaster beds, the appliance has been found suitable for continent patients not in plaster beds, provided that an air-ring or pillow is placed under the buttocks. The appliance has proved popular with patients, and soiling of the plaster beds has been consistently prevented. However, the patients must first be assured that the appliance will not leak and they must be carefully instructed in how to place it against the perineum. If the appliance is held as shown in fig. 3, supination of the hand will keep the cup firmly in position. A nurse can carry four or five of these urinals compared with one tray or two bedpans. After use the polythene bag and attachment are unscrewed from the cup and washed out. The whole appliance is sterilised once daily and a new bag attached as required.

I wish to thank Sister Donnelly, of the Royal National Orthopædic Hospital, Stanmore, and Miss H. Pearn, for their invaluable help and coöperation in the design and trial of the apparatus. The photograph was taken by the medical photographic department of the Institute of Orthopædics. The appliance, which was first shown at the Congress of the Combined English-Speaking Orthopædic Associations on July 2, 1952, can be obtained from the Medical Supply Association, Park Royal Road, London, N.W.10. This device forms the subject of British Patent Application no. 16132/52, which has been assigned to the National Research Development Corporation.

Reviews of Books

Problem Families

Five Inquiries. Editor: C. P. BLACKER, M.A., M.D., F.R.C.P., hon. secretary, Eugenics Society. London: Eugenics Society. 1952. Pp. 123. 5*s.*

THESE investigations of problem families, in North Kensington, Bristol, the West Riding, Rotherham, and Luton, "are to be regarded not as exhaustive factual reports but as experiments in method. They are, in fact, pilot inquiries." The object was to try to formulate a method of inquiry which could be applied on a national scale if at any time in the future this was thought desirable. The method employed, and the improvements which could be made in it as a result of experience, are well described.

Sponsored by the Eugenics Society, the inquiries were undertaken in 1948–49, at a time when the effects of new social legislation on local authorities made field surveys difficult. Nevertheless, valuable data have been collected and embodied in 29 tables dealing with size and composition of families; physical and mental health; occupation and income of the parents; intelligence of the children; and estimates of the incidence of illegitimacy and child loss from miscarriage, stillbirth and infant mortality, as well as of the national burden arising out of the need to care for many of these children apart from their parents. In a valuable introduction Dr. Blacker reviews the different contexts within which problem families have been considered in the last seventy years, and sets out the definitions, descriptions, characteristics, and possible causes put forward by various authors. The bibliography is comprehensive, and many detailed case-histories, chosen at random from the 379 households studied, have been included.

Child neglect, not necessarily amounting to deliberate cruelty, is one of the most disturbing features of the problem family. Local authorities took some action on receiving, in 1950, a joint circular from the Home Office and Ministries of Health and Education; but, even so, few have made any attempt to compile a register of these cases, which is a fundamental need in tackling the problem. The strength of the nation depends in the long run on the strength of its component families, and here is a study of some of the weakest links in the chain.

Medical Mycology

An Introduction to its Problems. G. C. AINSWORTH, B.SC., PH.D., F.L.S., department of botany, University College, Exeter. London: Pitman. 1952. Pp. 105. 15*s.*

ALTHOUGH Dr. Ainsworth writes as a trained mycologist, he has held a fair balance between the clinical or pathological and the essentially mycological interests. He has surveyed carefully recent papers on medical mycology and he has used current problems as the bases of discussions on groups of mycoses or of fungi.

Thus the ringworm fungi illustrate the problem of taxonomy; the mycoses of the respiratory system pose the question of the pathological significance of potentially pathogenic fungi in the sputum, which may also be common commensals in the mouth; mycetoma presents the problem of a pathological entity which can be caused by many different species of fungi; the more important systemic mycoses introduce the problem of dimorphism in pathogenic fungi and the possible influence of this phenomenon on the pathogenicity of the fungus and the epidemiology of the disease. Serological reactions and dermal-sensitivity tests help to mitigate the problem of specific diagnosis. Additional problems are found in the toxic effects of poisonous mushrooms and the allergenic properties of airborne fungal spores.

Dr. Ainsworth's lively manner of presenting his subject has made his book an effective introduction to medical mycology.

Principles and Practice of Anesthesiology

VINCENT J. COLLINS, M.D., director, department of anesthesiology, St. Vincent's Hospital, New York. London: Henry Kimpton. 1952. Pp. 528. 75*s.*

As the preface points out, the compilation of a single book covering all aspects of anæsthesia would be a monumental task. The author justifies his claim, however, to have written a textbook which is "concise, fairly comprehensive and documented from original sources."

The style is crisp, and tabulation is used to an extent to which British readers, accustomed to a more expansive literary style, may find oppressive. "Fairly comprehensive" is an understatement. The book includes, even if only briefly, every conceivable topic of clinical interest to the anæsthetist, though there is rather heavy emphasis on American sources in the extensive bibliographies. In the next edition the author might consider some rearrangement to bring related subject matter together: for example, all the complications of spinal anæsthesia might be gathered and inserted after the general account of the technique. Division of the planes of the third stage of anæsthesia into further subdivisions, all of somewhat dubious practical value, might well be given up, especially as little, if any, clear guidance is given on how to distinguish these subdivisions. He may also think of revising his good opinion of a mixture of 40% nitrous oxide in air as an obstetric analgesic, and may pause to doubt the value—even the wisdom—of smearing petroleum jelly (an ether solvent) on a patient's face to prevent the highly improbable occurrence of "ether burns."

These are but friendly criticisms of minor points. Dr. Collins has set a new standard for textbooks on his subject.

The Child's Conception of Numbers

JEAN PIAGET, professor at the University, and Institute of J. J. Rousseau, Geneva. London: Routledge & Kegan Paul. 1952. Pp. 248. 25*s.*

THIS volume, now added to the International Library of Psychology, Philosophy and Scientific Method, was published in Switzerland in 1941 under a title, *La Genèse du Nombre chez l'Enfant*, which gave a rather clearer indication of its contents.

Continuing his investigations into the growth of the child's ideas and power of thought, Professor Piaget here reports a large selection of his observations of the responses of children (aged 4–7$^1/_2$ years in the main) in situations involving the manipulation of simple apparatus—such as beads, sticks, dolls, flowers, and vases—contrived with a view to revealing the measure of their understanding of numbers. These responses are analysed with great subtlety, to make explicit the kind of thinking, in terms of classes and relations, which thinking in terms of numbers must imply. It is maintained that successful quantitative thinking is achieved, not after, but as soon as, the child can think operationally in the appropriate qualitative realm. Well-marked stages are shown to be recognisable in unreasonable to expect the railways, the owners of public buildings, and others in charge of places where accidents can happen to maintain any very considerable supplies. When it becomes clear that the casualty-list will be large, it is the custom for the ambulance control to order to the scene special bulk equipment, consisting of blankets, stretchers, hot-water bottles, morphine and other drugs, surgical instruments, and so on; and the senior ambulance officer goes in a large specially equipped ambulance which can be used as a casualty-clearing station or operating-theatre if need be. The promptitude and efficiency of this service has been demonstrated time and again. As the medical forces gather, many doctors may appear on the scene, and voluntary helpers come forward in large and heartening numbers. Indeed, Mr. N. P. JEWELL, F.R.C.S.I., in a letter to the *Daily Telegraph*,[2] said that at Harrow "most of the many doctors were wondering what to do"; and there seems little need for more than a few doctors on the spot or for a general alarm to doctors in the neighbourhood. The harnessing of the main tide of volunteers is not primarily a medical concern, but, as another correspondent in the same newspaper observed,[3] it should be included in any wider preparations for dealing with disaster. In a railway accident the director of operations, a senior member of the railway staff, takes control of rescue and clearance work; but at the moment there seems to be no clear provision for a *medical* authority—in other words, for a doctor who would be in direct charge of first-aid and other treatment, and who would decide when further help was required or when the scene was overcrowded with medical personnel. The local health authorities could, in consultation with the regional board, invite a number of doctors in each region to declare their readiness to act in this capacity; and, in the event, the regional board's emergency officer could then call on a leader for the medical advance party. Of course, in the past this responsibility has been willingly and efficiently accepted by somebody, but this is no reason for not delegating it in advance as part of the emergency plan.

Some further questions emerge. When many people have been killed, what special provision should be made for mortuary accommodation? A large building nearby could be used, and this would certainly relieve pressure on the hospitals. But there are risks and disadvantages in the suggestion, and it is probably advisable to make every effort to find space at the hospitals to which most of the injured are sent. Again, the hospitals should be relieved as far as possible of the burden of telephone inquiries, either by importing additional staff to deal with them or by setting up an inquiry bureau, as is sometimes done at present. Finally, could the medical resources of the Armed Services be brought into the plan? Recent disasters have shown how readily and effectively they can help. The routine machinery by which this aid can be quickly mobilised for civilian needs should be as simple as possible, and commanding officers should be authorised to use their discretion in bringing Service personnel and supplies into action in this way. The Royal Air Force maintains first-class mobile medical units for dealing with aeroplane crashes, and it is easy to think of occasions when such a unit might be of great value.

Our discussion of these possibilities does not imply that past experiences, at Harrow or elsewhere, have shown serious weaknesses in the present system. Indeed, both on the spot and in hospital the care of the Harrow casualties was very good. Most of them were evacuated very quickly, and no-one who was extracted alive died before reaching hospital. A few people had more than one injection of morphine, but no serious harm came of it; and this mistake (which many will think in the circumstances to be relatively trivial) could be avoided by the use of treatment labels to be filled in by the doctor giving the injection, or by some similar device. The most reassuring feature was the immediate and overwhelming surge of help from all sides. The situation was met, as others have been met in the past, by the national phenomenon of spontaneous amalgamation and teamwork, without which any plan, however careful its preparation, would remain lifeless. It does not follow, however, that the success attained at Harrow, in an area well served by roads, ambulances, hospitals, and doctors, would be attainable equally elsewhere; and we are quite sure that every region and every hospital ought to know in advance what it is going to do and how it is going to do it.

Resection for Pulmonary Tuberculosis

IN 1945 OVERHOLT and WILSON[1] said that "pulmonary resection will find its true place as a supplementary and not a competitive form of treatment to the already established methods of rest and collapse therapy." Two years later and still before the use of chemotherapy, they and their colleagues[2] added that the rapid growth of this form of treatment for pulmonary tuberculosis was due "largely to the fact that it was needed," and that the limitations as well as the usefulness of the various kinds of collapse treatment were being appreciated more keenly. Resection had, in fact, acquired an established position, before the introduction of chemotherapy, in the treatment of certain types of lesion. It is still true that there is no real rivalry between resection and surgical collapse in the case of a destroyed lung or a fibrotic stenosis of a main bronchus with associated secondary infection. Moreover, the failures of collapse therapy, such as persistent cavitation after thoracoplasty or a dorsal-lobe cavity which has failed to respond to the simpler collapse measures and chemotherapy, are generally accepted as indications for resection where this is possible. There is also a fair measure of agreement about the advisability of resection where the inadequacy of collapse therapy can be anticipated, as, for example, with many large cavities, particularly of the tension type. The arrival of effective chemotherapy, however, has not only increased the number of patients with such lesions who can be treated by resection but, partly from a certain dissatisfaction about the value of pneumothorax, has also led to a considerable widening of the indications for excision. At this point the controversy becomes clear. There are those who are unwilling to extend the indications very far beyond

[1] Overholt, R. H., Wilson, N. J. *J. thorac. Surg.* 1945, 14, 55.
[2] Overholt, R. H., Wilson, N. J., Szypulski, J. T., Langer, L. *Amer. Rev. Tuberc.* 1947, 55, 198.

the limits set in the era before chemotherapy; they point out that tuberculosis is not a localised disease and that thoracoplasty is a well-tried operation of proved and accepted value which it would be unwise to discard. On the other hand, the more radical view is that resection should be used for areas of localised active tuberculous disease, by which is implied not only cavitation but also caseous foci above a certain size. Such circumstances often require only a limited excision—lobectomy, segmental resection, or simple wedge excision. The mortality-rate of operation is low, complications are few, and the early results are claimed to be good.

Clearly, no conclusive verdict on the merits of excision can be reached until enough late results are available. However, the pathological evidence from resected specimens forms a useful means of assessment. Thus, NASSAU and PAGEL [3] noted that in 19 out of 26 lobectomy specimens the main lesion was "a tuberculoma of the primary complex type, either solid (12 cases) or cavitated (7 cases)": and a similar picture was seen in 4 out of 5 pneumonectomy specimens. The lung focus was recognisable as primary by its relation to a similar caseous focus in a corresponding lymph-node. Many of the solid foci not only were large and caseous but showed small areas of liquefaction on histological examination; and, as NASSAU and PAGEL pointed out, it is this type of focus which plays a decisive part in endobronchial dissemination to other parts of the lung. A lamellated structure was apparent in many of the foci, suggesting an increase in size by slow appositional growth, and the age of the lesion was also indicated by numerous calcareous nodules and particles. Indeed, obsolescent changes were often found in close proximity to fresh progressive changes, the inference being that a local recrudescence was the cause of focal extension. PAGEL [4] found that many apparently solid foci consisted of a pultaceous mass, often containing many tubercle bacilli, and, as RYAN, MEDLAR, and WELLES [5] observed, this caseous mass, even when apparently walled-off by fibrous tissue, remains in potential communication with the bronchus. Liquefaction of the focus with discharge of its contents, teeming with bacilli, into the bronchial tree is a common cause of relapse in patients who have made a good clinical recovery. It may, indeed, give rise to violent pneumonic spread, and favour the establishment of a tuberculous endobronchitis.

There is, on this evidence, a strong indictment to be made out against the caseous focus, particularly the large one, as the real culprit in clinical relapse; and the case in favour of resecting such lesions seems to be correspondingly strengthened. On the other hand, it has been shown[6] that some large foci remain unchanged for years, and collapse therapy—particularly when as permanent as a thoracoplasty—must certainly have been an effective control in many cases. Again, there are certain unfortunate consequences of resection which cannot be ignored. With upper lobectomy, overdistension of foci in the dorsal segment of the lower lobe may lead to breakdown; in many cases the ultimate effect on respiratory function must also be considered. The first difficulty can be countered to some extent by a post-resection one-stage thoracoplasty to reduce the volume of the dead space; and it is already clear that the removal of large amounts of functioning lung tissue must be avoided. There seems to be no simple answer to the question of what should and what should not be resected, but here again the pathology of the lesion can be a guide. RYAN et al. point out that there are really two types of tuberculous lesion: the pneumonic type, which does not proceed to necrosis, and the caseous type, which involves actual death of lung tissue. The former is largely reversible and heals either by resorption or by the formation of scar tissue; the latter is entirely irreversible, it cannot be absorbed, it is liable to slough (in other words, to cavitate), and it can only heal by becoming fenced-in with fibrous tissue, while liquefaction is a constant risk. RYAN et al. also think that caseous foci are more apt to form and to cavitate in the superior and posterior parts of both upper and lower lobes—i.e., in the apical and posterior segments of the upper lobe and the apical (dorsal) segment of the lower lobe. Elsewhere, they believe, even caseous foci are relatively harmless. Resection of such foci should therefore be reserved mainly for disease in the segments where cavitation is commonest, and wedge excision is, wherever possible, the method of choice. The corollary to this view is that a long preoperative preparation by bed rest and chemotherapy is essential, and all the patients described by RYAN et al. had negative sputa and gastric washings for many weeks before the operation. It was accepted as a principle that most postoperative complications are due to the presence of bacilli in the sputum at the time of operation, and these surgeons insisted on a repeatedly negative sputum. Before February, 1951, they performed 30 wedge or subsegmental resections, with bilateral resections in 3 patients (1 patient had 9 wedges removed). Pathological examination showed necrotic (caseous) lesions and the areas previously containing cavities showed filled-in cavities with *patent* bronchial communications. There was little change postoperatively in the cardiorespiratory reserve, and complications were negligible. Up to February, 1952, there was no evidence of clinical or radiological relapse in any of their patients, though 1 patient had had two positive sputum cultures.

Viewed in the perspective of a few years ago, it is rather startling to find that a consistently negative sputum has been made a strict essential for operations of this kind on patients with pulmonary tuberculosis. It is also a matter for thought that patients who have made what seems to be a good clinical recovery should be advised to undergo multiple resections of lung. But the change in outlook is backed by coherent pathological argument, as yet unrefuted, and certainly the fitter the patient the more likely he is to tolerate surgery well. Few would care to endorse without reservation the view of RYAN et al. that caseous foci, as small as 2 mm. in diameter and in certain specified situations, should be resected as a matter of course; but the plea for prolonged preparation with rest and chemotherapy, supplemented by pneumoperitoneum and postural treatment in certain cases, is entirely logical. The extended range of chemotherapy is making drug resistance less of a hazard, and the

highly desirable aim of limited resection with the greatest possible preservation of function can only be achieved with safety when all reversible lesions have been brought under control. In the final analysis only the chief foci of disease can be excised without an unwarranted sacrifice of lung tissue; and the fundamental biological processes which control the body's powers of resistance and recovery must be taken into account. Even on this point, however, it can be argued that removal of the major foci fortifies these powers and eliminates a considerable threat to the bodily economy. Here, no less than elsewhere, successful treatment depends on a careful study of the nature and behaviour of the local lesion, supplemented by an appreciation of the natural history of the disease.

Wernicke's Encephalopathy

THE main features of Wernicke's encephalopathy are loss of appetite, vomiting, nystagmus, diplopia, palsy of external ocular muscles, apathy or apprehension, loss of memory, disorientation, confabulation, and coma. Ataxia has occasionally been noted in the final stages; but its significance is doubtful since by that time the patient may be unable to coöperate.[1] The disease appears as a sequel to chronic alcoholism, long-continued vomiting of pregnancy, malignant lesions of the gastro-intestinal tract, and primary malnutrition. The pathological lesions are scattered throughout the whole brain and are localised particularly in the grey matter of the brain-stem and the structures near the third and fourth ventricles. They consist of hyperæmia, small petechial hæmorrhages, endothelial vascular proliferation, and slight nerve-cell necrosis with microglial reaction. Deficiency of vitamin B_1 is clearly responsible for much of this syndrome; but there is still doubt whether it accounts for the whole picture, and particularly the more severe mental deterioration. Most observers [1–4] agree that within a few hours of giving aneurine (*thiamine*) the vomiting and eye signs improve greatly and the emotional abnormalities lessen: "increased alertness and cheerfulness" was recorded by PHILLIPS et al.[4]; and DE WARDENER and LENNOX [2] remark that the patient may become "cheerful, coöperative, and voluble." These groups of workers also agree that if the disease has progressed to the point where loss of memory, disorientation, and confabulation are all evident, then recovery from these manifestations is slow and uncertain, however well the other features of the disease respond to aneurine. *It is this relative* unresponsiveness of these mental changes that prompts the question whether they are in fact due to vitamin-B_1 deficiency.

DE WARDENER and LENNOX [2] described 52 cases in underfed prisoners-of-war and found that "a patient with a well-established confusional state . . . was likely to take up to three months to return to normal mentality"; and one of their patients was still disorientated seven months after the onset of the disease. They pointed out that, as the whole vitamin-B complex had been given during the long recovery period, the "evidence that no vitamins other than thiamine is concerned in the profounder mental manifestations cannot be said to be complete." JOLLIFFE et al.,[1] whose patients were mainly chronic alcoholics, all of whom had advanced mental deterioration, found that among those whose life was saved by aneurine only a third made a complete mental recovery—again after protracted treatment with multiple vitamins. They concluded that confusion and confabulation in Wernicke's encephalopathy was probably due to some cause other than aneurine deficiency. PHILLIPS et al.,[4] on the other hand, who have confirmed JOLLIFFE's [1] findings in chronic alcoholics, point out that their own evidence does not exclude aneurine deficiency as the sole cause of the advanced mental deterioration.

In peace-time Wernicke's encephalopathy is found most commonly in chronic alcoholics. These patients are usually pathetic, elderly wrecks who have been adrift on a sea of alcohol for many years before they are finally shattered on the rocks of malnutrition; and their abnormal mental state is probably due to many causes. In non-alcoholics it is easier to disentangle the evidence, much of which suggests that aneurine deficiency alone can induce severe mental changes. CAMPBELL and RUSSELL [5] and CRUICKSHANK [3] each cite a case in which confusion disappeared and full mental recovery took place a few days after beginning treatment with vitamin B_1. DE WARDENER and LENNOX,[2] whose cases varied in severity when first seen, and who were thus able to observe the onset of the mental symptoms, noted that these followed the nausea, vomiting, and eye signs. Emotional changes were followed by loss of memory for recent events; then came disorientation, confabulation, and finally loss of memory for remote events. They found that if vitamin B_1 was given before the onset of disorientation, complete recovery ensued within a few days, indicating that loss of memory as well as emotional abnormalities could be caused by aneurine deficiency. They also showed that the time incidence of the classical forms of beriberi in the prisoner-of-war population coincided with the time incidence of Wernicke's encephalopathy; and they pointed out that if the other deficiencies in the diet had been concerned in the ætiology of Wernicke's encephalopathy it would have been reasonable to expect some overlap of the encephalopathy with the better-known manifestations of these deficiencies, which appeared later. WILLIAMS et al.[6] gave a diet grossly deficient in aneurine to healthy persons, who on this régime showed impaired memory and emotional balance; both these changes were corrected by aneurine.

These observations suggest that in Wernicke's encephalopathy disorientation and confabulation are the final evidence of one continuing process which, if untreated, may lead to irreversible cerebral damage. Nevertheless such patients are severely malnourished, and *treatment should include* a good mixed diet together with whole vitamin-B complex by mouth and for the first few days, aneurine and nicotinic acid (niacin) by intramuscular injection. Deficiencies of the vitamin-B group often manifest themselves *singly*; but the dietary deficiency is usually multiple.

Annotations

BLOOD CATALASE AND ORAL ULCERATION

FEW disorders are more mysterious, more troublesome to the patient, and more refractory to treatment than the recurrent oral ulceration that sometimes progresses to gangrene and spreads to the nose and maxillary sinuses. Commonly this disorder seems to be exacerbated, or started on its invasive course, by removal of a tooth; and it is not controlled by local application of antibiotics. In this issue Prof. Shigeo Takahara, of Okayama, Japan, records the connection he has observed between this condition and lack of catalase in the blood and tissues.

Catalase is a specific enzyme, present in many tissues, including blood, that decomposes hydrogen peroxide; it has been known for over fifty years. When hydrogen peroxide is added to blood, oxygen is evolved, but the colour of the blood remains normal; this is because the catalase present decomposes the peroxide to water, and oxygen is released. But if catalase is not present the blood darkens in colour owing to the formation of methæmoglobin; if excess hydrogen peroxide is added the mixture eventually becomes colourless; and the addition to this colourless mixture of potassium hydroxide and then a reducing agent such as sodium dithionate gives rise to a rose-coloured substance, named by Bingold "pentdyopent."

Professor Takahara's attention was drawn to the syndrome he describes while treating a girl, aged 11, who had had recurrent ulcers of the gums for 3 years. When Professor Takahara saw her the condition had become severe, and the right nasal cavity contained a tumour formed of putrefying granulation tissue. He removed the tumour; and when he washed out the cavity with hydrogen peroxide the wound tissue turned brownish-black, and he thought that he had used silver nitrate by mistake. When fresh hydrogen peroxide was used, however, the same thing happened, and it was noticed that the black colour was due to blood in the wound mixing with the peroxide without the usual bubbling. This child had five siblings, and the mother stated that two other children also had oral ulcers. Professor Takahara found that blood from the ear in the two affected children and one unaffected child showed this same blackening when hydrogen peroxide was added, and no oxygen was evolved. He reproduced this blackening reaction with blood in the test-tube, and he also brought about the Bingold pentdyopent reaction. All this suggested that the blood might be deficient in catalase, and by the Warburg manometric method he showed that the blood and tissues of the affected children were grossly defective in this enzyme. For example: the "quotient of catalase" (the ratio of the quantity of oxygen in cubic millimetres generated in 30 minutes at 38°C to the weight of dried tissue in milligrammes) in normal persons is 4500 for ear-lobe blood, 12,000 for the red cells of venous blood, 200 for nasal polyp tissue, and 250 for oral tissue; but in these affected children the corresponding figures were 7 for ear-lobe blood, 8 for red cells of venous blood, and 0 for nasal and oral tissue.

Takahara has found, in another family of ten, four children with lack of catalase in the blood; and two of these had had mild affection of the gums. He describes one other severely affected boy, 13 years of age, in a different family; but the siblings were normal. In all three families, the affected children were the offspring of consanguinous marriages, which suggests that the condition is inherited.

The predominating organisms in the oral and nasal lesions of these patients were hæmolytic streptococci and type-I pneumococci. Hæmolytic streptococci are known to generate hydrogen peroxide. In normal persons this will be reduced by the blood catalase; but in these patients without catalase the hydrogen peroxide produced would oxidise blood reaching the lesion and deprive the tissues of available oxygen, thus leading to a vicious circle with consequent spread of the lesions.

Takahara treated his cases on conventional lines; and it would be interesting to see if local application of a catalase preparation would relieve the condition. The richest source of catalase is mammalian liver, and potent materials have been prepared by several workers—for instance, Sumner and Dounce.[1] We expect that clinicians in this country will look for similar cases, especially since the syndrome can be detected by such a simple qualitative test.

PERSISTENCE OF POLIOMYELITIS ANTIBODY

VIRUS-NEUTRALISING antibody can be demonstrated in the sera of patients with poliomyelitis before the appearance of paralysis, and the antibody titre rises during convalescence. Winsser and Sabin[2] have now investigated the level of antibody at longer intervals after infection with type-1 poliomyelitis virus. They were encouraged to find that three months and three years after infection 6 children showed very high antibody titres in their sera. Is the persistence of antibody due to repeated infection with the virus? Winsser and Sabin are disinclined to accept this explanation, and point to the fact that their patients did not develop antibody to type-2 virus during the same three-year period. It is worth recalling the interesting observations of Paul and Riordan[3] on the antibody to type-2 virus in the sera of Eskimos living on the north coast of Alaska. Practically no Eskimos under the age of 20, but 80% of those over 20, had neutralising antibody in their sera. Paul and Riordan infer from these observations that there was an epidemic of type-2 poliomyelitis among the Eskimos twenty years before, that there had been no epidemic since then (both these deductions are supported by the epidemiological records), and that demonstrable antibody had persisted for more than twenty years. The Yale workers later found[4] antibody in high titre to all three types of poliomyelitis virus in the sera of some Eskimos; and their latest work,[5] among different populations, shows a general correlation between the ages at which clinical poliomyelitis and type-2-neutralising antibody are acquired. Once present, type 2 antibody seems to persist, and it seems clear that high levels of antibody to all three types can persist in man for a long time. The success of any scheme of immunisation against poliomyelitis would depend on the production of an equally sustained antibody response, and in this respect the yellow-fever virus set a good example in the past.

PROFESSIONAL SECRECY

LAST year[6] we discussed the question of professional privilege in courts of law, and we pointed out that while in this country medical secrets are not recognised or protected in the witness-box, Continental legal systems have, under pressure from the medical profession, deliberately adopted a different attitude which gives far greater safeguards to doctors and their patients. The wider implications of the disclosure of confidential medical information were discussed at this year's German Medical Congress, held in Berlin in September, and the debate led to a number of resolutions which are, in present conditions, of great interest to doctors everywhere.

[6] *Lancet*, 1951, i, 454.

It has been clear for some time that requests from public authorities for medical and statistical information are tending increasingly to encroach on the private and confidential relations between doctor and patient. Those who seek medical advice have a right to expect that whatever they as patients confide to their doctors will go no further, and doctors are equally anxious to respect absolutely the confidences they receive. Nevertheless, certain legislation, particularly that dealing with social insurance and health, tends to restrict, or even remove, this protection. Police regulations, notification and registration orders, tax and criminal laws, and the demands from public authorities, private concerns, and insurance companies for certificates of incapacity or health were all mentioned at the congress as causes for the gradual confounding of the patient's natural expectation that what he tells the doctor will be passed on to no-one else. The congress came to the conclusion that medical secrecy must be regarded as a fundamental human right which, for the sake of patient and doctor alike, needs far more definite protection by the law than it has hitherto received in Germany. Accordingly, a resolution was passed asking the Federal Parliament at Bonn to introduce comprehensive legislation establishing a definite medical code. This legislation is to be based on the principle that only the consent of the patient in each individual case can release the doctor from his duty, which is at the same time his right, not to divulge any knowledge gained in the consulting-room or elsewhere in the exercise of his profession. This would give him the necessary legal ground on which to resist firmly any unjustified request from whatever source.

In these discussions it was, of course, acknowledged that in certain situations a breach of secrecy may be necessary: the prevention of an epidemic or a serious crime would justify such a step; but there was unanimous agreement that the limits of such exceptions should be as narrowly drawn as possible, and that, in cases of doubt, the final decision should be left to the doctor's discretion. No doubt as a result of certain abuses in Western Germany,[7] practitioners in Germany are no longer required to report all miscarriages and abortions among their patients. The congress has gone much further in suggesting that by no means all the other notifications now demanded by law are justified, and that they are in constant danger of abuse. It was suggested that, when such returns were strictly necessary, in many cases the names of patients could be withheld without seriously interfering with the purpose of the regulations, and that, where names must be given, these should be sent in sealed envelopes to be opened only by the doctors directly concerned. One of the demands most strenuously made at the congress was that confidential medical details should not be known to non-professional civil servants or outsiders. It was proposed that, whenever a public authority or semi-official body asked for a report on a person's health or capacity for work, the information should be available only to the authority's health officer, and not to the authority at large. In these circumstances the health officer would himself be bound by professional secrecy, in the same way as the doctor acting on behalf of, for example, a private insurance company. He would pass on the result of the medical examination in the form of a definite recommendation or proposal, withholding the actual details. It was also proposed that medical certificates for employers should identify the disease by a code word, at the same time giving the seriousness and expected length of the illness.

How far these recommendations are likely to be put into practice in Germany is not yet clear. At all events, the German press and public have been strongly impressed by the practitioners' call for effective legal safeguards. Meanwhile it is interesting to note that, under an amending Bill to the German Criminal Code, which is before the Federal Parliament just now, the privilege of doctors in German courts of law is to be extended to their auxiliaries—consulting-room assistants, nurses, and midwives—and that secrecy is to cover not only what has been expressly entrusted to them by their patients, but all information which they have gained in the exercise of their profession. Past experience of overriding authority, and probably a knowledge of conditions in Eastern Germany, where all medical secrecy has been abolished and doctors have in many respects become the servants of a ministry of labour, have certainly made German doctors especially sensitive to encroachment on what they rightly regard as a fundamental principle.

THE YOUNG CHILD IN HOSPITAL

A FILM, *A Two-year-old Goes to Hospital*, has been made as part of the research work in progress at the Tavistock Clinic, and it was shown to the section of pædiatrics of the Royal Society of Medicine on Nov. 28. Opening the meeting, Dr. John Bowlby said that it might seem that the subject of a small child's stay in hospital for eight days for a minor operation, and the fact that she spent most of the time fretting for her mother, were hardly worth making a film about; but evidence was accumulating that prolonged periods of separation from the mother in early life could have serious effects on a child's mental health. He welcomed the film as a new and objective approach to the problem.

Mr. James Robertson, a psychiatric social worker at the Tavistock Clinic, who made the film, said that while he was studying the emotional reactions of children in hospitals and sanatoria he became aware of the bias both of the psychologist, who tended to identify himself with the small patient he was observing, and of the doctors and nurses, who were apt to develop a self-defensive unawareness of the child's mental suffering in order to spare their own feelings. He had therefore decided to make this film to record objectively what actually happened. Before the child went into hospital he had visited her at home, so that she was accustomed both to him and to the camera. Later, through the coöperation of the authorities of the Central Middlesex Hospital, he or a colleague was able to watch the child continuously during her waking hours. Each important event was filmed—the child's admission to hospital, the first bath, the administration of an anæsthetic by enema, and the parents' visits—and in addition films were taken each day from 11.0 to 11.40 A.M. at five-minute intervals. The only departure from routine was that a nurse was specially detailed to talk and play with the child during the morning filming. The little girl, Laura, aged 2½, had been selected at random from the waiting-list of children between 18 months and 3 years who were to come into hospital for an operation for umbilical hernia. This operation was chosen because it was minor and uncomplicated and not very painful.

The film opened with Laura playing happily with her parents in the garden of her home. Her mother had explained that she would be going into hospital and would stay there until she had had her operation and her tummy was better. On the day of her admission she was bright and interested as she sat waiting with her mother at hospital; but she was looking a bit hesitant some minutes later when the nurse took her into a strange bathroom, and she asked anxiously, "where's my Mummy?" When the nurse began to undress her she cried and struggled; but by the time she had been bathed, dried, and dressed in a nightgown she had regained her composure, showing remarkable self-control for her age. She was given a cot in a children's ward with 12 beds. She looked about her in a puzzled way, and cried when a nurse took her temperature in the axilla. But she cheered up again when her mother came to say good-bye: and she waved happily enough and watched the bus drive away. Her mother had told her she would come again tomorrow, and had left with her a teddy-bear and a piece of blanket she always cherished, her "blanket-baby." However, she spent most of the day crying and calling for her mother, and she did not take kindly to a visit from the surgeon.

---

[7] *Ibid*, p. 676.

Next day she had her operation. She was given an anæsthetic by enema, an experience which terrified her and made her scream with apprehension. She was next shown when both her parents came to see her as she was recovering from the anæsthetic. She cried most of the time, and was especially distressed because her mother could not take her up in her arms. When her mother left first, she clung to her father until he, too, had to go. On the third day she seemed very sad and subdued. She was unresponsive to the nurse, and tears came easily. She called for her mother, but when her mother came she received her without enthusiasm, and it was some time before she became lively and joined in a game. From this time onwards, she became less and less responsive both to the nurses and to her mother. She spent a good deal of time watching another child who was howling lustily, and she exclaimed, "He wants his mummy." She clung to her teddy and her blanket-baby and to some books her mother had brought, but she still cried for her mother whenever some kindly grown-up came to speak to her. When her mother came to take her home, she was extremely reserved, but she brightened up considerably when her shoes were put on. She insisted on gathering up all her toys and books, and she waved good-bye as she got to the door of the ward. Then she dropped a book and for the first time showed real temper. She left rather unsteadily, but not holding her mother's hand.

In the discussion which followed, the first reaction of the audience seemed to be a frank refusal to admit that the child was distressed. However, Dr. Mildred Creak pointed out that it had taken a second showing of the film to overcome her initial resistance to the fact that most young children in hospital were unhappy. Of those who agreed that the film showed the child's distress clearly enough, many were reluctant to admit that such an experience might cause long-continued or even permanent emotional disturbances. They felt that the emotional after-effects were negligible, and depended largely on the individual child's upbringing and home life. There was a need, they thought, for control films of normal children's emotional upsets at home, and of the effects both of a longer stay in hospital and of a stay undisturbed by an alarming operation. In reply, Mr. Robertson said it was hoped that other films would eventually be made. He felt that, in spite of Laura's exceptional self-control, the film gave a fair idea of the typical reactions of a child in hospital, and he disagreed with the view that the mental suffering was negligible. Dr. Bowlby agreed that we needed detailed evidence on the effects of a period of separation from the mother, but he thought that this evidence would be of little scientific value unless it was collected and weighed by people with the necessary psychological training.

Despite daily visits by her mother, this child was shown in silent grief during most of her stay in hospital. Her self-control broke down under frankly terrifying situations. For most of the day she sat quietly clutching her treasured possessions, preoccupied with her grief. Despite this unhappy picture, the film left an excellent impression of the treatment and kindly handling of a small child in this particular hospital. However, there seemed no need for this particular operation at such a psychologically vulnerable age; and even if the operation was thought vital the child might possibly have been treated as an outpatient. If hospital is unavoidable, there are certain ways in which, on the evidence of this film, matters could be improved. Laura was kept in virtual isolation and given little physical comforting, even by her mother, who thought that it was not permitted in the ward. A strange nurse gave her a bath while her mother waited outside; and some nursing procedures were carried out without any attempt to explain them to the child. Doctors and nurses can do much to help in reducing the number of mother-child separations and to make those that are unavoidable as happy as possible. The words of one pædiatrician to his student nurses are memorable: "When you are admitting a child to hospital always try to behave as though you were welcoming a strange and nervous child who has come to spend a weekend in your home."

SISTER KENNY

Miss Elizabeth Kenny, the Australian nursing sister, died on Nov. 30. Doctors have disagreed about the value of her contribution to the treatment of poliomyelitis, but none has failed to admire the energy and perseverance with which she upheld her beliefs in the face of incredulity and discouragement. The ideas which were to cut so sharply across orthodox medical opinion were planted in her mind by her early nursing experiences in Queensland; and they grew into a system of treatment and a concept of the disease which aroused discussion and controversy all over the world. For one thing, she challenged the doctors' insistence on rest and immobilisation in the early stages of poliomyelitis, and she claimed that, given the chance of treating a patient soon enough, she could improve on the results of any other form of treatment.

Her views were at first entirely rejected, and then hesitantly acknowledged as worth investigating. The report on the year's trial at Queen Mary's Hospital, Carshalton, in 1937–38 was almost wholly discouraging, and, added to the lukewarm findings of the Royal Commission appointed by the Queensland State government in 1936, would have brought despair to the champions of most causes. But if Sister Kenny ever despaired it was certainly not for her treatment, but for the perception of the doctors who refused to see what to her was abundantly clear. She did not realise that her own enthusiasm could go against her; for the doctors thought that their treatment, energetically pursued, could achieve as much as her own, and they suggested that the benefits she brought to paralysed patients owed more to her confidence and optimism than to any originality of method.

She went to the United States in 1940, and though at first her methods gained no wider acceptance than elsewhere, things went more happily for her in the end. The Elizabeth Kenny Institute was set up in Minneapolis, and here, and in other clinics devoted to her treatment, much of her work was more favourably received than ever before. She never won for her methods or theories the unconditional approval that she and her many supporters believed them to deserve. Nevertheless, she whipped up so world-wide an interest in the treatment of poliomyelitis that, whatever the final judgment of her teaching may be, the sum of her work, in terms of suffering directly or indirectly relieved, places her among the foremost members of her profession.

Prof. R. S. AITKEN, F.R.C.P., vice-chancellor of the University of Otago, has been nominated vice-chancellor of Birmingham University.

Special Articles

GENERAL MEDICAL COUNCIL

SESSION NOV. 25–28

Prof. David Campbell's presidential address to the council was reported last week. The council appointed Dr. I. Grant to a vacancy in the Medical Disciplinary Committee.

DISCIPLINARY CASE

The council considered only one medical disciplinary case.

In November, 1950, it postponed judgment until November, 1952, after finding that *William Melrose*, registered as of 15, St. Paul's Square, Liverpool, L.R.C.P.E. (1924), had been convicted of being found drunk, for which he had been fined 10*s*. Dr. Melrose appeared and testimonials as to his conduct were read. In view of these the Registrar was not directed to erase the practitioner's name.

BRITISH PHARMACOPŒIA

Dr. H. GUY DAIN, presenting the report of the Pharmacopœia Committee, of which he is chairman, said that sales of the *British Pharmacopœia, 1948*, up to Oct. 31 totalled 48,843, and of the *Addendum, 1951*, 13,274. In preparing the new *Pharmacopœia*, which was now complete and would be published next year, care had been taken to consult other countries in the Commonwealth.

The committee had approved the issue of two further lists of approved names for various medicinal substances. Since the practice of issuing approved names was instituted in 1940, thirteen lists had been issued. Where possible, official names were given to all new substances likely to be found useful. Such substances were not necessarily entered later in the *British Pharmacopœia*.

The committee's report states that the Pharmacopœia Commission has consulted with the World Health Organisation subcommittee on international non-proprietary names, in an endeavour to achieve uniformity; but some of the names proposed by W.H.O. have had to be rejected because they conflict with trade-marks registered in this country.

The committee, on the recommendation of the commission, has arranged to publish amendments to the *British Pharmacopœia, 1948*, in relation to methods of preparation of substances which will not appear in the new *Pharmacopœia*. Dr. Dain explained that it was important that these new methods should be made statutory before the new *Pharmacopœia* came into effect.

The council approved the committee's recommendation that the British Pharmacopœia Commission, 1948–53, should end its existence on Sept. 1, 1953, when the new *Pharmacopœia* comes into effect; and that the new commission to prepare the next *Pharmacopœia* should be appointed by a selection committee consisting of four persons nominated by the council, three persons nominated by the pharmaceutical societies, and two persons nominated by the Medical Research Council.

PROVISIONAL REGISTRATION

The council considered a report by the Special Committee on Provisional and Full Registration, which made various procedural recommendations in respect of the compulsory period of service as a house-officer, which comes into operation on Jan. 1.

The PRESIDENT, who was chairman of the committee, explained the difference between the official Register and the printed Register. The council was empowered to produce a printed Register of persons provisionally registered, but such a Register would soon be out of date and nobody would want to buy it. The council authorised the amendment of standing orders to provide for the keeping of separate Registers of persons provisionally registered. It also authorised the fees which will be payable: for provisional registration the fee will be 5 guineas, and for full registration of a provisionally registered person 6 guineas; for others the fee will be 11 guineas.

The committee proposed a form of certificate for use by hospital authorities in certifying to licensing bodies that a provisionally registered practitioner had satisfactorily completed a period of employment as a house-officer. This would say that he had been employed for the period specified "and that his service while so employed has been certified by a member of the consultant or specialist staff as satisfactory." It would be signed by an officer of the board of governors, hospital management committee, or other employing body authorised to act on its behalf.

Sir RUSSELL BRAIN asked the meaning of the word "*specialist*." *If the intention* was that all house-officers provisionally registered should work under consultants, the wording should be limited to consultant. Sir HENRY COHEN, a member of the special committee, replied that the suggested wording was necessary. Most would work under consultants, but some might be under senior hospital medical officers who were not consultants under the Act but were specialists. Sir RUSSELL BRAIN agreed that in the circumstances there was no option but to have the wording as suggested, but they should "keep an eye on it."

Dr. O. C. CARTER said that there was a great deal of anxiety among students because the word "satisfactory" was not defined. Sir SYDNEY SMITH said this was a matter for individual licensing bodies. The certificate was approved for sending to licensing bodies for their observations.

The committee also recommended a form of certificate of experience to be circulated to licensing bodies, examining boards, and medical schools, for their observations.

The committee was satisfied that the compulsory internship schemes adopted in New Zealand and South Africa could be regarded as substantially equivalent to the United Kingdom scheme, and the council agreed that full registration should be accorded to practitioners who had been registered in New Zealand or in South Africa after rendering appropriate service under schemes there. In the matter of recognising hospitals in the Colonies the committee recommended, and the council agreed, that particulars furnished by the Colonial Office of recommended hospitals and posts, as revised in the light of observations received, and subject to any further adjustment which might be undertaken by the Colonial Office, be circulated to licensing bodies for their information.

A special committee was set up to consider and determine on behalf of the council applications made under Section 1 (*b*) and (*c*) or Section 4 (*c*) of the Medical Act, 1950, by persons whose applications do not fall to be determined under any *general resolution;* this concerns the registration of Commonwealth or foreign practitioners on proof of "satisfactory experience."

Medical Disciplinary Committee

The Medical Disciplinary Committee, under the chairmanship of the President, at its first sitting, on Nov. 26, heard three applications for restoration of names to the Register.

The Committee, after hearing evidence, directed the registrar to restore the names of Ralph Martin Case and Illtyd Gwyn Williams.

Stewart Quarterman Servanté applied for restoration of his name. Mr. J. B. Trier, solicitor, said that his client's name had been erased in February, 1950, following his conviction for unlawfully using an instrument to cause a miscarriage. He had made an unsuccessful application for restoration in November, 1951. In sentencing him the judge had said that there was no evidence that Dr. Servanté was a habitual abortionist. At present he was doing manual work; but he had received an offer, if he was restored to the Register, to become medical officer at a whaling station in Antarctica. The committee did not think fit to direct the registrar to restore to the Register the name of Stewart Quarterman Servanté.

FALSE ENTRY IN REGISTER

The committee heard the case of a fraudulent and incorrect entry in the Register which was made without the knowledge of the doctor concerned. The entry was that of "Joseph Claude Guyneruer Cyr," the address being recorded as "Royal Canadian Naval Hospital, Halifax, Nova Scotia, Canada," and the qualification "L.M.S. N. Scotia P.M. Bd, 1951." Mr. F. P. Winterbotham, solicitor to the committee, explained that no blame attached to Dr. Cyr, who was in no way responsible for the incorrect entry, which was made without his knowledge. Mr. Winterbotham read an affidavit from Dr. Cyr stating that the signature on the application was not his, that he had no knowledge of the application and did not authorise it, that he held medical degrees in Canada but not that of L.M.S. Nova Scotia P.M. Bd, and that his address had never been that given. The person whose name appeared on a certificate of character submitted with the application stated that the signature purporting to be his on the certificate was a forgery.

The Committee found that the entry had been made fraudulently and incorrectly and ordered its removal. The President stated: "There is not the slightest evidence that the real Dr. Joseph Claude Guyneruer Cyr had anything whatever to do with this case."

ALLEGED IMPROPER BEHAVIOUR

James Watson Richmond, registered as of Rosskeen, Kelty, Fife, M B. Glasg. (1929), appeared on having been convicted at the Sheriff Court, Fife, of offences involving improper behaviour to women, for which he was fined £25.

Mr. Gerald Howard, Q.C., M.P., stating the facts, said that the doctor had pleaded guilty and there were no notes of the evidence. Mr. Howard had obtained a newspaper cutting, and he submitted that it was proper for him to make a statement of the facts from this. The chief constable and the Lord Advocate's office had refused production of the statements taken by the police; and the chief constable had sent the officer in charge of the case, who had not been in court at all.

After legal argument as to using the newspaper cutting the Legal Assessor said that the doctor should be shown the cutting and asked if he agreed to its being read. He did not do so; and after consideration in camera the President announced that the committee had decided to proceed on the evidence produced. Mr. Howard said that, so far as he had been able to ascertain, Dr. Richmond had an excellent character. Dr. Richmond told the committee that he did not remember anything about the alleged incidents.

The President said that the committee considered the convictions disgraceful to a member of Dr. Richmond's profession; but in view of his explanation and the certificates which he produced it had postponed judgment for one year.

PAYMENT BY N.H.S. PATIENTS

William Pitt, registered as of Chatham, Sydenham Avenue, Belfast, M.B. Belf. (1942), was found to have been convicted at Birmingham Assizes of accepting payment from three National Health Service patients for treatment which should have been free. He had been fined £100 to be paid within three months, or six months' imprisonment in default. The President announced that the committee took a very serious view of the charges: but taking into consideration the assurances as to Dr. Pitt's future conduct it had decided to postpone judgment for one year.

CHARGE OF CANVASSING REFUTED

James Joseph Magill, registered as of 64, Vernon Avenue, Clontarf, Dublin, L.A.H. Dubl. (1950), was charged with infamous conduct in a professional respect. It was alleged that he had endeavoured to obtain patients of the practices of Mr. Gervase Brennan-Kelly and Mr. John Adami by means of an agent or canvasser, and by other improper means. The President announced that the committee had determined that none of the facts alleged against Dr. Magill had been proved to their satisfaction. "They have accordingly found that you are not guilty of infamous conduct in a professional respect."

UNLAWFUL REMOVAL OF A MOTOR-CAR

Jonathan Shutt, registered as of 118, Ebury Street, London, S.W.1, M.R.C.S. (1925), was charged with having been convicted at Hull of taking and driving away a motor-car without the consent of the owner or other lawful authority, in respect of which he had been sentenced to a fine of £10 or in default fifty-one days' imprisonment. The President announced that after careful consideration, and to give Dr. Shutt an opportunity to rehabilitate himself, the committee had decided to postpone judgment for one year.

IMPROPER PRESCRIPTION

Carl Xavier Rühen, registered as of Mexborough House, Market Street, Mexborough, M.B. N.Z. (1925), admitted, through his counsel, Mr. Gerald Howard, a conviction at Doncaster on May 13 of attempting to cause £1 7*s*. to be paid by the West Riding Executive Council to Boots Pure Drug Co. Ltd. by means of a false pretence. He had been fined £42 5*s*. 6*d*. The President announced that the committee took a grave view of a conviction of this nature, but in view of the testimony as to Dr. Rühen's character had directed the registrar not to erase his name from the Register.

DRUNKENNESS IN CHARGE OF A CAR

James William Hay, registered as of 51, Spencer Street, Carlisle, M.B. Aberd. (1924), had had judgment against him postponed for one year by the committee in May, 1951, in respect of convictions for driving a car whilst under the influence of drink, of driving a car without due care and attention, and of being found drunk. The committee directed the registrar not to erase Dr. Hay's name from the Register.

The registrar was directed not to erase the name of *William Allan*, registered as of 31, Hill Crest, Burnley Road, Sowerby Bridge, Yorks, M.B. Glasg. (1926), who had been convicted of driving a car whilst under the influence of drink. Judgment in this case had been postponed from the sitting in December, 1951.

The committee had similarly postponed judgment for one year in respect of *Hugh McNicholl*, registered as of Bangour Villa, High Road, Mottingham, London, S.E.9, M.B. N.U.I. (1933), who had been convicted of being in charge of a motor vehicle whilst under the influence of drink. The registrar was directed not to erase his name.

The committee postponed judgment for one year on *Archer Wilson Dunn*, registered as of 5, Airlie Place, Dundee, L.R.C.P.E. (1927), who had been fined £20 and disqualified from holding or obtaining a driving licence for six months in 1949 after being convicted of driving a car while under the influence of drink and driving without due care and attention, and in August of this year had been fined £30 and disqualified for twelve months from driving while under the influence of drink.

Gerald Francis Adye-Curran, registered as c/o Lightbounds, Jones & Co., 18, Water Street, Liverpool, L.M.R.C.P.I. (1934), was charged with having been convicted in 1947 of driving a car whilst under the influence of drugs (when he was not disqualified for the special reason that the overdose of drug was taken inadvertently, but was fined £5); in the same year of being in charge of a motor-car while under the influence of drink; and of being convicted in May last of being in charge of a motor vehicle whilst under the influence of drink and of assaulting a police constable. In the last instance he was sentenced to four months' imprisonment and disqualified for five years on the first charge, and fined £10 on the second charge. The committee postponed judgment until November, 1953.

Patrick Joseph Conlin, registered as of 1, North Terrace, Mardy, Ferndale, Glam., M.B. N.U.I. (1920), had had judgment postponed in December, 1951, to the present session after he had been found to have been convicted of being in charge of a motor-car whilst under the influence of drink. Dr. Conlin was not present but sent a telegram apologising and stating that he was on his way. After consideration in camera the President announced that the committee had decided to further postpone judgment until their session in November, 1953, when they would require testimonials as to his habits during the interval.

ABORTION

The registrar was directed to erase from the Register the name of *Archibald Miller*, registered as of 2, Douglas Drive, Ashgill, Dalserf, Lanarkshire, M.B. Glasg. (1928), who had been sentenced in June of this year to twelve months' imprisonment after being convicted in the High Court of Justiciary in Glasgow of supplying to a pregnant woman pills containing aloes and ferrous sulphate, and a liquid containing ergotamine tartrate, with intent to cause abortion. The erasure of his name is subject to appeal to the Privy Council within twenty-eight days.

HEALTH SCHEMES IN EIRE

AFTER eighteen months of comparative quiescence health schemes are once again causing controversy in Dublin. The Irish Medical Association has rejected the government's plans for improved and extended health services as outlined in the White Paper published last July. Clearly the association feels that, although the child has a different mother, the child closely resembles one which they removed from their doorstep last year.

A leading article in the association's journal[1] objects to the provision of a maternity and child-welfare scheme which would be free to all, irrespective of income. Such a development, says the article, would represent a dangerous growth of State control and a further intrusion of the civil service into one of the most intimate branches of medicine. This, it points out, is the only section of the proposals which is "free for all." While no-one would be obliged to use these free services they must, in fact, be paid for out of increased rates and taxation; and each taxpayer would naturally seek a return from this compulsory outlay. In any case the number of maternity beds is "utterly inadequate" to deal with such a scheme.

After protesting at the way in which the "so-called autonomy of our voluntary hospitals is being steadily undermined," the article goes on to say that the association is pressing strongly for an active Health Council. This would have its own secretariat, the duty of publishing an annual report, and the right of approach to the minister for health. It would advise him on health legislation and health affairs generally, and would be representative of the profession and other interested bodies.

> "... it must not be lost sight of that any Health Scheme, to operate successfully, must have the goodwill of the doctors. Is it reasonable to look for this goodwill while at the same time denying the fundamental right to representation of the very men and women in whose hands the working of the Scheme must rest?"

The article concludes that the ideal is a voluntary contributory State-aided scheme as proposed by the association over twelve months ago. Under this the local authority would pay the full premium for every poor person; for all others the State would pay one-third of the premium. A family health policy worth £200 per annum would be available in return for a weekly payment of 1*s*. 4*d*. by the head of the family. Such a scheme would be at once more comprehensive and more realistic than the government's proposals.

The reply of the minister for health, Dr. James Ryan,[2] was couched in robust terms. Referring to the association's remarks on civil service intrusion it stated:

> "The White Paper proposals involve no such intrusion and none is intended and the statement is either deliberately dishonest or arises from a confusion in the minds of the Association as to the primary function of the medical profession which is the practice of medicine and not administration."

After denying any interference, or intention of interference, with the voluntary hospitals the statement continues:

> "The Association also ignores the fact that additional maternity beds are being provided rapidly and that in this country, as in practically every country, it is not practicable to provide 100 p.c. hospitalisation."

Elsewhere the minister has given the total number of maternity beds of all kinds in local-authority and voluntary hospitals as 1503 in 1952, compared with 1215 in 1942.[3] The average number of births per year is approximately 65,000.[4] Under the terms of the White Paper, priority for admission of maternity cases to hospital will be given on medical grounds or on grounds of social need.

On the question of the Health Council, the minister stated that what the association requested was, in effect, a council that would be responsible, through him, for running the country's health services. This he rejected, but he was prepared to consider any proposals which the association might put forward for a council with advisory functions.

The minister also regards the association's insurance scheme as impracticable. Particular exception is taken to the need for a qualifying period before benefit is payable. After referring to "inconsistencies" in the I.M.A. scheme the statement refers to

> "the discrepancies between the Association's recent statement that under the scheme the full premium would be paid by the local authority and its statement in the course of a discussion with the Minister on December 20th last, that each local authority would be free to decide whether to avail itself of the scheme or not."

The minister has stated that the scheme will not be introduced without the fullest consultations with all interested parties.

PHYSIOLOGY OF THE NERVOUS SYSTEM

IN his presidential address to the Royal Society at the anniversary meeting on Dec. 1, Prof. E. D. ADRIAN, O.M., considered some of the ways in which our picture of the nervous system is changing. The work of the biophysicists, he said, was beginning to reduce the problems of cell organisation in the nervous system to the molecular level. It was likely to explain many of the characteristic properties of nervous tissue and to give a clear picture of the cell mechanism; but the cell units subserved the integrative action of the whole animal, and we had to determine how they were organised as well as how each one stored and discharged ions.

Dr. Adrian continued:

> "Since we are still searching for the physical changes which accompany learning—the changes, structural or molecular, which make the nervous system react differently after training—there is little as yet to bridge the gap between the biophysics of the nerve cell and the fully elaborated activity of the whole system. And if we could find, for instance, the cell changes which establish a conditioned reflex, we should still have only the general principles of nervous organisation. We could not forecast in detail how any particular nervous system would react unless we knew every detail of its past history. ... To understand the integrative action of the nervous system we have to relate the unit to the whole system and the system to the work it has to do. The study of the unit is advancing rapidly, though it is mostly concerned with the immediate response to stimulation and we know little about slower and more persistent effects. When we do know more, it may be that the general plan on which the units are organised will become much clearer. Perhaps a complete revision of outlook may be necessary. At all events there is no need to be pessimistic. There is a wealth of new material and new methods and a branch of natural science is in a healthy state when it has advanced to the stage where its traditional conceptions begin to look inadequate."

COMPLAINTS ABOUT A PRACTITIONER

IN connection with the case of a general practitioner in the National Health Service about whom there have been repeated complaints, the medical service committee of London Executive Council has taken the unusual course of suggesting that representatives of the council and of the local medical committee should discuss means for safeguarding the interests of the service.

The committee reported to the council on Nov. 27 a complaint by a patient and his wife that the doctor had been very rude and that he had forcibly ejected the wife rom the surgery. According to these witnesses, the onditions in his surgery virtually defied description. he place was said to be dirty and littered with old lothes, old shoes, used matchboxes, and books and apers. There was a "filthy rug" on the floor, and the esk was so littered that there was no space on which to rite; and dust and tobacco ash was all about. The espondent practitioner did not appear when the case as heard. On the ground that the doctor had failed to rovide proper surgery accommodation, as required by he Terms of Service, the committee recommended, and he council agreed, that representations should be made o the Minister of Health that £50 should be withheld rom his remuneration.

---

[1] *J. Irish med. Ass.* November, 1952, p. 328.

[2] *Evening Herald*, Nov. 7, 1952.

[3] Dail Eireann Official Reports (unrevised), vol. 134, 2, columns 223–226, 229–236.

[4] *Ibid*, col. 222.

In its report the committee pointed out that this doctor had been the subject of three previous inquiries.

In March, 1951, the Minister of Health instructed that £25 should be withheld from his remuneration because of his failure to return to the council the medical records of 236 of the persons who had been removed from his list in 1949. In February, 1952, the Minister, because of the doctor's continued failure to submit the medical records of his patients, directed that the council should withhold a further £100. On Jan. 3, 1952, the council considered a report by the committee of an allegation by a patient that the doctor had struck him on the face. The doctor, who had not appeared at the committee's hearing, appealed successfully against the council's recommendation that 25 guineas should be withheld from his remuneration; but a letter from the Ministry of Health to the practitioner said that the Minister "takes a most serious view of your conduct towards the patient which he regards as highly reprehensible. Should such conduct occur again in the future, the Executive Council would no doubt need to consider whether your continued inclusion in the Medical List was consistent with the efficiency of the medical service."

The council agreed to the committee's suggestion that the case should be discussed jointly with the local medical committee. The council has power under paragraph 13 of the First Schedule to the National Health Service (General Medical and Pharmaceutical Services) Regulations, 1948, with the consent of the Minister of Health and after consulting the local medical committee to give notice to the patients on a practitioner's list that he is, in their opinion, not in a position to carry out his obligations under the Terms of Service.

Parliament

School Dental Service

IN the House of Commons on Nov. 26, Mr. JOHN BAIRD said that the school dental service had been one of the major headaches within the health service, though there had been some recent improvement. In 1938 it had 783 dental officers: on Jan. 1, 1952, the service reached its lowest ebb with 712 officers; in October, 1952, the figure had risen to 827. But the Minister of Health admitted that an efficient school dental service would need 2000–3000 full-time dental officers. Mr. Baird did not think there were any grounds for the optimistic view that more dentists would come into the service. The barrel had already been scraped. The only way to get further recruits would be to impose further charges on dentists in private practice, which would destroy the whole basis of the health service.

A short-term solution had been worked out by the British Dental Association which could be operated while a new priority dental service was being built. 1743 dentists had agreed to set aside some time each day to treat children in their own surgeries. In all over 10,000 hours would be available each week. The Ministry of Health had turned down this offer on the ground that it was better to treat children in clinics associated with schools. But the hard fact was that we did not have enough clinics. Mr. Baird admitted that he was not himself convinced that treatment in clinics was best. In the old days when working-class people could not afford to take their children to the dentist the school service was valuable. Nowadays under the N.H.S., he thought parents should be encouraged to bring their children to the family dentist. He looked forward to the time when the school dental service would inspect the children, but most treatment would be carried out in the general-practitioner dental service. The Ministry's second reason for refusal was that children could be treated more economically in clinics than on the scale of fees for the general dental service. He deplored the neglect of children's teeth while the local authorities and the Treasury struggled as to who should pay for the school dental service.

Miss PATRICIA HORNSBY-SMITH recapitulated the Ministry's reasons for believing that the best method of treating children was in school, or in local-authority clinics on a full-time or part-time basis.[1] She added that the Government intended to ensure the provision of increased facilities for the treatment of children through the local-authority clinics. Surely in the interests of the children, as well as the most efficient use of the dental skill available, dentists should be willing to give part-time service of even one session a week in the school clinics.

Hospitals in North-west Wales

In the House of Commons on Nov. 28 Mr. CLEDWYN HUGHES called attention to administrative difficulties in the hospital services in this area. In reply Miss HORNSBY-SMITH said that sparse and scattered population, poor communications, and the absence of any really large centres, had made difficult the organisation of hospital services in the rural area of Anglesey and Caernarvonshire. Despite repeated advertisements in the press for doctors to fill hospital posts, registrars did not easily go there. It was difficult to see what other steps could be taken—short of direction, which she was sure Mr. Hughes would not suggest. This difficulty was under discussion nationally by the medical profession as a matter of urgency. Demoting peripheral hospitals was no part of the policy of the Ministry of Health. But there must be a balance and a limit to which they could go in upgrading a very small unit, and the extent to which they could impose upon it all the specialties normally available in a large general hospital serving a greater area.

She realised that there was a serious tuberculosis problem in North Wales. Anglesey and Caernarvon had some of the worst figures in England and Wales. The waiting-list for T.B. hospitals in the area was 58, but the real shortage was not one of beds but of nurses, and there were 223 unstaffed T.B. beds.

The need for a new hospital for the Bangor area was acknowledged; and there was a suggestion that a hospital of 500 beds should be built there. The first priority for Wales had been allocated to the new teaching centre at Cardiff, and there were other rivals for second priority, but she had no doubt that the claims of Bangor stood high.

Beds for the Aged Sick

In the House of Commons on Nov. 19, Mr. H. HYND pointed out that, owing to the increasing proportion of old people in the country, there were 8800 chronic sick waiting for beds in the hospitals, and hospitals which took these patients had 3100 beds understaffed. It was often assumed that old people were either well or sick, but in practice many were in the borderland between health and sickness. Unfortunately neither the hospitals nor the county councils seemed to have the power to set up for the aged infirm homes linked with the geriatric service of the nearest hospital.

Miss HORNSBY-SMITH, parliamentary secretary to the Ministry of Health, did not deny that there was a shortage of beds for the aged. Hospital authorities were responsible for the sick, and local authorities were responsible for those who were only in need of care and attention. Hospitals had been asked not to refuse borderline cases who were recommended by a general practitioner or a welfare officer. To make a new classification of a borderline section would not, she pointed out, provide more beds. The need for more accommodation was reflected in every part of the National Health Service. At present there were 57,000 chronic sick beds, and from a survey taken during the war it was believed that something like 80,000 beds were required. The waiting-list was 8800. Yet in 1951 there were 2000 more beds than in 1949 and the accommodation both in old people's homes and by adaptation of the old public-assistance institutions was being steadily increased. There were 3800 beds understaffed.

---

[1] See *Lancet*, Nov. 29, 1952, p. 1076.

Geriatric services in hospitals had been greatly developed. No less than 40% of the so-called chronic sick could today be rendered fit for discharge from hospital, but there were not enough old people's homes and hostels to receive them. Progress had been made with long-stay annexes for those not fit enough to go to old people's homes, and the King Edward's Hospital Fund had provided capital for a number in the Metropolitan area which were working with great success. The proposal that the general practitioner should have greater authority to decide whether or not a patient should be admitted to a bed raised great difficulties. There might be many general practitioners in one area but only one hospital, and the only person who could decide the priority was the hospital superintendent. But Miss Hornsby-Smith assured members that a medical officer of health had the power and the responsibility to apply to the bed service to do all they could to find a bed for an acute case.

QUESTION TIME

Doctors Surcharge for N.H.S. Prescriptions

Mr. JAMES CARMICHAEL asked the Secretary of State for Scotland whether he was aware that doctors in Glasgow were having accounts submitted to them by the executive council for prescriptions issued to patients; who was responsible for this charge: and whether he realised that if this policy continued doctors would refuse to issue such prescriptions, with consequent suffering to patients, most of whom were suffering from tuberculosis.—Commander T. D. GALBRAITH replied: A doctor who writes a prescription under the National Health Service for a preparation that ranks as a food and not a drug is in breach of his terms of service, and is liable to repay to the executive council the cost of dispensing the prescription.

Mr. CARMICHAEL: I have evidence from doctors who have declared to the executive council that they gave the prescriptions as medicines.

Commander GALBRAITH: When selecting prescriptions which apparently relate to food the pricing bureau and the executive council are guided by advice from an expert committee, which is circulated to all doctors so that they know whether they are prescribing drugs or not.

Army Medical Services

Mr. FENNER BROCKWAY asked the Secretary of State for War what steps he was taking to ensure adequate supervision in the Army Medical Services.—Mr. ANTONY HEAD replied: Measures to improve the supply of experienced medical officers are under urgent consideration. The young National Service doctors have done a very good job and I would like to pay a tribute to them. I think the supervision is being carried out extremely well with the numbers available, though we are anxious to increase them.

Anthrax

Mr. A. C. BOSSOM asked the Minister of Agriculture whether he was aware that a great proportion of the cases of anthrax now occurring could be traced to imported feeding-stuffs which only had a certificate that they had been properly sterilised in their country of origin; if he would see that some more reliable arrangement was introduced to avoid continuance of this serious trouble; and if, in view of the fact that 73 outbreaks of anthrax were confirmed between Sept. 1 and 15, 96 from Sept. 16 to 30, and 52 from Oct. 1 to 9, he would call for an official investigation at the earliest possible moment as to the cause, so that a remedy might be devised.—Sir THOMAS DUGDALE replied: The requirement about the sterilisation of imported bones and bone products in their country of origin is confined to imports from Europe. The certificates that accompany such imports are signed on behalf of the government of the country of origin and I have no evidence that they are not reliable, or that imports received under these certificates have been a source of infection. My department is already conducting inquiries into the sources of infection of anthrax and the possibility of introducing further safeguards.

Crimes of Violence

In answer to a question Sir DAVID MAXWELL FYFE stated that the number of indictable offences involving violence to the person known to the police from January to June, 1952, and during the two preceding periods of six months was:

Offence	January–June, 1951	July–December, 1951	January–June, 1952
Murder	68	64	87
Attempts and threats to murder	97	75	93
Manslaughter, infanticide, child destruction	101	96	111
Felonious and malicious wounding	2608	2825	2788
Rape	180	155	147
Robbery with violence, &c. (section 23 (1) of the Larceny Act, 1916)	328	305	359
Robbery and assault with intent to rob (section 23 (2) and (3) of the Larceny Act, 1916)	101	66	116
	3573	3586	3701

Stomach Ulceration

Brigadier FRANK MEDLICOTT asked the Minister of Health if his attention had been drawn to the increase in the number of people suffering from stomach ulceration; and if he would make a statement as to what special researches were being undertaken to discover the reason for the increase.—Mr. MACLEOD replied: The evidence seems to be that the incidence of all forms of peptic ulcer has not increased recently and that of stomach ulceration is decreasing. Deaths from peptic ulceration have decreased in recent years. Research into causes and treatment is in progress in many centres.

Public Health

Coöperation in the Health Service

IN his presidential address to the 77th congress of the Royal Sanitary Association of Scotland on Oct. 21, Sir Andrew Davidson, chief medical officer of the Department of Health for Scotland, discussed some of the criticisms that have been made of the National Health Service. Apart from the cost of the service, he said, criticism tended to fasten on the tripartite administration of regional hospital boards, executive councils, and local authorities and on the overemphasis on the treatment services. He thought that the tripod structure arose from compromise rather than from tidiness of administration, and that the many appeals which had been for closer coöperation between the various bodies were not unreasonable.

But Sir Andrew's own view was that the particular need at the present time was for a proper understanding between individual workers—between the public-health staffs, hospital staffs, and general practitioners—and for more team-work and less isolationism. What is lacking, he said, is a clear understanding and appreciation of what the other fellow is trying to do. For example, domiciliary health care demands the coöperation of the family doctor and the public-health team, for social and medical needs are well-nigh inseparable. Many patients are admitted to hospital for social as well as medical reasons, or kept in hospital when they might be sent home if the home conditions were suitable, or made suitable. Expensive hospital treatment could then be reserved for people who need it from a strictly medical point of view.

In England Now

A Running Commentary by Peripatetic Correspondents

ONCE upon a time, for the advancement of Science, an experiment had to be performed on a pig.

A suitable pig was found at a neighbouring farm, and to ensure a quiet and peaceful passage to the laboratory it was thought that a draught of 'Bovril' laced with 'Nembutal' would prove suitable. A control draught of bovril was eagerly consumed by the pig; but it thought nothing of the mixture, and an impasse arose and the blandishments of scientists in white coats were of no avail.

The scene was watched with interest by a supposedly feeble-minded boy on loan from a local institution. Remarking "I'll show 'ee," he went to a manure heap and from it collected a boot, green with age. Borrowing a knife, he cut a small hole in the toe, advanced on the pig, and proceeded to belabour it on the snout with the boot. The pig resented this and seized the boot by the toe. The boy then relieved the chief scientist of his flask of bovril and barbitone and with the air of a conjuror poured it into the boot, whence it rapidly disappeared into the pig.

After a couple of fast turns round the stye, scattering the assembled scientists, who vaulted over the side with extraordinary agility, the pig lay down in a corner and sank into an untroubled sleep.

* * *

External examiners are often cynical men, who affect to be able to mark a candidate accurately from the first paragraph of his paper or from an inspection of his finger-nails. It is, however, clearly desirable that they should be versed in the theory and practice of examining in order that they may present a façade of judicious impartiality towards the candidate. The College of Medical Examiners and its affiliated body, the Chartered Society of Licensed Invigilators, have been founded to standardise the accomplishments of examiners in this respect. At present the college offers two diplomas: the membership enables its possessor to examine for the various qualifying degrees and diplomas, while the fellowship is necessary for examiners aspiring to higher things. It is intended shortly to institute a third diploma, that of tropical examining (D.T.E.), but the syllabus for this diploma has not yet been fully approved by the court.

The diploma of fellow is granted only for outstanding contributions to the science of examining, such as the raising of the failure-rate in the Conjoint to 80%, or the introduction of pin-striped trousers and a stand-up collar to a biochemistry viva.

The syllabus for the membership includes the theory of ambiguous questions, the elucidation of hieroglyphic writings and the Rorschach interpretation of ink blots, the effects of adrenaline on the speech centre, the use and abuse of sarcasm, and the care and retention of the mark sheet. Candidates are also required to undergo a practical and viva voce examination at which their reactions to bad spelling, dirty collars, and unshaven faces will be assessed. The following is a specimen paper:

COLLEGE OF MEDICAL EXAMINERS

PRIMARY EXAMINATION FOR THE DIPLOMA OF MEMBERSHIP

Human Anatomy

Time allowed: 3 hours. Not more than *six* questions to be attempted.

1. A candidate appears for his viva voce examination wearing spats. Outline the steps you would take to deal with the situation, giving your reasons.

2. Identify (*a*) the seraphic vein; (*b*) the abducter tubercal; (*c*) the vegetable pole; (*d*) the accessory do; (*e*) the antero-posterior surface of the ileum; (*f*) the uterine ossicles.

3. Enumerate the methods used to give the impression of immense knowledge frustrated by writer's cramp, other than the basic "Sorry, no time."

4. Illustrate the following situations by clearly labelled diagrams:

(*a*) "The bursar lying between the two joints is often fenestrated."

(*b*) "The kidney excretes the surplice."

5. Write a short essay on the ball-point pen.

6. What did the candidate have in mind when he wrote the following:

(*a*) "a capsular joint with an articulating capsule in the joint cavity."

(*b*) "these bones are concerned with maintaining body stature."

(*c*) "the uterus turns inside out and there you are."

* * *

May I confirm my fellow vintner's advice (Nov. 22) that bacteriological vintages should be allowed to mature. My own basic recipe is as follows:

Prepare a fermented sucrose broth by boiling 7 lb. of fruit or vegetable (even turnips will do) to a gallon of tap-water in an enamel breadbin. The water of evaporation is replaced, and sucrose (from the Food Ministry allocation for bees; 7 lb. per hive) added at the rate of 3 lb. to a gallon. This makes an approximately 30% solution, which, when fully fermented, gives a yield of 15% of alcohol. Deficiency of sugar, and therefore of alcohol content, encourages the contamination of the culture by an aerobic dishwater-producing organism, miscalled by the French *Fleur*, which floats on the surface of the mixture while it converts alcohol to water and CO_2. For removing suspended yeast cells, which give a cloudy appearance to a white wine, suction filtration through a Buchner funnel, or addition of gelatin solution which brings down the yeast when it precipitates, can be used. The usual protein precipitants are to be avoided.

For my first attempt I used a potato extract flavoured with orange juice (say, 6 to a gallon). At three months the orange flavour had vanished and had been replaced by pure pineapple (ethyl butyrate). A beaker of 100 ml. brought on in half an hour, in 100% of drinkers, a curious frontal headache, "right between the eyes." Control tap-water drinkers had no headache in 24 hours. In six months this toxic material had changed into a magnificent sauterne. The headaches were now normal in cranial distribution and did not show themselves until the morning after sampling, and then only if extensive trials were carried out. In a bad year for potato wine the product may be distilled into potato gin, after, of course, applying for an excise licence.

* * *

Ever since the age of 10, when I developed an enteric fever through eating, so my parents believed, polluted oysters in Brittany, I have been a passionate admirer of this fish, though rising costs have forced me to an increasingly platonic courtship.

Trial will show that the turbidity of an oyster's liquor is at once increased if a fork is inserted into the flesh, the assumption being that a severe wound causes evacuation of its alimentary tract. If this simple operation is performed and the liquor is not consumed, possibilities of infection should be lessened. I should add that the safety of British oysters is now such that this addition to the manuals on oystermanship will be chiefly valuable during travels abroad.

Letters to the Editor

HOSPITAL COSTS

SIR,—It seems to me that your leading article last week avoids a number of important issues arising from the reports of King Edward's Fund and the Nuffield Provincial Hospitals Trust. Apart from the two general recommendations—(1) to scrap the present system of accountancy, and (2) to install a system based on departments and services—there is little agreement between the two reports: for the methods of allocating and charging cost and sometimes the units to be used differ appreciably.

There is also disagreement between the Trust and the Fund on the immediate advantages of installing departmental costing systems. The Trust states that no dramatic economies can be effected because "there is no dramatic waste to be cured." The Fund states, on the other hand, that "handsome dividends in the way of economies and increased service may be secured by more effective control of expenditure." The conflict between these two statements points to a major weakness of the findings when taken jointly. If no great economy can be achieved, one must presume that the main reason for installing a uniform costing system would be its advantage to the "management"; and you yourself state there is "need to link executive and financial responsibility." It is not, however, clear how a uniform costing system will by itself have this effect in the hospital service. To a live management there is no mystery about the reasons for the present differences of cost between hospitals. To call for a comprehensive costing system to indicate these is like calling for a micrometer for measuring to the nearest foot. Nor can a costing system of itself, even if it forms part of a budgetary system, prevent hospital authorities scrambling to spend "balances in hand" and frittering money away on "short-term palliative maintenance work, pieces of equipment, furniture, and so on," before the end of the financial year. If this has been the case in the past, such authorities will not be prevented by a costing system from doing likewise again if tempted by underspending on their total approved expenditure.

The practicability of introducing that departmental or functional or standard costing has never been seriously doubted. The real problem is the value of the results in a milieu where the cost may be of secondary importance. It is difficult to avoid the conclusion that the enthusiasm of the Fund and Trust for their systems reflects the association of these bodies with the pre-1948 form of general administration of the voluntary hospitals, who were supplicants for grants. For better or worse there is now a new and unique form of administration where decisions are taken centrally by separate statutory bodies largely advised on hospital matters and local conditions by medical advisory committees. Local service may transcend purely monetary considerations; and the use of a big stick marked "costs" by the higher authorities might provoke local storms which would affect adversely the hitherto mainly successful, but admittedly loose, structure of the service.

There is at the moment no uniformity in hospital administration or medical organisation, and such uniformity is probably neither desirable nor even possible. In the circumstances it is doubtful whether the hospital service possesses the basic conditions for a uniform intricate system of costing of the sort that is no doubt necessary for an organisation whose policy is governed by the inescapable facts given in a balance-sheet and trading and profit-and-loss account.

This is not to deny the need for investigations locally into the "business" side of hospital administration; many anomalies in cost and comparative statistics call for investigation. It is, however, well to realise that there are limitations to the purely costing approach to analysis—and there may indeed be dangers if the final arbiter is a remote authority not concerned with day-to-day administration under local conditions.

Both the Fund and the Trust are too firmly rooted in the great tradition of social service to claim too much for costing in a public organisation dealing primarily with intangibles such as medical treatment and human needs. Yet their reports come perilously near to providing fuel for the extremists and ultimately for the centralist-minded.

In your leading article you refer to the dangers of uniformity, but dismiss the risk as slight compared with the apparent (sic) advantages. A special article in the *Times*,[1] welcoming these two costing investigations, said:

> "The Minister has in prospect through the development of departmental accounts in some of the hospitals, with the help of the King's Fund and the Nuffield Trust, a yard-stick which should enable him to say with considerable accuracy what the services provided by such and such a Regional Board ought to cost if they are efficiently managed."

If this is indeed the prospect, it implies eventual rationalisation with, inevitably, a measure of uniformity. This seems the only end that would justify at present the universal application of a full-scale comprehensive costing system.

London, S.W.6. GORDON MCLACHLAN.

THE UNIDENTIFIED DRUG

SIR,—Your annotation on Accidental Poisoning in Children (Nov. 22) draws attention to the difficulties in treatment if the nature and quantity of the poison are unknown. It is not generally realised, until the information is required in an emergency, that drugs supplied on the National Health Service prescription form E.C.10 lose their identity when they pass into the hands of the patient. In some instances, of course, a distinctive colour, shape, or smell may provide a clue to the identity of a drug; but without such a clue the rapid identification of the drug may be virtually impossible.

It is by no means rare for a supply of the offending drug to be sent with the patient admitted to hospital for suspected poisoning. The drug may be in a properly labelled container bearing the name and address of the pharmacist from whom it was obtained; but if the pharmacist is asked to identify the drug, he will be unable to do so unless he happens to remember what was dispensed for the patient in question. The pharmacist is required to record transactions of dangerous drugs, but with the N.H.S. prescriptions he is not required to keep a record of any other drug. At the end of each month the E.C.10 prescription forms (his only record) are sent in bulk to a pricing bureau.

The pricing bureau in due course, during working hours, may be able to trace a single prescription; but it is not empowered to disclose the nature of the drug without the authority of the local executive council. The unknown drug may thus be known, but not to those who need the vital information.

The Ministry of Health have been informed of this curious anomaly, and no doubt permission will be given to pricing bureaux to disclose information in such emergencies. But much more than this is required: E.C.10 forms should be issued in duplicate, like the N.H.I. prescription forms, so that a facsimile of every prescription would be retained by the pharmacist, for tracing and naming the unknown drug.

W. TRILLWOOD
Director of pharmaceutical services.

United Oxford Hospitals.

AGGLUTINATION TEST FOR RHEUMATOID ARTHRITIS

SIR,—In their article in your issue of Feb. 23 (p. 389) Dr. Hobson and Dr. Gorrill suggested that there is a close relation between the factor in normal serum responsible for the agglutination of sensitised red cells and the fourth component (C'4) of complement. Both are destroyed by ammonia and hydrazine, and both are increased in serum from patients with rheumatoid arthritis. However, Dr. Ball (March 22, p. 614) remarked that, provided the concentration of the ammonia is not too high, the C'4 can be destroyed, whereas the agglutinating factor remains unaffected.

We have found that the same holds good for hydrazine. We performed the reaction with human red cells (group O),[1] sensitised with rabbit amboceptor (half the minimum agglutinating dose). Using human cells has the advantage that absorption of heterophil antibody is unnecessary. Wager[2] has shown that sensitised human red cells can give positive agglutination with rheumatoid-arthritis serum, in the same way as sheep cells.

Adding 0·1 ml. of 0·16*M* solution of hydrazine to 1 ml. of serum[3] with a positive Waaler-Rose test and incubating the mixture for one hour at 37°C destroys the lytic activity, whereas the agglutinating activity of the serum is only slightly affected. It is remarkable that the influence of hydrazine on the agglutination reaction is seen only where the serum concentration, and consequently the hydrazine concentration, is greatest—in the tubes with serum-dilutions 1:4, 1:8, 1:16. In the higher dilutions of the serum the reaction is just as strong as in the control series without hydrazine. Consequently the titre of the serum is affected little or not at all. The first tubes show a somewhat weakened reaction when the serum is strongly positive; with low titres the reaction may become completely negative (see table I).

These results suggest that hydrazine may influence the sensitised red cells rather than the agglutinating factor of the serum. To verify this supposition, a negative serum of a healthy person was treated with hydrazine as described above. The Waaler-Rose test was carried out, and was, of course, negative. The cells from each tube were then centrifuged, washed, and again suspended in 0·5 ml. of saline. To each tube 0·5 ml. of a positive serum was added in a dilution which had previously produced a distinct reaction. In the tubes where the original serum concentration and consequently the hydrazine concentration had been greatest, the positive serum produced no agglutination, whereas in the originally higher dilutions positive reactions appeared (see table I).

TABLE I—AGGLUTINATION OF SENSITISED RED CELLS BY DIFFERENT DILUTIONS OF VARIOUS SERA

Serum dilutions	Agglutination of sensitised red cells						Red cells from experiment A resuspended in positive serum	Red cells from experiment B resuspended in positive serum
	Positive serum		Positive serum*		Negative serum			
	Treated with hydrazine	Untreated	Treated with hydrazine	Untreated	Treated with hydrazine (experiment A)	Untreated (experiment B)		
1 : 4	±	++	−	+	−	−	−	++
1 : 8	±	++	±?	+	−	−	−	++
1 : 16	±	+	±?	+	−	−	−?	++
1 : 32	±	±	±?	±?	−	−	±?	++
1 : 64	−	±	−	±?	−	−	±	++
1 : 128	−	−	−	−	−	−	±	++
1 : 256	−	−	−	−	−	−	+	++

*In this case the reaction was performed with sensitised sheep's red cells.

The next step was the investigation of sensitised red cells brought into contact with varying quantities of hydrazine. To tubes containing 7 ml. of a suspension of sensitised human group-O red cells 1·4, 0·7, 0·35, 0·14, 0·07, and 0·02 ml. of 0·16*M* hydrazine solution were added respectively. The tubes were incubated at 37°C for one hour. The cells in the first three tubes changed to a brown colour after a short time. The red cells were centrifuged, washed twice with saline, and added to a known-positive serum (see table II).

The sensitised human red cells pretreated with hydrazine in concentrations of 1·4, 0·7, and 0·35 ml. per 7 ml. were not agglutinated by a positive Waaler-Rose serum. As the concentration decreases, the effect of hydrazine on the red cell diminishes; and agglutination by the positive serum conforms more and more to the pattern visible in the untreated control.

TABLE II—AGGLUTINATION OF SENSITISED HUMAN RED CELLS TREATED WITH DECREASING AMOUNTS OF HYDRAZINE

Dilutions of positive serum	Agglutination of sensitised group-O red cells						
	Amount of hydrazine used (ml. of 0·16*M* solution per 7 ml. of cell suspension)						
	1·4	0·7	0·35	0·14	0·07	0·02	0
1 : 16	−	−	−?	+	++	+++	+++
1 : 32	−	−	−?	+	++	+++	+++
1 : 64	−	−	−	±?	±	+++	+++
1 : 128	−	−	−	−	−?	±?	++
1 : 256	−	−	−	−	−	−	±?
1 : 512	−	−	−	−	−	−	−

It seems probable therefore that the inhibition of agglutination by hydrazine in the Waaler-Rose test is due to an influence of this compound on the sensitised red cell.

No difference was observed in the action of guineapig-complement on untreated and hydrazine-treated sensitised red cells.

On the whole, therefore, it seems unlikely that the agglutinating factor in rheumatoid serum is identical with the fourth component of complement.

H. H. COHEN.

THE NOTIFICATION OF DISEASE

SIR,—In his article (Oct. 11) Dr. Irvine referred to the need for extending notification to include some non-infectious conditions. This is the one subject which few would deny that the medical officer of health can call his very own, and yet only one medical officer of health has written to comment on Dr. Irvine's views.

The problem of notification and prevention of disease is complicated by: (1) the difficulty of maintaining the local health authorities' interest in the prevention of disease without the stimulus of their bearing the cost of, or the satisfaction from, medical treatment; and (2) the hospital boards' inherent reluctance to be interested in prevention, which can only result in the reduction of professional and administrative empires. My only criticism, if that is the word, of Dr. Irvine's paper is that today the use of notification as an essential prelude to the control of disease should not be limited to immediate control in the form of direct action as practised by the health-department staff.

If the medical officer of health of the future is to be continuously aware of the state of the public health, he must be able to evaluate the medical, social, and economic problems of many diseases. He cannot do this without the figures. This work would not require an increase of the public-health staff, as immediate visits would not be made, but rather a study by the medical officer of health according to a well thought out plan and only giving results after some years.

In the case of cancer of the lung we are obviously in the early stages of an epidemic process of unknown duration; and, as with other diseases, the most suitable time to study cause is during an epidemic phase. As history shows, the causative factors can be postulated with some accuracy by epidemiological study, and some degree of control achieved without knowing the specific cause. There is a case for the notification of many conditions; but cancer of the lung is an urgent public-health problem, and if it were tackled in this way we would have the greatest chance of achieving some control.

BOVINE TUBERCULOSIS AND HUMAN TUBERCULOSIS

SIR,—In a letter which you published a year ago [1] I expressed the opinion that eradication of tuberculosis from cattle is leading to an increased incidence of pulmonary tuberculosis in man. In support of this opinion I presented figures showing that in Scottish counties where more than 50% of the dairy herds were attested (i.e., free from reaction to tuberculin in three successive tests) the incidence of pulmonary tuberculosis had risen. By contrast, in Scottish counties where less than 16·5% of the herds were attested the incidence had fallen.

In assessing this evidence I have now had the help of the Scientific Computing Service Ltd., who have related my figures to the populations of the counties during the relevant periods and have recast my tables as shown below. It should be noted that the Attested Cattle scheme began in 1936.

Commenting on the figures, the Scientific Computing Service point out that the notifications of pulmonary tuberculosis per 100,000 population after the introduction of the scheme were markedly higher in the counties where a large proportion of the dairy herds were attested: "the difference was found to be highly significant, as was the correlation coefficient (*r = 0·58 with 20 degrees* of freedom) between the percentage increase notifications and the percentage of attestation." They go on to say:

> "In the above results each county *has of necessity* been considered as an independent unit. This is only justified if the type of milk consumed in the counties considered is not greatly upset by the flow of milk between counties. However, unless this flow of milk is considerable—and even then its effects may cancel out—it is not likely to upset the above findings."

They add that "if the policy of attestation was accompanied by other measures which could affect the number of notifications of pulmonary tuberculosis—for example, a greater drive to detect tuberculosis in the high-attested than in the low-attested cattle counties—this itself could explain the trends in the Scottish figures." But they agree that, if their reservation and their alternative explanation can be ruled out, the data reproduced in the tables well support my thesis that the policy of attestation has actually led to an increase in pulmonary notifications.

L. PITCHER.

DENTAL TREATMENT OF CHILDREN

SIR,—Undoubtedly "wastage" does occur in the New Zealand school dental nurses scheme, since a proportion of dental nurses leave the service a few years after completing their training—*often before the cost* of that training has been justified. If we introduce dental ancillaries in this country and recruit mainly women for training, we may experience a similar economic loss. No-one can possibly say in advance, however, whether the degree of "wastage" would be as great as in New Zealand; and it could, in any case, be reduced by recruiting men as well as women for training.

This kind of economic loss is inevitable whenever women are trained for skilled work, and it applies to the training of women as dental surgeons with even greater force than to their employment as dental ancillaries. Women dentists usually retire upon marriage and the *loss to the community* is greater, since their training has been so much more expensive than would be that of an ancillary. Had Mr. Rosenstiel any experience of the very real problem of "wastage" of women dentists from the school service, for example, he might be less tempted to dismiss my argument as mere "shadow-boxing" (Nov. 29, p. 1083).

Mr. Rosenstiel contends that it is "an established fact that the high wastage factor in the New Zealand school dental nurses scheme nullifies the advantage of short training." *To whose satisfaction*, one wonders, has this "fact" been "established"? *If it had been established* to the satisfaction of public *opinion in* New Zealand, presumably the scheme would have been wound up long ago and some other method of solving the problem of children's dental health would have been tried in its place. In fact, of course, the dental nurses scheme there has been expanding continuously throughout its thirty years' existence, and it is hoped soon to extend its benefits to adolescents who have been cared for by the *dental nurses throughout* their school careers.

Evidently the New Zealanders have found they can only have a children's dental service worthy of the name when the dental profession is supplemented by ancillaries, and if this method entails a degree of "wastage" the price has to be paid for the sake of the nation's health.

There are twice as many qualified dentists in New Zealand, in proportion *to* the size of the population, as there are in this country, which gives some measure of the shortage of dentists from which we suffer. If the dental health of the United Kingdom is not much better

---

1. *Lancet*; 1951, ii, 786.

than that of the population of New Zealand (it is difficult to believe that it can be, after so many years of neglect), the dental profession here could be doubled in size and we should still need to supplement it with ancillaries to have a school dental service as comprehensive as that in New Zealand.

There are, of course, many real problems associated with the training and employment of dental ancillaries. If we, in this country, do not always feel that the solution reached in the New Zealand scheme best suits our own conditions, at least the experience gained there shows that the problems themselves are not insoluble.

SENIOR SCHOOL DENTAL OFFICER.

REACTION TO PROCAINE

SIR,—When using procaine in the treatment of muscular rheumatism there is always a lurking fear of procaine sensitivity, an extreme example of which was described by Dr. Penny (Nov. 1). This can be most alarming. Even if there is no immediate reaction, patients usually complain of an access of pain lasting several days before relief ensues. The investigation described below was originally started with a view to finding an effective substitute for procaine.

Treatment of muscular rheumatism by the injection of myalgic spots is entirely empirical since we do not yet know their pathology. On the assumption that a local ischæmic area might be the cause of pain, a minute amount of a vasodilator, 'Trafuril,' was injected and was found to act just as well as procaine. It seemed time to initiate a carefully controlled experiment. The first step was to establish the effect, if any, in a control series injected with physiological saline. To my surprise this seemed to have just as good an effect as either procaine or trafuril.

Dr. Harry Coke kindly provided me with a numbered series of ampoules containing either ½% procaine or physiological saline. From time to time as the ampoules were used and their effect recorded, the key to the series was consulted by an independent observer and the results in each case allocated. The observations were entirely objective, no notice whatever being taken of subjective response.

The technique was as follows:

The presence of a myalgic spot was assumed when on deep digital pressure the patient winced. After cleansing the skin the position was marked with ink and the syringe filled from a numbered ampoule. The needle of the syringe was touched with an indelible dye so that there could be no mistake as to the position of the puncture. At each puncture fresh dye was applied to the needle.

To find the myalgic spot the needle point was used as a probe. When the patient winced a fractional amount (0·1–0·2 ml.) of the fluid was pushed home. Usually further probing from the same spot disclosed one or two more tender points, which were treated likewise. On the record, however, injections through one point in the skin counted as one. The needle was then withdrawn. If the injections had been properly carried out, further pressure on the point of entry did not produce a wince. Other myalgic spots were then sought and treated in exactly the same way.

A week or a fortnight later the patient was seen again and pressure applied to the areas marked with the dye. If there was no wince on pressure at the spot or within 1 in., the result was class I. If a wince could be produced within 1 in. the result was class II. Where a wince occurred as before the injection, the result was class III. The figures were then transferred to their respective columns.

EFFECT IN 100 CASES WHERE MYALGIC SPOTS WERE INJECTED WITH PROCAINE OR SALINE OR WERE NEEDLED

—	Procaine	Saline	Needle alone
No. of cases	44	56	16
No. of myalgic spots	161	162	16
Class I	113	108	0
Class II	21	22	1
Class III	27	32	15

It soon became clear that sodium chloride and procaine were equally effective; so a further series of controls was desirable. 16 myalgic spots were "needled" without introducing any fluid. Here also the wince was abolished, but the effect was transient. All cases were class III, except 1 doubtful class II, when examined after a week. The results in 100 cases are shown in the accompanying table.

This experiment does not throw much light on the problem beyond establishing that the relief afforded by injections of procaine is not, as has been assumed, due to its anæsthetic property. Two advantages of injecting saline are the absence of any risk of sensitivity or of a local reaction with increased pain.

London, W.1. H. WARREN CROWE.

REVIEW OF MEDICAL ESTABLISHMENTS

SIR,—There are times when the most reticent of us are bound to be drawn into the correspondence columns. The letter which was penned by Sir Russell Brain (Nov. 22) is one such occasion. He is obviously correct in his righteous indignation, and few amongst your readers who have read the contents, and between the lines, will fail to be moved, as he undoubtedly is. What I find most interesting in his letter is his reference to the implied promise of security of tenure to consultants, &c.

Sir Russell is, of course, in a difficult position. Yet he cannot be absolved from all blame for the present consequences of the misdeeds of his immediate predecessors. A good deal of criticism went, and still goes, unheeded. Some of us maintain that the Joint Consultants and Specialists Committee represents only the colleges and a small party of interested members of the teaching schools. There must, however, be other members of the staffs of the teaching schools who, in the aloofness of their academic ivory towers, must now realise that they have been isolated. They, too, must bear their share of the burden of guilt.

The Terms and Conditions of Service were first turned down but within the short space of one week, and without reference to the periphery for their views, were accepted by the self-appointed spokesmen. I claim that in this area alone (western area of the South-west Metropolitan Region) was some attempt made at cohesive action to call a halt to this autocratic method. I warned my colleagues at that time that, if they did not make a stand over the terms of service, the whip of bureaucracy would one day hit them hard, and that their cries would go unheeded.

My prognostications appear to have been correct. Sir Russell must surely know that the committee of which he is chairman is not a joint body; there is no equitable representation of the consultants outside the teaching hospitals. He must also be aware that in the provinces resentment and frustration are widespread among consultants. He has a great opportunity now of infusing a new spirit of coöperation by the simple process of creating a more democratic representation on the so-called Joint Committee. I am satisfied that this is a necessary prerequisite for a successful outcome to any complaints, of which lack of "security of tenure" is only one.

Bournemouth. ARNOLD CLARK.

SIR,—The letter from Sir Russell Brain reveals a situation which is ominous for all those holders of posts in registrar grades who had hoped to become consultants. The Ministry's letter to boards of governors must bring to a standstill any plans for the expansion of the consultant service, and although not so directed the regional boards cannot fail to have observed the trend of ideas.

To the average senior registrar approaching the end of his four-year term it had recently become clear that his only real chance of a senior appointment lay in the expansion of the consultant service. When the North-west Metropolitan Regional Hospital Board found it possible to create some 40 new posts (as announced in the middle of this year) it seemed that the way was clear and that other regions might follow suit. The new posts were created to close the gap in the hospital service caused by the reduction in senior-registrar establishment and it seems to us that similar action is needed elsewhere. Now instead comes a standstill order, and to the naïve eye of a registrar it appears that the Ministry are alarmed by the initiative of the North-west Metropolitan Board and are taking steps to avoid the extension of their fair and far-sighted policy to other areas.

To the Registrars Group it has always appeared that the Ministry have either disclaimed responsibility for their problems or misjudged their size. At the present time the Joint Committee are in the middle of discussions with the Ministry, and one of their main points has been the need for expansion of the consultant service. This new instruction reveals either a cynical disregard for the Joint Committee—and those whom they represent—or else a major degree of incoördination between the departments which decide and the departments which discuss.

It is to be hoped that Sir Russell's views will have the widest possible support, and that employing authorities will not be deterred from making the additions to consultant staffs that will be needed when their senior registrars go. Registrars everywhere will support Sir Russell and the Joint Committee in their efforts to secure a fair solution to the registrar problem.

R. M. FORRESTER

Chairman, Registrars Group,
British Medical Association.

SEASONAL VARIATIONS OF ALCOHOLISM

SIR,—Such is the difficulty of assessing alcoholism in statistical terms that the yearly number of convictions for drunkenness has to serve as evidence. *Offences of Drunkenness, 1951*,[1] states that the number of offences proved was 51,932 in England and 1744 in Wales. The report also gives the number of offences by month; this is welcome since figures bearing on seasonal variations of alcoholism are hard to come by, although they abound for suicide.

In a previous communication,[2] discussing the monthly distribution of 9601 first admissions to institutions for the alcoholic in Zürich during 1912–44, it was shown that such admissions were most numerous in June and least numerous in October. Although admissions for alcoholism and convictions for drunkenness are not the same thing, it is tempting to compare their seasonal trends. This is done in the accompanying table. It shows that with the exception of October, November, and, notably, December, the seasonal trend is very similar. Offences of drunkenness were most numerous in July in England and in Wales; and least frequent in February in England, and in December in Wales. The fact that for the festival month of December offences of drunkenness rank second in number (England), while admissions for alcoholism rank sixth (Zürich), is interesting to speculate on.

COMPARISON, BY MONTHLY DISTRIBUTION, OF 9601 ADMISSIONS FOR ALCOHOLISM IN ZÜRICH DURING THE YEARS 1912–44 WITH 51,932 OFFENCES OF DRUNKENNESS IN ENGLAND AND 1744 IN WALES DURING THE YEAR 1951

Month	Admissions, 1912–44 (%)	Offences, 1951	
		England	Wales
January	8·8	7·0	6·6
February ..	8·6	*6·7*	7·4
March	9·5	8·2	7·3
April	8·1	7·6	8·7
May	8·7	8·6	9·7
June	**9·6**	8·9	9·3
July	8·1	**9·8**	**11·7**
August	7·6	9·1	10·9
September ..	7·4	8·4	8·4
October	*7·2*	9·0	8·3
November ..	8·2	7·6	6·1
December ..	8·2	9·2	*5·6*

The figures for the months with most admissions or offences are in bold type; those for the months with least admissions, &c., are in italics.

Despite their inherent smallness, the figures for Wales are given for comparison; with alcoholism, we have to take our figures where we find them. With minor exceptions the seasonal trend in Wales is similar to that in England. A pronounced discrepancy, however, is shown for the month of December. Whether this has reasons of its own, or is merely accidental (considering the relative smallness of the figures for Wales), cannot be answered here.

Isleworth, Middlesex. H. PULLAR-STRECKER.

SKIN LESIONS OF ACUTE LUPUS ERYTHEMATOSUS AND ACUTE X-RAY DERMATITIS

SIR,—Some workers, including Ungar and Warren,[1] have held that radiation lesions of the skin depend largely on changes in the underlying dermis. A similar view of the action of carcinogenic hydrocarbons on the epidermis was first advanced by Orr.[2] Devik[3] states that bombardment of the skin by alpha particles produces only slight damage to the epidermis of mice, even when extremely heavy doses are given, and that this is probably because the alpha particles do not reach the capillaries of the dermis.

While studying the development of acute skin lesions in mice exposed to a single focal dose of 3000 or 4000r of 60 kV X rays, it was noticed that the histological changes in the radiated skin closely resembled those accepted as being characteristic of the skin lesions of acute lupus erythematosus. The published descriptions of the histology of acute X-ray dermatitis in man provide a similar correlation of the skin changes in the two conditions. In addition to purely histological resemblances, certain similarities also exist in the behaviour of the lesions. The various features of resemblance that may occur in the course of the two conditions may be summarised as follows:

EPIDERMAL CHANGES

(1) Hyperkeratosis with hyperkeratotic plugging of follicles.

(2) Atrophy of epidermis with vacuolation degeneration of basal cell layer. Formation of intra-epidermal and sub-epidermal vesicles. Degeneration of basal appendages and follicles, with depilation.

(3) Pigmentation of epidermis.

DERMAL CHANGES

(1) Swelling, fragmentation, and fibrinoid degeneration of collagen fibres. Metachromatic staining of ground substance.

(2) Destruction of elastic tissue in areas of severe reaction.

(3) Nuclear pyknosis and degeneration of fibroblasts.

(4) Inflammatory cellular infiltration of slight degree in proportion to degeneration of tissue involved.

(5) Intense hyperæmia and telangiectasia of small vessels; fibrinoid degeneration of arteriolar walls has been described in the skin in lupus erythematosus, and may also occasionally be observed in X-ray lesions.

SIMILARITIES IN BEHAVIOUR OF LESIONS

(1) Exacerbation by sunlight.

(2) Lesions of acute lupus erythematosus are suppressed by cortisone. Acute X-ray dermatitis may be similarly suppressed.[4]

---

1. Ungar, J. jun., Warren, S. *Arch. Path.* 1937, 23, 299.
2. Orr, J. W. *J. Path. Bact.* 1938, 46, 495.
3. Devik, F. *Acta radiol., Stockh.* 1951, 35, 119.
4. Marshall, A. H. E. 1952 (in the press).

(3) Malignant change is rare or unknown following acute upus erythematosus, and is very rare following a single acute -ray lesion. In the chronic skin lesions of the two conditions, owever, malignant change may take place.

Some of the changes given above are also seen in nimals in the early skin reaction following painting with arcinogenic hydrocarbons.

It is clear that caution is needed in the interpretation f these similarities. No single change given above is athognomonic of lupus erythematosus or of acute X-ray dermatitis. As Klemperer[5] points out, fibrinoid ecrosis of collagen is not peculiar to the group f "collagen" diseases, or to the lesions of hypersensitive tates, but may be produced by various agents, including imple mechanical trauma. The same lack of specificity might be adduced against the action of cortisone in the wo conditions. The existence, however, of a correlation etween some of the separate lesions and characteristics f the two conditions suggests the possibility of a basic imilarity of the pathological processes involved. In this onnection it is possible that lupus erythematosus is ot the only "collagen" disease affecting the skin that esembles radiation lesions, since the pathological changes n scleroderma may possess a considerable resemblance o those of the rare "post-radiation sclerosis."

Any similarity between the pathological processes in acute lupus erythematosus and X-ray lesions probably consists in the infliction of a similar type of damage on the collagen and ground substance of the dermis, although the agents by which the damage is produced in the two conditions may be quite unrelated. This hypothesis implies that the acute degenerative change in the cells of the epidermis, and possibly in other elements of the dermis, following exposure to X rays is mainly secondary to the primary collagen lesion, a view accepted by some workers in the case of the similar changes in acute lupus erythematosus. Whether such a concept of radiation damage could apply to other tissues than the skin requires further investigation, but clearly does not exclude the occurrence of direct cellular damage in such sensitive tissues as the bone-marrow and germinal epithelium.

In view of the commonly accepted concept of radio-equivalence between chemical carcinogens and ionising radiation, such a theory of radiation damage might also be applicable to experimental skin carcinogenesis.

A. H. E. MARSHALL.

INTUSSUSCEPTION DUE TO ECTOPIC PANCREATIC TISSUE

SIR,—Mr. Kitchin's account (Nov. 15) of an intussusception in a 6-year-old girl caused by ectopic pancreatic tissue at the site where a Meckel's diverticulum is usually found is extremely interesting but by no means unique.

Pancreatic tissue may in fact be found in a Meckel's diverticulum,[6] and no less than 14 examples of this had been reported by 1934.[7] As long ago as 1904 Bize[8] operated on a girl, also 6 years old, and found an intussusception caused by a diverticulum containing pancreatic tissue. He suggested that the diverticulum was not of the Meckel's type but due to traction by the tumour.

The clinical history in Mr. Kitchin's case is typical of that in cases of an intussusception which starts by invagination of a Meckel's diverticulum—a history clearly described by Harkins.[9] This can be distinguished from the common variety of intussusception because it occurs in older patients, a history of previous attacks is common, the course is milder until the major illness, vomiting is more intense, and if a mass is palpable at all it is more apt to be on the right side.

Mr. Kitchin is to be congratulated on his excellent result in a frequently lethal condition.

King's College Hospital,
London, S.E.5.

SELWYN TAYLOR.

ANÆSTHESIA FOR TONSILLECTOMY IN CHILDREN

SIR,—There must be few anæsthetists of experience who would not support Dr. Bullough in his plea (Nov. 22) for consideration for the feelings of children who are to undergo tonsillectomy or, for that matter, any other operation. Many, however, will question the wisdom of taking to the operating-theatre a child fortified only by atropine.

Both methods described by Dr. Bullough are undoubtedly less unpleasant than induction with ethyl chloride. I use one or other of them myself to anæsthetise conscious children. This is rarely necessary, because for the past six years I have employed rectal premedication —formerly with paraldehyde but now with thiopentone. Both have been satisfactory; but thiopentone, being given in smaller bulk, is the easier to administer. Subsequently anæsthesia is induced with nitrous oxide, oxygen, and ether, in much the same way as Dr. Bullough describes. The only disadvantage I have encountered is that now and again the child parts with some of the drug. When this happens the child is not unconscious, but is nearly always so sleepy that he is very easily anæsthetised and remembers little or nothing of the proceedings. Even should the whole dose be returned the position is no worse than that when Dr. Bullough's routine is followed.

Dr. Bullough states that the child's only recollection of his visit to the theatre is the prick of a needle. I find it hard to believe that this is so; and surely children do not often accept the prick of the needle so willingly as Dr. Bullough suggests. Would it not be even better if the child were to have no recollection at all of his visit?

Sutton, Surrey.

JOHN H. WILLIS.

SIR,—Dr. Bullough is to be congratulated on his excellent article on intravenous thiopentone for the induction of anæsthesia for tonsillectomy in children.

I have been using intravenous thiopentone for induction of anæsthesia in children where there has been no premedication other than atropine, with so far no untoward results, in a variety of cases. I have never used an amount greater than that required to produce unconsciousness. I have usually given a $2^1/_2$% solution to children aged 4–6.

The terror which induction of anæsthesia can produce in fully conscious children is illustrated by the following case.

> An Army officer, aged 23, subsequently decorated for gallantry in the field, refused to have an anæsthetic for removal of two ingrowing toenails. He was warned that it was a painful procedure, but insisted that it was preferable to losing consciousness. He retained vivid and terrifying recollections of induction of anæsthesia ten years previously. He insisted that severe pain was preferable to what he described as "that ghastly feeling of suffocation."

Wokingham, Berkshire.

MARGARET JOAD.

SIR,—I have been using the technique described by Dr. Bullough since early 1949. During this period some 500 cases, in patients aged 3–12, have been covered, in association with five different surgical colleagues.

True laryngospasm has not been encountered. I have not noticed that this method has much effect on operative bleeding, which seems to vary a good deal between one operator and another. Most of the children have been surprisingly coöperative; and postoperatively

the tendency to "climb the wall," as with medium-acting preoperative barbiturates, is absent—an important consideration with present-day shortage of nurses.

I can strongly recommend the technique.

Maidstone. A. W. H. Ashbery.

CAUSE AND TREATMENT OF LEG ULCERS

Sir,—Dr. Anning's interesting article (Oct. 25) on the ætiology of "varicose" ulceration has caused the usual divergence of opinion regarding this all too common complaint. There are those who are blaming the superficial venous system and those who lay the onus on blockages and valvular defects of the deep veins of the leg.

As a contribution to this argument I would like to suggest that the majority of ulcers have not one but many antecedent causes. Incompetence of the valves and varicosities of the superficial venous system are usually present in association with deep vein damage. In addition, superadded factors are often present—to quote but a few, fungoid infection, lymphatic obstruction, obesity, or anæmia. When considering treatment all these factors must be remembered and the appropriate therapy applied to each and every one of them.

London, W.1. R. Rowden Foote.

ADRENOCORTICOTROPIC ACTIVITY AND DIABETES IN ACROMEGALY

Sir,—In a leading article[1] you mentioned, that in animals A.C.T.H. potentiates the diabetogenic action of the growth hormone. In man overproduction of the growth hormone alone does not produce diabetes. Coggeshall and Root,[2] in a follow-up of 153 cases of acromegaly, found that the incidence of glycosuria was 36% and of diabetes only 17%. The majority of acromegalic patients do not have diabetes, even in the active phase of the disease.

Last year we studied in 8 acromegalic patients and in 2 patients with gigantism the adrenocorticotropic activity in relation to the carbohydrate metabolism. We found that of the 10 patients, who were examined by the modified Thorn test,[3] 7 showed diminished adrenocorticotropic activity. These 7 patients with a negative eosinopenic response had a normal or low sugar-tolerance curve, while the 2 acromegalic patients with a normal Thorn test were diabetic. In the 3rd acromegalic patient with diabetes the test was not performed, because the illness was severe. This case eventually came to necropsy where we found, in addition to a greatly enlarged hypophysis (4·1 g), enlarged adrenal glands. The adrenals weighed 18·7 + 14·5 = 33·2 g.; and histologically they showed mainly hyperplasia of the zona fasciculata.

In our series overproduction of the growth hormone gave rise to glycosuria only in the cases where production of A.C.T.H. was unimpaired. Overaction of the growth-hormone-producing cells may suppress production of A.C.T.H. either directly or indirectly by pressure of the eosinophilic adenoma on the hypothalamus. The variable course of the diabetes in acromegalic patients may be connected with changes in the influence of the eosinophilic adenoma on the production of A.C.T.H. Daughaday et al.[4] determined the urinary excretion of the free corticosteroids and 17-ketosteroids of an acromegalic patient with diabetes. The excretion of these substances —which reflects also the functional activity of the adrenal cortex—increased with the severity of the diabetes, while during remissions it decreased to a subnormal value.

The findings of Reid[5] and Engel et al.[6] in animals corroborate our hypothesis that in man overproduction of growth hormone produces diabetes only where production of A.C.T.H. is not suppressed. According to our findings, in most cases of acromegaly production of A.C.T.H. is decreased; and this may be one reason why not every patient with acromegaly or gigantism is diabetic.

PITUITARY GROWTH HORMONE

Sir,—I read with interest the article by Dr. Black and his colleagues.[7]

From experience of pituitary transplantation in a large number of cases[8] we have invented 'Proserin' (transplantation injection of pituitary gland). The effect of two injections of proserin 6–8 mg. per kg. body-weight persists for about five months. In adults one injection of 40 mg. suffices to cure alopecia areata.

I think that Wilhelmi's growth hormone[9] is too weak to promote growth in man. Daily administration of 60–100 mg. is a very large dosage compared with that of proserin. We have had no case of hypo-insulinism with treatment by proserin in our very small dosage. The growth-promoting mechanism cannot be explained by a pure chemical substance. Only the operation of many factors will set this mechanism in action. This is the reason why a pure hormone has to be given in much larger doses than a complex preparation.

Syuzô Naka.

DOWNWARD TREND IN BREAST-CANCER MORTALITY?

Sir,—The letter from Professor McKinnon last week attacks me by name in nearly every paragraph, and so perhaps some reply is due.

Who would think, reading his letter, that my lecture was concerned with the many reasons other than improved treatment which influence individual hospital survival-rates, the facile belief that any improvement noted must be due to the particular treatment method adopted, and the fact that the prognosis depends more on the nature of the tumour than on any other factor?

In the course of this lecture on the general subject of progress in the treatment of breast cancer,[10] I said that there were a number of reasons why there has been no great fall in the general mortality-rate from this disease. I concluded this section by remarking that, nevertheless, if you take the Registrar-General's figures for breast-cancer deaths and make corrections "both for the growth of the population and its increasingly adverse age composition a slight downward trend in mortality-rate for England and Wales appears." This is a fact; these figures are the Registrar-General's; this trend is there, and it has a greater negative slope than can readily be accounted for by chance. I did not then say what I thought it might be due to. My colleagues and I[11] had, however, previously offered some possible explanations, such as a decrease in incidence, greater accuracy in death certification, earlier treatment, or more efficient treatment, all of which Dr. McKinnon rejects in favour of

the explanation that it only represents a trend confined to older people which is itself artificial.

Dr. McKinnon's explanation may well be correct, but it is based on an unexplained artificiality, and has been frequently maintained with a heat out of all proportion to its importance since general mortality-rates cannot be sound indicators of the value of treatment for small groups of patients in hospitals. My lecture dealt with this and even gave seven different reasons why results may have improved in special hospitals, only two of which had anything to do with treatment. Ultimately we may look for improvement in results of treatment for patients with breast cancer in national mortality statistics, but first that improvement must be sufficient to show itself through the general nation-wide mortality, stand out from variations in morbidity and in the "book-keeping" troubles of which Dr. McKinnon makes so much, and be accepted by doctors to the extent that they are more ready than at present to write other causes of death on certificates for patients who have once been treated for this disease. In the meantime we should not be unduly worried by the fact that Dr. McKinnon is not prepared to believe that any improvement has taken place until this stage is reached, and should continue to expect attack if we remark on the downward trend in the age-standardised mortality from breast cancer even when we do not give it prominence or attach much importance to it.

Dr. McKinnon's argument is that since the downward trend in death certification from breast cancer is only to be found at present in older people where the rates are more subject to error, this is not good evidence that treatment has lowered mortality. I did not say in my lecture that it was. In fact I have said before that the difficulties with death certification are greatest in the old and that this may explain the fall. It is not more difficult to diagnose breast cancer in the old; in fact generally the older the patient the easier the diagnosis. What is difficult, particularly in the old, is to decide whether to certify death as due to breast cancer or to some other cause when a person dies who has once been treated for breast cancer. The tendency is to give preference to cancer whenever there is doubt, even in some patients who have been treated many years before and lived their normal span of life. The Registrar-General's office added to this difficulty up to 1940 by altering the certified cause of death to cancer in some cases where this was mentioned as a subsidiary cause. Since 1940 they have accepted the doctor's certificate. Three-quarters of Dr. McKinnon's letter, in fact, is concerned with the refutation of an implication I did not make, presumably because he feared that someone else may take the fact I stated to be evidence against a belief he holds.

It does not help us to understand this problem or to improve the lot of our patients when someone takes the attitude of a knight with sword in hand defending the castle of cancer from all those who believe that it may be attacked by education and earlier and better treatment.

The last part of Dr. McKinnon's letter deals specifically with his inability to find evidence that early diagnosis in breast cancer makes any difference to length of life. He might look at table 26 in an article by my colleagues and myself[2]; explain why we call the disease "cancer of the breast" if it does not start there and then spread elsewhere; tell us why it is not more important to be quick about a patient with a tumour which tends to spread early than about one which tends to spread later; account for the fact that the Royal Cancer Hospital 10-year survival-rate for patients with grade-2 breast tumours with a history of less than 3 months is 38·6%* and with a history of more than 9 months only 16·2%†; and, in fact, generally let us know why, because he cannot find figures which he is prepared to regard as "clear-cut and conclusive," he should keep insisting that what clinicians have found from practical experience, concluded from the evidence of their own observations and established from their study of the natural history of the disease, is nonsense.

Royal Cancer Hospital,
London.

R.M.B.F. CHRISTMAS GIFTS FUND

SIR,—The distribution of Christmas gifts will be made in a few days. I ask your readers who have not yet responded to the President's appeal to forward their contributions as soon as possible to the Royal Medical Benevolent Fund, 1, Balliol House, Manor Fields, Putney, London, S.W.15, marked "Christmas Gifts."

I hope there will be a very generous response to this reminder.

F. A. JULER
Hon. Treasurer.

Obituary

FRANK HARWOOD JACOB

M.D. Lond., F.R.C.P.

Dr. Jacob died on Nov. 25 at his home in Malvern, where he had lived since his retirement from the staff of the Nottingham General Hospital in 1937. He was 80 years of age.

He qualified in 1895 from King's College Hospital where he had held in turn the Warneford, Sambrooke, Rabbeth, and Clothworkers scholarships. After holding house-appointments at King's, in 1898 he obtained his M.B. degree and he took up a resident appointment at Nottingham General Hospital in the same year. Three years later he was appointed to the staff of the hospital as assistant physician, becoming physician in 1905. He also joined the staff of the Nottingham Children's Hospital. Dr. Jacob was twice president of the Nottingham Medico-Chirurgical Society, and in 1921 he was elected F.R.C.P. After his retirement from the staff of the Nottingham General Hospital a ward was named after him in appreciation of his services. His *History of the General Hospital, Nottingham* appeared in 1951.

Of his years of busy and useful retirement R. and W. H. McM. write:

"Frank Jacob retired to West Malvern in company with a brother and two sisters, also unmarried. They chose a house high up on the hillside with an unrivalled panoramic view of the Herefordshire landscape and of the Welsh mountains beyond. In a downstairs room he unpacked his books and spread his papers. His knee-hole desk was placed in the bay window, so that whilst at work he could enjoy the hills and the changing skies in the west. The walls and table-tops of his library were peopled with photographs and memorabilia of Nottingham, and ere long a growing pile of manuscripts told of his interest in the medical lore of that city.

"He loved the countryside, especially the remote hamlets and churches which he and his brother explored together. Then there were the birds: he knew them individually by song and antics. Jacob was often to be found in the garden clad in a shaggy Harris-tweed jacket, navy-blue roll-top pullover, aged grey trousers and a battered turned-down felt hat: round his neck hung the much-used field-glasses, at hand his staff and a generous supply of apples, and on his knees the poems of Alfred Noyes. He was tallish with fresh colouring, a twinkling grey eye, ruffled sandy-grey hair and moustache, and a soft musical voice. 'Halloaloalo' was his usual greeting. With his slight limp he would advance to meet you, always friendly if a little shy.

"When war broke out Jacob insisted on working again. He assisted the local doctors and his help was always in demand. On these occasions he seldom completely abandoned his informal country attire although he was punctilious in wearing a jacket with intact elbows. One would see him standing at the door of a surgery talking to a patient leaning on his great staff which he was seldom without. At clinical meetings in Worcester, which he always found time to attend, or when his opinion at the bedside, always given so generously, was sought he was more formally dressed. Many a problem did he modestly succeed in solving with his years of accumulated wisdom.

"After the war he felt free to retire once more, and he resumed in earnest the task of writing the history of the Nottingham General Hospital. His library took on a less orderly and busier aspect. On summer days he withdrew with his papers to a sheltered summer-house in an overgrown pleasance adjoining a wood."

HAROLD EDWARD RIDEWOOD

M.D., M.S. Lond., F.R.C.S.

FIFTY years ago Ridewood qualified at the London Hospital, and during his years as a resident and as surgical registrar he made a good and lasting impression on his colleagues both as a man and as a surgeon.

He was born at Enfield in 1878, the son of the headmaster of Enfield Grammar School. He took the London M.D. in 1904, and the B.S. and M.S. in 1906 and 1909 (both with gold medal); and he also took the F.R.C.S. in 1906. He seemed to be destined for the surgical staff, and it was a great loss to the "London" when in 1910 he left England and found scope for his surgical talent in Canada, starting in Victoria, British Columbia. During the first world war he served in the C.A.M.C. as lieut.-colonel, working at Cliveden, Mudros, and Wimereux, and later with No. 1 Canadian Casualty Clearing Station, and as a surgical consultant. After the war he returned to Victoria where he steadily acquired a large and varied practice, and his comprehensive hospital experience in both medicine and surgery came to full fruition. That was a time and place where a surgeon had also to be a physician and a master of his craft so as to be able to undertake general surgery in the fullest sense. Ridewood by his gifts and by his experience was the very man and he did not spare himself. He had great dexterity and speed as a surgeon, as his former colleagues at the London knew well; and behind it all was an energetic and manly spirit with a rare judgment. It was no wonder that he acquired and maintained a great reputation throughout Western Canada as a great surgeon, and became a highly valued and beneficent member of a wide community.

Ridewood was a small lithe figure, energetic but not restless, eager not only to learn but to apply his knowledge. One felt that he was proud and thrilled by his work and purpose, and it was a service to others—for he was not self-seeking. His enthusiasm was contagious. Among his colleagues and friends he was lively and cheerful; and the same qualities were carried to his patients, inspiring them also with confidence and affection. His life work as a surgeon was a pattern which has seldom been woven so beautifully and to such good purpose.

He married in 1919 and had one son and three daughters. His home life was successful and happy, and his character and achievements were proudly felt in his own home. He returned to England to seek relief from the malignant disease from which he died in London on Nov. 8.

J. P.

ARNOLD LOEWENSTEIN

M.D. Prague

Prof. Arnold Loewenstein, who died in Glasgow in October, was born in Carlsbad. He took his M.D. in 1906 at Prague, where he became assistant in the eye clinic and later professor extra-ordinarius. A few months before the outbreak of the late war he came to this country as an exile and was given shelter in the Tennent Institute of Ophthalmology in the University of Glasgow. There he worked happily for the rest of his life and added to his world-wide reputation for devotion to his chosen specialty. Outside his work he had many interests and he was devoted to the mountains and scenery of Scotland. He wrote with confidence upon a wide range of topics based upon his exceptional experience. Until the end he maintained an active correspondence with many workers in many lands. His death is a great loss to European ophthalmology and international friendship.

W. J. B. R.

Notes and News

A CHRISTMAS-CARD CAROL

Piping voices in the porch,
Christmas greetings on the mat
(Evidences of the restive
Human spirit feeling festive),
Help to foster those digestive
Pleasures we are aiming at.

Life in Labrador is tough,
Weather searching, people poor.
If your friends are fond of seeing
Skating, sledges, huskies, skiing,
Bears and seals and Christmas-treeing,
Send them cards from Labrador.[1]

A graver card: N.A.M.H.
Gives health of mind the pride of place.
For troubled minds, distorted feeling,
Familiar world estranged and wheeling
A child and donkey, sure of healing,
Make a pilgrimage of grace.[2]

Creatures that on earth do dwell—
Fur and feather, fin and wing,
Lions, leopards, conies, asses,
Reindeer, moles (and all Fougasse's!)—
For friends of these unvocal masses
UFAW has the very thing.[3]

Children also have their charm:
And some, alas, are evil-starred.
In tundras snowy, tropics reedy,
Blue of eye, or black and beady,
Sixty million still are needy.
UNICEF provides the card.[4]

PAIN IN THE BACK

IN the course of his Gilbert Scott lecture at the Charterhouse Rheumatism Clinic, London, on Nov. 20, Sir Adolphe Abrahams spoke of difficulties in diagnosis. Pain in the back ("the worst of all diagnostic terrors"), he said, "may be due to a lot of local conditions, such as postural strain, hypertrophic arthritis, a protruded disc, spondylitis, spondylolisthesis, some forms of fibrositis; but it may also be due to various infections—tuberculosis, brucellosis, typhoid—or it may be due to malignant disease of the spine, primary or metastatic. It may also be due to visceral disease. One sees middorsal pain in cancer of the œsophagus; one sees pain in the back as well as the abdomen with cholecystitis, sometimes severe pain over the right inferior angle of the scapula in the absence of epigastric pain. One sees it in that very elusive condition, diaphragmatic hernia; and one sees it of course in perforated gastric ulcer; and one sees severe backache in cancer of the pancreas. One sees it in diverticulitis, and above all (perhaps one of the worst terrors) one sees it in cancer of the prostate, which I am informed accounts for 5% of deaths in men above the age of 50, and when very often there is nothing whatever to suggest disease of the prostate, not even nocturia."

LIFE STORY

EVERY elderly doctor has a story to tell, and between the wars medical autobiography enjoyed a great vogue. In a style conversational and somewhat staccato, Dr. Nicoll[5] tells the story of a Scottish minister's son, educated at George Watson's, who graduated in medicine at Edinburgh. If he errs a little on the side of prolixity, he writes with engaging frankness and sincerity, and his book is full of the joy of living. Especially attractive is the account of his life and work in the Highlands. Of the illness that compelled an early retirement he writes with courage and cheerfulness; of

his religious beliefs and experiences with deep conviction. Doctors and those who like them will enjoy the tale. Particularly should it commend itself to those north of the Tweed.

INFORMATION SOUGHT

ON Nov. 13 the body of Patricia Curran, aged 19, was ound in the grounds of her home at Whiteabbey, Belfast. She had received a number of stab wounds.

The police inform us that they wish to interview a man born about 922, 6 ft. in height, of thin build, with sharp features and a noticeable *old* scar on the left side of his face, running from the eye to the mouth. The scar is said to pucker up the mouth a little and pull the eft eye slightly. Information may be given to Superintendent Capstick, c/o Inspectors General Office, R.U.C., Waring Street, Belfast (tel. Belfast 25421) or to Detective Sergeant Tebbell of New Scotland Yard (tel. Whitehall 1212, ext. 253).

University of Oxford

On Nov. 22 the following degrees were conferred:

D.M.—P. M. Peters, G. L. L. Reynolds, G. D. Walker, R. A. B. Drury.

University of Cambridge

Mr. S. Storey, M.P., has informed the university that the trustees of his settlement for charity will, over the next six years, provide £17,780 for research in the department of medicine on leukæmia and allied diseases. The benefaction is to be known as the Elisabeth Storey fund.

Royal College of Physicians of London

Dr. Maurice Davidson will deliver the FitzPatrick lectures at the college, Pall Mall East, S.W.1, on Tuesday and Thursday, Dec. 9 and 11, at 5 P.M. The subject of the lectures is Medicine in Oxford, a Historical Romance.

Royal College of Obstetricians and Gynæcologists

At a meeting of council held on Nov. 29, with Mr. Arthur Gemmell, the president, in the chair, Prof. Lutherus Johannes te Groen of Pretoria University was elected to the fellowship. Diaa Seif-Eldin was admitted to the membership.

Dr. Henry Roberts and Dr. James Walker were appointed William Blair-Bell lecturers for 1953.

Royal Medico-Psychological Association

At recent examinations for the D.P.M. the following were successful in part II:

D. S. G. M. Bailey, D. R. Moore, D. G. D. T. Smedberg, W. L. Walker.

A Course for Teachers

The Postgraduate Medical School of London is holding a conference-course on teaching on Jan. 9 and 10. A series of demonstrations by young teachers to a small group of undergraduate students, ranging from beginners to those about to sit their examinations, will form the basis of discussions on technique. Dr. John Burton, director of the Central Council for Health Education, and Miss M. L. Johnson, research associate in the anatomy department, University College, London, will open a discussion on group methods of instruction. Other speakers will include Prof. G. Payling Wright (Teaching and Learning), Dr. Keith Simpson (Museums in Teaching), and Prof. Max Rosenheim (Introduction to Research). Further particulars may be had from the dean of the school, Ducane Road, W.12.

Cortisone Produced in Britain

Dr. Ripley Oddie, medical director of Bayer Products Ltd., gave a luncheon in London last week to celebrate his company's synthesis of cortisone acetate (see *Lancet*, Nov. 15, 1952, p. 992). He explained that, using at present an intermediate product imported from the United States, rather more than the final third of the stages of synthesis were carried out in the English laboratories. He hoped that the amount of cortisone produced would by next March be about a third of what was now used in this country, and by next August more than the present total. Sir Henry Cohen said that in therapeutics cortisone had been variously assessed as the elixir vitæ and as a glorified aspirin; but unquestionably it was a valuable research tool. The history of endocrinology in recent years had shown the importance of different kinds of worker coming together, and for such coöperation or symbiosis medicine provided an appropriate milieu.

The guests included Sir Robert Robinson, F.R.S., Sir John Charles, Sir John Taylor, Mr. Geoffrey Keynes, Mr. Tudor Thomas, Sir Horace Evans, Prof. E. C. Dodds, F.R.S., and Mr. Eric Miller, assistant chemist of Bayer Products, who was responsible for the synthesis.

London Hospital Medical Society

On Monday, Dec. 8, at 5 P.M., at the London Hospital E.1, Prof. J. F. Brock, of Cape Town, will speak to this society on Kwashiorkor. Professor Brock has been carrying out an investigation on this disease for the World Health Organisation (see *Lancet*, Nov. 29, 1952, p. 1070).

International Neurological Congress

The fifth International Neurological Congress will be held in Lisbon from Sept. 7 to 12, 1953, under the presidency of Prof. Antonio Flores. The programme will include discussions on Vascular Diseases of the Brain, in which Prof. P. C. P. Cloake and Prof. Norman Dott will speak: on the Parietal Lobe, in which Dr. Macdonald Critchley and Dr. D. E. Denny-Brown will speak; and on Metabolic Diseases of the Brain, in which Sir Russell Brain will speak. Information may be had from Dr. F. M. R. Walshe, F.R.S., 11, Wimpole Street, London, W.1, or from the secretary-general of the congress, Prof. Almeida Lima, 53, Avenida do Brasil, Lisbon, Portugal.

Medical Art Society

The next meeting of this society will be held on Wednesday, Dec. 10, at 8 P.M., at 11, Chandos Street, London, W.1, when Mr. David Birch will discuss members' work.

French Appointment

Dr. Frank Falkner, who is at present research medical officer to the Institute of Child Health, London, has been appointed research fellow and director of growth studies to the Centre Internationale De L'Enfance, Paris.

CORRIGENDUM: The title of the report by the Nuffield Provincial Hospitals Trust mentioned in our leader on Hospital Costs last week was, of course, An Experiment in Hospital *Costing*.

EMERGENCY BED SERVICE.—In the week ended last Monday, applications for general acute cases numbered 1335. The proportion admitted was 88·53%.

Sir Andrew Davidson, chief medical officer of the Department of Health for Scotland, has been elected an honorary fellow of the American Public Health Association.

Births, Marriages, and Deaths

BIRTHS

BRYCE-SMITH.—On Nov. 9, at Cleveland, Ohio, to Peggy (née Adams), wife of Dr. Roger Bryce-Smith—a daughter.

FLEMING.—On Nov. 23, to Yvonne (née Foden), wife of Dr. J. A. C. Fleming—a daughter.

GIBSON.—On Nov. 21, at the Lambeth Hospital, London, to Sarah (née Wells), wife of Dr. Michael Gibson—a son.

HAYTER.—On Nov. 25, at Maidenhead Nursing Home, to Elizabeth (née Hallett), wife of Dr. A. G. Hayter, of Marlow—a daughter.

MUNDIE.—On Nov. 23, to Dorothie Betty (née Clement), wife of Dr. J. H. F. Mundie, Memorial Hospital, Bulawayo, Southern Rhodesia—a son.

WILMOT.—On Nov. 29, at Tyrone County Hospital, Omagh, N.I., to Patricia (née Harmsworth), wife of Mr. T. J. Wilmot, F.R.C.S.—a son.

MARRIAGES

CAREY—TOPPING.—On Nov. 29, Richard John Carey, M.R.C.S., of Bristol, to Margaret Rosamond Topping, M.B., of Dulwich, London.

MUIR—WILSON.—On Nov. 18, William Adams Muir, M.B., of Kokstad, Cape Province, to Nancy Elizabeth Wilson, of Bosham, Sussex.

DEATHS

BUNCOMBE.—On Nov. 25, Guy Hope Buncombe, M.R.C.S., of Gorleston-on-Sea, aged 52.

GARDEN.—On Nov. 26, at Didsbury, Manchester, William Sim Garden, M.D. Aberd.

GOFFE.—On Nov. 28, Ernest George Leopold Goffe, M.D. Lond., of Green Park, Ferring, Sussex; formerly of Kingston upon Thames, aged 85.

HENDERSON SMITH.—On Nov. 26, at Harpenden, John Henderson Smith, M.B. Edin.

INGLES.—On Nov. 12, John Stewart Ingles, M.A., M.B. Edin., of Shrubbery Avenue, Worcester, aged 58.

JACOB.—On Nov. 25, at Brockhill Road, Malvern, Frank Harwood Jacob, M.D. Lond., F.R.C.P.

LATHAM.—On Nov. 16, in Nigeria, John Hulme-Latham, M.R.C.S., lieutenant, R.A.M.C.

MURRAY-SHIRREFF.—On Nov. 25, at Lambridge, Bath, Graham Murray-Shirreff, M.R.C.S.

REEVES.—On Nov. 23, Gordon Harry Reeves, PH.D., D.SC., F.R.I.C., of the biochemistry department, St. Bartholomew's Hospital, London, aged 58.

WICKHAM.—On Nov. 21, in Salisbury, Catherine Mary Wickham, L.R.C.P.E., late of Rajkot, Kathiawar, India, aged 87.

Diary of the Week

DEC. 7 TO 13

Monday, 8th

UNIVERSITY OF LONDON

5.30 P.M. (London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1.) Prof. P. György (Pennsylvania): Blood Group and Related Polysaccharides in Growth and in Resistance to Disease, with special reference to Human Milk.

INSTITUTE OF CHILD HEALTH, The Hospital for Sick Children, Great Ormond Street, W.C.1

5.30 P.M. Dr. C. H. Andrewes, F.R.S.: Virus Infections Before and After Birth.

INSTITUTE OF PSYCHIATRY, Maudsley Hospital, Denmark Hill, S.E.5

5.30 P.M. Dr. E. Stengel: Lecture-demonstration.

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, S.E.1

5 P.M. Dr. T. H. Whittington: Physiology of Accommodation Clinically Considered. Treatment of the Hypermetrope.

HUNTERIAN SOCIETY

8.30 P.M. (Talbot Restaurant, London Wall, E.C.2.) Dr. A. H. Douthwaite, Dr. H. Gardiner-Hill: Obesity.

MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1

8.30 P.M. Mr. A. C. Palmer: Results of Injury to Pelvic Diaphragm in Women.

LONDON HOSPITAL MEDICAL SOCIETY, Whitechapel, E.1

5 P.M. Prof. J. F. Brock (Cape Town): Kwashiorkor.

Tuesday, 9th

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.1

5 P.M. Dr. Maurice Davidson: Medicine in Oxford—a Historical Romance. (First of two FitzPatrick lectures.)

BRITISH POSTGRADUATE MEDICAL FEDERATION

5.30 P.M. (London School of Hygiene and Tropical Medicine.) Dr. C. E. Dent: Chromatography in Study of Amino-acid Metabolism.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1

5.30 P.M. *Section of Experimental Medicine.* Dr. M. Romansky (St. Louis): Erythromycin. Dr. M. A. Floyer, Dr. J. M. Ledingham: Experimental Hypertension.

8 P.M. *Section of Psychiatry.* Dr. N. O'Connor, Dr. J. Tizard: Resettling Defectives.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE, 28, Portland Place, W.1

4.30 P.M. Lord Horder: Fifty Years of Medicine. (First of three Harben lectures.)

INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2

5.30 P.M. Dr. D. I. Williams: Erythrodermias.

WEST END HOSPITAL FOR NERVOUS DISEASES, 40, Marylebone Lane, W.1

5.30 P.M. Mr. K. I. Nissen: Prevention and Treatment of Deformity in Infantile Paralysis.

CHADWICK LECTURE

4.30 P.M. (St. Mary's Hospital Medical School, Norfolk Place, W.2.) Dr. A. I. G. McLaughlin: Prevention of Dust Diseases of Lungs. (Malcolm Morris lecture.)

ROYAL ARMY MEDICAL COLLEGE, Millbank, S.W.1

5 P.M. Prof. A. A. Moncrieff: Children in Hospital.

MANCHESTER MEDICAL SOCIETY

5 P.M. (University of Manchester.) *Section of Surgery.* Dr. R. W. Fairbrother: Antibiotics.

Wednesday, 10th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2

4 P.M. Prof. F. Wood Jones, F.R.S.: John Hunter as a Geologist.

ROYAL SOCIETY OF MEDICINE

4.30 P.M. *Section of Physical Medicine.* Dr. I. H. Curwen, Dr. B. O. Scott: Short-wave Diathermy and Ultrasonics.

4.15 P.M. *Sections of Pathology and Medicine.* Discussion on Chemotherapy of Tuberculosis.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE

4.30 P.M. Lord Horder: Fifty Years of Medicine. (Second of three Harben lectures.)

ROYAL EYE HOSPITAL

5.30 P.M. Mr. L. H. Savin: Surgery of Ocular Injury.

INSTITUTE OF DERMATOLOGY

5.30 P.M. Dr. H. Haber: Bullous Eruptions.

INSTITUTE OF UROLOGY, St. Paul's Hospital, Endell Street, W.C.2

5 P.M. Mr. A. R. C. Higham: Diminished Fertility in the Male.

MIDLAND MEDICAL SOCIETY

8.15 P.M. (Birmingham Medical Institute, 154, Great Charles Street, Birmingham, 3.) Prof. G. W. Pickering: Natural History of Essential Hypertension.

MANCHESTER MEDICAL SOCIETY

4.30 P.M. *Section of Pathology.* Dr. M. T. Parker: Epidemiology of Enteric and Salmonella Infection in Manchester area.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS, 242, St. Vincent Street, Glasgow, C.2

5 P.M. Sir Sydney Smith: Medicine, Magic and Religion—the Persistence of an Idea. (Finlayson lecture.)

Thursday, 11th

ROYAL COLLEGE OF PHYSICIANS

5 P.M. Dr. Davidson: Medicine in Oxford—a Historical Romance. (Last of two FitzPatrick lectures.)

ROYAL COLLEGE OF SURGEONS

5 P.M. Prof. George Perkins: Rest and Movement. (Robert Jones lecture.)

BRITISH POSTGRADUATE MEDICAL FEDERATION

5.30 P.M. (London School of Hygiene and Tropical Medicine.) Dr. A. Neuberger, F.R.S.: Biochemical Genetics.

ROYAL SOCIETY OF MEDICINE

5 P.M. *Section of Ophthalmology.* Dr. Alice Carleton, Mr. J. H. Doggart, Dr. Peter Borrie: Association of Eye and Skin Diseases.

ROYAL INSTITUTE OF PUBLIC HEALTH AND HYGIENE

4.30 P.M. Lord Horder: Fifty Years of Medicine. (Last of three Harben lectures.)

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, 26, Portland Place, W.1

7.30 P.M. Dr. G. W. A. Dick: Epidemiological Notes on some Viruses Isolated in Uganda.

VICTOR HORSLEY LECTURE

5 P.M. (B.M.A. House, Tavistock Square, W.C.1.) Sir James Learmonth: Ischæmia in Surgery.

ST. GEORGE'S HOSPITAL MEDICAL SCHOOL, Hyde Park Corner, S.W.1

5 P.M. Sir Paul Mallinson: Psychiatry lecture-demonstration.

INSTITUTE OF DERMATOLOGY

5.30 P.M. Dr. R. W. Riddell: Subcutaneous Mycoses.

ALFRED ADLER MEDICAL SOCIETY

8 P.M. (11, Chandos Street, W.1.) Dr. A. Spencer Paterson: Crisis of Adolescence.

ST. JOHN'S HOSPITAL DERMATOLOGICAL SOCIETY

4.15 P.M. Dr. Bernard Lennox: Simplification of Pathology of Epithelial Skin Tumours.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY

Appointments

AINSWORTH, JOSEPH, M.B., M.RAD. Lpool, D.M.R.D.: consultan radiologist. in charge of the diagnostic radiology services West Manchester hospitals.

BOULGER, L. R., M.B. Manc.: pathologist, Nigeria, Colonial Medica Service.

FOX, F. W., M.B. Manc.: asst. M.O., North West Kent area.

PHILIPP, E. E., M.A., M.B. Camb., F.R.C.S., M.R.C.O.G.: second honorary gynæcologist, French Hospital, London.

TURNER, W. M. L., M.D. Lond., M.R.C.P., D.L.O., D.C.H.: consultant pædiatrician, Burnley and district hospitals.

North-East Metropolitan Regional Hospital Board:

BURN, R. A., M.B. Durh., F.R.C.S., D.O.M.S.: part-time ophthalmic surgeon (consultant), East Ham Memorial Hospital.

CRAWFORD, A. S., M.D. Edin., D.A.: part-time anæsthetist (consultant), Harold Wood Hospital and Brentwood Mental Hospital.

DAVIDSON, HILDA, M.B. Lond., D.P.M.: part-time psychiatrist (consultant), Ilford child-guidance clinic.

GIBB, W. E., M.A., D.M. Oxfd, F.R.C.P.: part-time physician (consultant), Metropolitan Hospital.

HALPER, HOWARD, M.R.C.S., D.M.R.E.: part-time radiologist (consultant), South East Essex group of hospitals, and Runwell Mental Hospital.

JOAD, MARGARET, M.R.C.S., D.A.: part-time anæsthetist (consultant), St. Mary's Hospital, Plaistow.

KELLY, R. E., M.D. Lond., M.R.C.P.: part-time neurologist (consultant), Prince of Wales's General Hospital.

KOPELMAN, HARRY, M.D. Lond., M.R.C.P.: part-time physician (consultant), St. Margaret's Hospital, Epping.

LLOYD-DAVIES, D. G., F.R.C.S.E., D.L.O.: part-time E.N.T. surgeon (consultant), Queen Mary's Hospital.

LUNN, G. M., M.B. Camb., F.R.C.S.: part-time surgeon (consultant), St. Leonard's Hospital and St. Matthew's Hospital.

MAXWELL, JAMES, M.D. Lond., F.R.C.P.: part-time physician (consultant), Enfield War Memorial Hospital.

PRENTICE, A. I. D., M.C., M.A., M.B. Camb.: pathologist (consultant), Black Notley Hospital.

VINCENZI, J. E. G., M.R.C.S., D.P.M.: part-time psychiatrist (consultant), Chelmsford child-guidance clinic.

South Western Regional Hospital Board:

BOLTON, J. R., M.B.E., M.D. Camb., M.R.C.P.: consultant physician (with a main interest in geriatrics), Bath clinical area.

DUMOULIN, J. G., M.B.E., M.D. Lond., M.R.C.O.G.: consultant obstetrician and gynæcologist, Plymouth clinical area.

MANDELBAUM, LISA, M.B. Brist., M.R.C.P., D.C.H.: senior registrar in diseases of the chest, Bristol clinical area.

NOBLE, NAIZBY, M.R.C.P., F.R.C.S.E., M.R.C.O.G.: senior registrar in obstetrics and gynæcology, Plymouth clinical area.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

UTERINE INFLUENCES UPON INTRARENAL BLOOD DISTRIBUTION *

K. J. FRANKLIN
D.M. Oxfd, D.Sc. Lond., F.R.C.P.
PROFESSOR OF PHYSIOLOGY IN THE UNIVERSITY OF LONDON, AT ST. BARTHOLOMEW'S HOSPITAL MEDICAL COLLEGE

THE uterus is unmentioned in the index—and scarcely mentioned in the text—of Homer Smith's *maximum opus* (1951) on the kidney. So a uterorenal talk may at least help to fill a gap, and will doubtless be provocative. I shall also present some experimental findings which have not before been synthesised and which in large measure have not yet been published.

* * *

So long ago as 1929 Dr. J. C. Beker, of Arnhem in Holland, began a series of publications about pregnancy conditions, particularly eclampsia, associated with renal troubles; the conditions included multiple pregnancy, hydramnios, and hydatidiform mole, with primiparity an aggravating factor, and undue stretching of the uterus appeared to be common to many of the cases. In Beker's view (1942, 1948, 1950) eclampsia—including that which occurs within the week after birth but not eclampsia puerperalis tardissima—was caused by a disturbance in the hæmodynamic equilibrium.

From 1941 onwards, van Bouwdijk Bastiaanse (1949), also in Holland, was similarly engaged in trying to find some ætiological basis for what has been termed "the disease of hypothesis," and there are many others who have been discontent to let pregnant women be exposed to dangers that might conceivably be reduced by a proper correlation of, and insight into, the facts. I cannot mention all these others; but I must name one, for he figures largely in my subsequent story. He was Mr. John Sophian, who for some twenty years was collecting clinical data, though without basing any publications upon them.

* * *

In 1945 Dr. Trueta, the late Dr. A. E. Barclay, and I discussed plans for a thoroughgoing radiographic study of the effects of direct, central, and reflex nervous stimulation upon the functioning cardiovascular system (see Trueta 1945), and we began work that autumn in the Nuffield Institute for Medical Research, Oxford, with Miss M. M. L. Prichard as the fourth member of the team; before long a fifth, Dr. P. M. Daniel, pathologist, was added. When the research had progressed a comparatively short way, certain findings about the blood-flow through the kidney focused our attention on that organ to the exclusion of others—though in retrospect I think we should first have completed our preliminary survey of the whole system, and only thereafter have come back to organs, such as the kidney, that had been specially indicated as worthy of further study.

The main point I wish to make, in the present connection, from our *Studies of the Renal Circulation*, is that we showed, for the first time, a parallel between the distribution of renal ischæmia produced by nervous/humoral action in the experimental animal and the distribution of bilateral renal cortical necrosis pathologically occurring in the human being.[1]

* * *

His reading of our book suggested to Mr. Sophian the hypothesis that distension of the human uterus in multiple pregnancy, hydramnios, and hydatidiform mole might reflexly cause diversion of the renal cortical blood-flow and thereby tend to minor troubles, to oliguria/anuria, and at the worst to bilateral renal cortical necrosis.[2] His hypothesis in its initial form did not, so far as I know, account for renal troubles occurring after parturition, nor did it specify the type of receptor end-organs that he thought would be stimulated as a result of the uterine distension.

In 1948 he discussed the hypothesis with me, and the obvious first test was to ascertain by experiment whether distension of the mammalian uterus could affect the intrarenal blood distribution. The positive results obtained (Franklin 1949) encouraged further experimental work and strengthened Mr. Sophian's belief that the primary change within the kidney in human pregnancy troubles was vascular constriction (Sophian 1949).

* * *

About the same time I began to test another hypothesis—namely, that the renal cortical blood-flow would be diverted in an animal subjected to anoxia/asphyxia. The tests showed that this happened in the innervated but not in the denervated kidney[3] and further, quantitative, work was done later by Miss E. A. Ullmann and Dr. L. E. McGee (Franklin, McGee, and Ullmann 1949, 1951). In the present connection certain results may be mentioned.

The tracheal occlusion test[4] depends for its positive vasoconstrictive reaction on the integrity of the renal nerves; it can, therefore, be used to determine the completeness or otherwise of extrarenal denervation of the kidney. The renal cortical vascular constriction is independent of the changes in general systemic arterial blood-pressure, and is mediated through certain spinal-cord levels. While the small cortical vessels constrict completely, the main renal artery is never fully occluded during the test. Finally, the renal cortical blood-flow diversion in such experiments appears to be the maximal response possible and it has been found not only in the rabbit, but in all the other laboratory mammals studied and also (personal communication from Prof. E. C. Amoroso) in the seal.[5]

* * *

---

* Based on a lecture, given at the invitation of Prof. N. J. Eastman, in the Department of Obstetrics, Johns Hopkins Hospital, on April 28, 1952, and repeated at the Naval Medical Research Institute, Bethesda, Md., four days later. An abbreviated version formed a communication to the Annual Meeting of the National Academy of Sciences, Washington, D.C. (Franklin 1952). The author was at the time visiting professor of physiology in the University of Illinois.

[1] Unfortunately, the term "renal shunt" was introduced, though not by us, for the diversion of the renal cortical blood-flow which we observed and described. In the absence of a universally accepted definition, this admirably brief term has been more often a stumbling-block than a help.

[2] I understand that he presented a fuller account as a thesis to the Royal College of Obstetricians and Gynæcologists in March, 1948.

[3] A 16 mm. silent colour film, produced in October, 1948, with the technical assistance of Mr. Douglas Fisher, demonstrated this to audiences at home and abroad.

[4] Seeing the effect upon the renal cortical blood distribution of the occlusion of a glass tube tied into the trachea.

[5] At this point in the lecture diversion of the rabbit's renal cortical blood-flow was demonstrated by projection of the first shots of a new 16 mm. silent colour film, *Asphyxia and the Kidney*, produced in 1951 by Professor Franklin with the technical coöperation of Mr. Douglas Fisher and other members of the Wellcome Film Unit. This Wellcome Research Record no. 3 is lent gratis for projection on application to the Wellcome Foundation, 183, Euston Road, London, N.W.1. The shots projected were of the diversion and subsequent recovery (*a*) at normal speed, (*b*) speeded up three times, and (*c*) speeded up twelve times.

I pass now to the main part of my lecture—namely, an account of certain experiments done since 1947 in the department of physiology at St. Bartholomew's Hospital. The subjects were rabbits, anæsthetised with intravenous injection of pentobarbitone sodium solution, followed as necessary by open administration of ether. During the experiments, paling of the kidney surface was taken as evidence of reduction of intracortical blood volume and it was usually not possible to watch more than one kidney. At the ends of experiments the appearance of the second kidney surface also was usually noted, while both kidneys were cut open so that the colour of the cortices and medullæ could be observed, and provide extra evidence.

In 1948 several experiments were performed in collaboration with Mr. Sophian. Suitable quantities of Ringer's solution at body-temperature were injected into uterine horns, bladders, and portions of intestine in order to produce acute distension, ligatures being used as required to prevent escape of the injected fluid. The findings were that distension of any of the three hollow viscera caused reduction in the renal cortical blood volume, intestinal distension being commonly the most effective.

In 1950 and 1951 further experiments were done in which blood was used as the distending agent in order to parallel more closely the concealed accidental hæmorrhage of human obstetrics. Later, when blood had been shown to act like saline, the latter was again used from time to time. Independent assessment of the results was always made by at least two observers. Brief résumés will be given of eight of these experiments.

EXPERIMENT 1 was performed in collaboration with Miss P. J. Lindop and Mr. J. F. Pearce. The uterus was non-pregnant but (?) parous. The ends of a thin plastic tube were tied into the left carotid artery and the right uterine horn respectively, and blood passed into the latter at the rate of 1–2 drops per second. The right kidney surface became progressively paler as the uterus got fuller, and at the end of the experiment it showed, on section in situ, a pale cortex and a congested medulla. The left kidney was not watched during the course of the experiment, but its surface was similarly pale at the end. When the plastic tube was withdrawn from the uterus, blood was still passing through at the original rate.

This experiment showed that distension of a uterine horn with the subject's own blood caused progressive reduction in the amount of blood in the cortices of both kidneys.

EXPERIMENT 2.—As hæmorrhage that is adequate in degree can cause diversion of the renal cortical blood-flow (Trueta et al. 1947), it seemed worth while to eliminate this possible criticism of the previous experiment, even though the blood-loss in it had not been great. In a new test, therefore, two animals were used, a buck providing the blood for the distension of the uterus of a doe which had large mammary glands and was, apparently, puerperal.

The left uterine horn was tied off at both ends, and a narrow 'Polythene' tube had one end inserted, pointing distally, into the buck's common jugular vein at the base of the neck, the other tied in the left uterine horn near its ovarian end. As there were competent valves in both internal and external jugular veins of the donor animal, regular intermittent compression of the main vein as it kept filling with blood was used to propel that blood into the uterus of the receiving animal. The surface of the left kidney of this latter was observed to get progressively paler as the uterine horn became ever fuller with blood. On section in situ, the left kidney showed a pale cortex and congested medulla; so did the right kidney, the difference in degree, if any, being very slight. The kidneys of the donor animal likewise had pale cortices at the end of the experiment, but the medullæ were not congested. The blood in the uterus appeared to be 2–3 ml. in amount.

This experiment showed that distension of one uterine horn of animal A with blood from animal B caused progressive reduction in the amount of blood in the cortices of both kidneys of animal A.

EXPERIMENT 3.—As renal cortical blood volume can be reduced both by renal nerve stimulation and by hormones such as adrenaline, another two-animal experiment was made, the receiver being a (?) virgin doe, and blood transmission being as in experiment 2. This time, however, the blood went to the *right* uterine horn, and the recipient's left kidney was denervated by division of the periarterial nerves, the completeness of the denervation being demonstrated by a tracheal occlusion test. As blood was propelled into the uterine horn, the surface of the innervated right kidney became progressively paler, while that of the denervated left kidney paled much less and was somewhat dusky. On section, the cortex of the right kidney was much paler than that of the left one, though the latter also was subnormal in coloration; the medulla of the right kidney was more congested than that of the left.

It appears, then, that distension of one uterine horn of animal A with blood from animal B caused some degree of (?) hormonal reduction in cortical blood volume in both kidneys of animal A, and in addition a reflex reduction in the same in the ipsilateral kidney, which retained its innervation; the reduction in this kidney, through both influences acting together, appeared to be maximal.

EXPERIMENT 4 was essentially the same as the previous one except that this time the donor's blood passed into the *left* uterine horn of the recipient—i.e., the horn on the side which had the denervated kidney. The uterus was a virgin one, and very little blood sufficed to distend the horn. As it became distended, the surfaces of both kidneys became paler, but the innervated one more than the denervated one. The appearance of the two organs on section confirmed the view that the effects were greater in the right kidney.

Here distension of one uterine horn caused some degree of (?) hormonal reduction in cortical blood volume in both kidneys, and in addition a reflex reduction in the same in the contralateral kidney, which retained its innervation.

EXPERIMENT 5.—The rate of transfer of blood was now increased by using the distal part of the donor's abdominal aorta as the supply vessel. After the aorta had been occluded by an artery clip, cannulæ were tied into it and into the left horn of the virgin uterus of the recipient, and were connected by narrow rubber tubing and adapters. Then the artery clip was removed, and the left kidney surface paled rapidly as the uterine horn rapidly became tense; the right kidney surface was found to be similarly pale when it was examined. Thereafter, the rubber tube was clamped and the uterine horn emptied of blood, with consequent reduction in pallor of the left kidney surface, through (?) not complete return to its previous depth of colour; the right kidney surface could not be simultaneously observed throughout.

Next, a stretch of about 3 cm. of the recipient's smooth colon was tied off at each end, a cannula was inserted, and blood was passed into it from the aorta until it became very tense. As this happened, both kidney surfaces paled. Then the left kidney was denervated, and colour returned to some extent to its surface.

Finally, both kidneys were sectioned. The cortex of the right one was very pale, of the left one somewhat less so. The medullæ were congested, the effect again being more marked in the right kidney.

Thus the rapid introduction of blood into a uterine horn or into a segment of the large intestine produced a rapid reduction in cortical blood volume in both kidneys. The paleness was reduced, though not completely so, when the uterine horn was emptied of blood; it was unilaterally reduced, in the case of the bowel distension and while that distension continued, when one kidney was denervated. The effects were thus both reflex and (?) hormonal.

EXPERIMENT 6.—The left kidney of a doe was denervated, the completeness of the denervation being demonstrated by the results of a tracheal occlusion test. Thereafter, injection of saline at body-temperature into the right horn of the virgin uterus, which became enlarged and tense, caused rapid paling (though much less than that produced by tracheal occlusion) of the right kidney surface. When the fluid was withdrawn from the uterus, the right kidney pallor was reduced but not abolished, and at this stage the left kidney surface was as pale as the right one. Section showed pallor of the cortices and some congestion of the medullæ of the two kidneys, the right one slightly predominating.

While distension of one uterine horn lasted, then, it caused reflex reduction in cortical blood volume in the ipsilateral, innervated kidney; it also produced (?) hormonal reduction in cortical blood volume in both kidneys and this persisted after distension had ceased. The reflex and (?) hormonal effects summated in the innervated kidney.

The next experiment was performed to determine the reflex/(?) hormonal reactions of the kidneys, following functional exclusion of the adrenal glands, to distension produced by injection of normal saline at body-temperature into one uterine horn.

EXPERIMENT 7.—A virgin doe had its left kidney denervated, the completeness of the denervation being confirmed by a tracheal occlusion test. Then both adrenal glands were functionally excluded by ligation of their vessels; for a while the kidney surfaces were somewhat paler than at the outset of the experiment, presumably because the manipulations had caused some extra liberation of adrenaline. Distension of the right uterine horn with saline at body-temperature caused some paling of the right (innervated) kidney surface, but not of the left (denervated) one; the original degree of coloration of the right kidney surface returned when the saline was removed from the uterine horn. At adequate intervals of time, the procedures were twice repeated with the same results. On section in situ, with distension continuing, at the end of the experiment, the right kidney cortex was obviously paler than the left one.

EXPERIMENT 8 was a repetition of experiment 7 in another animal, with identical results.

Comparison of the conditions and results of these last two experiments with those of the earlier ones indicates that distension of either uterine horn in a doe rabbit produces reduction in the cortical blood volume of both kidneys (i) by uterorenal reflex action, and (ii) by action upon the adrenal glands, with consequent hormonal action upon the kidneys. The effect of (i) is conterminous with the uterine distension, the effect of (ii) outlasts it.

* * *

Before adducing further evidence from observations on pregnant animals, I shall cite an experiment performed by Professor Amoroso (see Franklin 1949). In the rabbit, the several conceptus are spaced out in the uterus, and in consequence there is room for each, as it grows, to encroach upon the intervening no-man's land. By ligating the uterus on each side of each conceptus early in gestation, Professor Amoroso restricted the encroachment and thus increased the distension in each conceptual region. This put the uterorenal reflex upon so hair-trigger a basis that mere laparotomy and a touch to a conceptual region caused immediate diversion of the renal cortical blood-flow. I did not myself see Professor Amoroso's experiment, but since then, both with him and with Mr. Sophian and alone, I have noticed how manual compression of a conceptus can cause paling of the kidney surfaces; the latency of the response is so small that the effect is obviously reflex, at least at its outset.

The tension in the rabbit's uterus is maximal at about the 22nd day of gestation (Reynolds 1949). I have not got enough observations to correlate his curves of tension quantitatively with renal surface colour, but I can say without fear of contradiction that when pregnancy is reasonably advanced there is some paling of the kidney surface as compared with what is seen in the non-pregnant animal; the fœtal kidneys are not noticeably affected.

A further line of evidence is one which I have not so far succeeded in duplicating more than once, and then only less completely; it was obtained through a doe giving birth spontaneously during an experiment which Dr. A. M. Miles (now Fergusson) and I had planned for another purpose.

Before parturition began, the left kidney had been denervated; so when things began to happen we were able to compare the effects upon the innervated and denervated organs. The surfaces at the onset were as stated above—i.e., a little off colour as compared with non-pregnant. Then the intestinal movements and the uterine movements increased, the kidney surfaces became paler (denervated somewhat more than innervated), there were strong contractions of the doe's abdominal muscles and strong ventroflexions of its hind limbs, and parturition occurred. Kidney surface paling was increased for some minutes after birth, the innervated side now being paler than the denervated; thereafter there was return to more colour than existed before parturition began. Only the first two fœtuses were delivered spontaneously; the other four had to be evacuated. To begin with, after the evacuation, the right kidney surface was paler than the left, but within a few minutes both were darker than at the outset of the experiment—i.e., they were becoming non-pregnant in colour.

A less successful attempt at spontaneous parturition in another subject gave some extra details, and from the two experiments together one can add the following further points: (i) that after an unsuccessful attempt at parturition the intestines, kidney surfaces, and uterus returned to their previous conditions in about ten minutes, (ii) that during parturition the cortex of the fœtal kidney was paler than the medulla, and (iii) that after complete evacuation red streamlines appeared in the uterine veins.

We have then, during spontaneous parturition, renal cortical blood volume reduced first humorally and then reflexly. The humoral agent is, perhaps or even probably, posterior pituitary secretion, for this could produce the triple visceral effect noted, whereas adrenaline would inhibit the intestinal activity; histamine from the placenta is, I think, less likely because increased activity of the intestine preceded contraction of the uterus. I have still to find out whether posterior pituitary extract pales the denervated kidney to a greater extent than the innervated one, and whether paling produced by it and equal to that which we observed takes about ten minutes to subside. If, however, all that is discovered, the argument will have been strengthened and we shall also have a good idea of the amount of secretion produced in relation to a labour effort. The reflex uterorenal effect occurring after parturition must, I think, be evoked by the strong contracting down of the involuting uterus, and it is of particular interest as suggesting a possible mechanism for puerperal renal effects in the occasional human subject (see Franklin 1949).

Here I should say that, although there is individual variation in the experimental rabbit, the renal cortical blood diversion is usually of minor or medium degree compared with the maximal effect produced by asphyxia. Probably, therefore, we should regard the uterorenal effects in pregnancy and the puerperium as parts of the total physiological adjustment picture, not excessive in degree or very urgent in character. Nevertheless, the mechanisms are there, and more severe uterine distension before birth, or excessive uterine spasm after birth, could result in a greater response.

* * *

In the experimental animal nervously evoked renal cortical ischæmia of sufficient duration can result in renal cortical necrosis. I imagine that there are generic variations in the length of time required, as there are in the lengths of time different genera can undergo complete renal ischæmia, produced by clamping of their main renal arteries, without irreversible changes occurring. Clamping of the artery is a less natural process than stimulation of the renal nerves, for while the latter can completely cut out the circulation to the "cortical" glomeruli it does not cause complete occlusion of the main artery.[6] Adrenaline, administered in unphysiologically high dosage, can shut down the main renal artery, but there is at present no evidence that it does so in the concentrations in which it naturally occurs in the arterial blood passing to the kidney.

Two or three years ago, in conjunction with Mr. Sophian, I planned some experiments to see whether faradic stimulation of the rabbit's renal nerves could result in cortical necrosis. From the literature on the effects of clamping of renal arteries in various genera I thought it would suffice if we could keep the renal cortical blood-flow diverted for 3–4 hours, and I decided to do this by stimulating the renal nerves for 30 seconds every 2 minutes, for the effect of appropriate stimulation outlasts the stimulus.[7] In 1950 I wrote as follows about the results:

> "It appears that about four hours of continuous [renal cortical blood-flow] diversion . . . may be more than the rabbit's kidney can stand. In one instance, however, there was diminution in extent of a superficial area, visibly affected by the stimulation, during a subsequent recovery period of a few hours' duration. Effects which have been produced by such stimulation have included, according to reports by Prof. J. H. Dible and Dr. G. J. Cunningham, localised cortical necrosis, and elsewhere very considerable tissue damage."

Prof. H. L. Sheehan (1950) later examined the sections and gave a more detailed report; he also put the results into one of his new categories of the effects of human renal arterial spasm—i.e., our acute experimental results in rabbits paralleled findings in the human obstetrical field. "A point of interest in one experiment was that the unstimulated kidney showed superficial paling during the recovery of the stimulated one."

Beginning their work somewhat later, I imagine, E. C. Hoff and his colleagues (1951) found that diversion of the renal cortical blood-flow could be produced in acute experiments on cats by electrical stimulation of foci on the anterior sigmoid gyri of the cerebral cortex; the effects were greatly exaggerated when the brain was stimulated through the intact cranium with Offner's brief stimulus therapy apparatus; they were essentially abolished by renal denervation. In the acute experiments there were some changes in tubule cells (fatty degeneration, leading on to pyknosis and fragmentation of nuclei) when stimulations were multiple. In chronic experiments there were pathological changes in the kidneys presenting a picture of lower-nephron nephrosis. "It is suggested," wrote the authors, "that these changes are probably the result of repeated arteriolar vasoconstriction leading to tissue anoxia and alterations in capillary permeability."

* * *

In 1951 I listed the mammals in which evidence had so far been presented of diversion of renal cortical blood-flow under various conditions of nervous and humoral stimulation. These mammals were the rabbit, monkey, dog, cat, rat, mouse, guineapig, and seal—i.e., all those that had been studied. Lövgren has since found it in normal cats barked at by dogs, but not in control animals, and the recent angiographic studies of Daniel, Peabody, and Prichard (1951, 1952) confirm previous findings in the cat, dog, and monkey, add findings in the sheep, and give much interesting extra information. The general pattern of renal vascular response first found by our team at the Nuffield Institute in 1945–47 has, therefore, been demonstrated in all the lower animals so far used, though it remains to be proven beyond doubt in man—or such is the view of a number of nephrologists.

Let us see what has been found in human obstetrics; but first let us state that the various renal clearance tests are rendered difficult in oliguria, and are inapplicable in anuria. So they cannot be used to discover what is happening within the kidney in the severer cases of that organ's failure.

I have been told by Mr. Sophian of two interesting obstetrical cases, about which he was given information. In the first a bag was introduced with the object of inducing labour, but in fact the extra distension resulted in fatal renal cortical necrosis. The opposite side of the story was given in another case in which anuria was abolished by withdrawal of fluid. A number of workers (e.g., Solymoss 1949, De and Sengupta 1951, Solymoss and Molnar 1952) believe that renal cortical blood-flow diversion, of the type that we described in lower animals at the Nuffield Institute in 1945–47, is the mechanism through which human intra-uterine events produce their renal effects, and Sheehan, without adopting this view as such, has given a graded classification implicating vascular spasm as the initial intrarenal step, though it may be followed by vascular paralysis. I myself am still strongly impressed by the case described to me by Prof. T. N. A. Jeffcoate (see Franklin 1950).

> "The patient had concealed accidental hæmorrhage, and anuria from the time of its onset. After twenty-eight hours, when she had recovered from the initial shock, looked well, and had a blood pressure within normal limits, she was operated on and one kidney was exposed. Superficially it did not look pale, but congested. The pedicle was completely denervated without any change becoming apparent on the kidney surface and, when incised, the capsule did not bleed at all, nor did the cortex. On the other hand, as soon as the medulla was reached there was bleeding. The patient died on the fourth day after delivery, and at autopsy both kidneys showed the classical picture of complete cortical necrosis."

* * *

My main object here has been to submit some further experimental evidence about the mechanisms through which intra-uterine and intrarenal effects are related in a particular laboratory mammal. The work owed its inception to a desire to see whether there was in that species a uterorenal reflex pathway such as Mr. Sophian postulated in the human subject. The research has gone farther than the demonstration of such a pathway, but many more points have to be elucidated before the full story is known in even that one mammal—e.g., the exact part played by the adrenal glands has to be revealed and the receptor end-organs in the uterus to be determined.

How far the findings in animals can at present serve as a basis for the explanation of happenings in human obstetrics is a question which each must for the moment answer in the light of his own experience and of that of others as recorded in the literature. We are, however, justified by the positive animal findings in supposing that the human uterus *may* react upon the human kidney in somewhat the same way that the rabbit's uterus *can* react upon that animal's kidney; and a search for the truth is facilitated when one has precise *ideas* of the possibilities to be tested.

I should like to express my thanks to Mr. Sophian, whose hypothesis led to the experimental work which I have described, and who has been an enthusiastic collaborator in parts of that work. His views about the applicability of the findings to the field of human obstetrics are more definite than my own, and are, I understand, being published elsewhere.

[6] In a tracheal occlusion test the constrictor nerves to the artery outside the kidney appear to be maximally stimulated, but if a branch of the artery at the hilus has previously been denervated the part of the cortex supplied by this branch continues to receive a blood-supply while the rest of the cortex blanches.

[7] The choice of intermittent stimulation periods was fortunate, for Miss E. A. Ullmann subsequently found that continuous stimulation results in failure to maintain the end-effect.

ANTRODUODENECTOMY AND X-RAY IRRADIATION IN THE TREATMENT OF DUODENAL ULCER

PHYSICIANS and surgeons should be dissatisfied with the generally accepted surgical treatment of duodenal ulcer—subtotal gastrectomy with gastrojejunostomy. To remove most of the stomach for a small lesion of the duodenum is often successful, but the operation is not without risk to life, postoperative complications are not uncommon, and the patient's subsequent health is sometimes marred by minor or major discomfort (Wells and Welbourn 1951).

Many alternative operations have been devised, such as vagotomy, usually combined with gastro-enterostomy or pyloroplasty (Healy et al. 1951), and even replacement of the stomach by an excised portion of the colon (Moroney 1951), but none appears to be entirely satisfactory.

A study of patients subjected to subtotal gastrectomy for chronic duodenal ulcer (Grayton Brown 1951, Doig and Wood 1952) encouraged us to seek a better method of treatment. A series of 10 cases were treated by X-ray irradiation of the stomach (Ricketts et al. 1949), but the result was disappointing, 4 cases relapsing after six to nine months. In November, 1951, we decided to combine resection of the gastric antrum and the first part of the duodenum containing the ulcer (antroduodenectomy) with X-ray irradiation of the stomach so as to reduce the high concentrations of acid and pepsin in the gastric secretion which remain after this limited resection. Antroduodenectomy was followed by an end-to-end anastomosis allowing the food still to pursue its physiological course. The patient was thus left with a stomach of good capacity enabling liberal meals to be enjoyed. So far, 12 cases of chronic duodenal ulcer in recent relapse have been subjected to this treatment and the results have been encouraging. Though at least five years must elapse before the true worth of this treatment can be assessed, we report here our technique and early observations.

Antroduodenectomy combined with X-ray irradiation is also applicable to innocent antral and preantral ulcers. Antral ulcers are included in the antroduodenectomy; preantral ulcers are included by extending the excision along the lesser curvature. This will be reported elsewhere.

Three plans for the treatment of chronic duodenal ulcer were tried: X-ray irradiation alone; antroduodenectomy followed two months later by X-ray irradiation; and X-ray irradiation followed two months later by antroduodenectomy.

METHODS OF STUDY

Most of the patients in each group were studied by the following methods:

Clinical observation, special attention being paid to appetite, abdominal discomfort, weight, and general sense of well-being.

Serial histamine test-meals using 0·3 mg. of histamine (indicator, Töpfer's reagent) immediately before and two weeks after operation, immediately before and after irradiation, then usually at monthly intervals for six months, three-monthly till the end of a year, and then six-monthly.

Serial "overnight" test-meals (complete emptying every two hours for twelve hours) at intervals of three to six months. Also occasional insulin test-meals (15 units intravenously).

Serial gastric biopsies before and two months after operation, before and after irradiation, then at intervals of one or two months for six months, and then at longer intervals.

The gastric biopsy fragments were obtained from the body of the stomach with the flexible gastric biopsy tube designed in our clinical research unit (Wood et al. 1949a and b). Sections of these fragments were stained with hæmatoxylin and eosin, Best's mucicarmine, and the trichrome stain described by Motteram (1951). In the present series 138 successful gastric biopsies were performed at 151 attemps on 25 of the cases reported here. There were no complications.

The total experience of our unit with this method of gastric biopsy in patients with a wide range of diseases is 926 successful biopsies on 645 patients at 1060 attempts (Wood 1951). The only complication was immediate hæmorrhage, 10 patients having slight or moderate hæmatemesis, frank melæna, or clinical anæmia; none was critically ill, and all responded well to medical treatment.

X-RAY IRRADIATION ALONE

In September, 1949, we began to treat duodenal ulcer with X-ray irradiation alone, following the lead of Walter Palmer and his colleagues of Chicago (Ricketts et al. 1949) and Holman and Lewis (1941) in Tasmania. Experience caused gradual modification and improvement of our initial technique of irradiation until a satisfactory one was evolved. Briefly, this consisted in giving

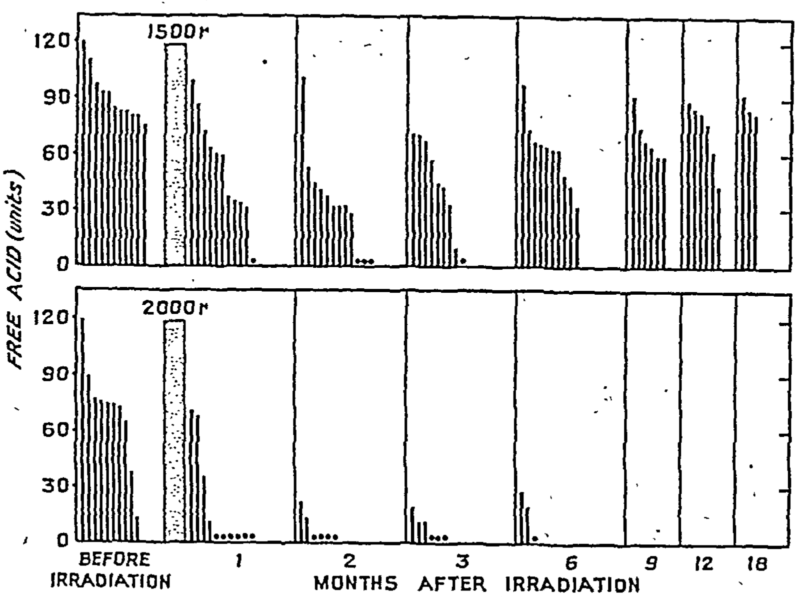

Fig. 1—Effect of X-ray irradiation of stomach on secretion of free acid shown by serial histamine test-meals. Each vertical line represents the greatest increase of free acid in a single test-meal ; dots represent achlorhydria.

It will be noted that 1500r produced reduction in secretion of free acid with a slow return to higher levels after two months. In the few cases receiving a dose of 2000r the response was increased, but sufficient time has not elapsed to observe its duration. This increased response may have been due, in part, to improved technique in centring the irradiation over the stomach. Two patients, who had a second course of irradiation after their gastric mucosa and secretions had returned to pre-irradiation structure and levels, are included twice. Two other patients, who had antroduodenectomy after irradiation, are not included.

2000r during three weeks, great care being taken to ensure accurate centring over the stomach so that a small port could be used. To achieve accurate centring attention was paid to the maintenance of uniform posture and constant gastric distension. With this technique the response was optimal.

Serial histamine test-meals revealed that X-ray irradiation decreased the volume of secretion and the concentration of free acid and pepsin (fig. 1). Serial gastric biopsies showed a corresponding change (fig. 2). Before irradiation the biopsy fragments were usually within normal limits or near normal; after irradiation there was infiltration of the mucosa with polymorphonuclear leucocytes, lymphocytes, and plasma cells, together with slight to moderate atrophy or loss of the normal staining characteristics of the cells secreting acid and pepsin (figs. 3 and 4). The early changes were in the superficial layers, but later an active atrophic gastritis developed. These biopsy findings have been described in detail by Doig et al. (1951).

The greatest change in gastric secretion and in the biopsy fragments took place during the second and third months. This was followed by a return of gastric secretion to the pre-irradiation level and by regeneration of the mucosa. With the dosage first used in this series, 1500r, complete or almost complete recovery was usually evident six to nine months after the irradiation. This recovery time may be prolonged with 2000r, the increased dosage used in our more recently treated cases, but sufficient time has not yet elapsed to ascertain this.

With this technique most patients remained well and able to work during the course of irradiation. A few experienced moderate nausea; one who had had recent hæmorrhage had a slight hæmatemesis. The dosage used produced, at the most, minimal skin erythema.

The case of one of our early patients, a man aged 35, who responded very satisfactorily to X-ray irradiation alone, has been reported in detail by Doig et al. (1951). After irradiation there was a pronounced change in his gastric secretion and biopsy fragments, with restoration to the original levels and structure after fifteen months. When seen in July, 1952, three years after the irradiation, he was still free from symptoms.

The following case is also of interest:

Case 1.—A fitter, aged 18, was admitted to hospital in July, 1950, with a severe hæmatemesis. He had had intermittent ulcer dyspepsia for four years following a hæmatemesis. Barium-meal radiography showed a grossly deformed duodenal cap but no crater. X-ray irradiation 1500r was given five weeks after the bleeding had ceased, and he remained well until last seen two years later. After the irradiation the gastric acidity was reduced for five months and serial gastric biopsies showed moderate cellular infiltration and atrophy, which resolved completely after eight months. Barium-meal radiography showed no change.

Our observations indicated that a dose of 1500r often caused a suboptimal reduction in the gastric secretions (fig. 1). Moreover, often there was very little histological change in the gastric biopsy fragments (fig. 2). The dose was therefore increased to 2000r, and this led to an increase in the average response, in both the gastric secretions and the gastric mucosa, without causing any additional inconveniences to the patient (figs. 1 and 2). Some of this increase in response may be attributed to better centring during the X-ray irradiation.

It soon became evident that one course of X-ray irradiation usually produced immediate and complete

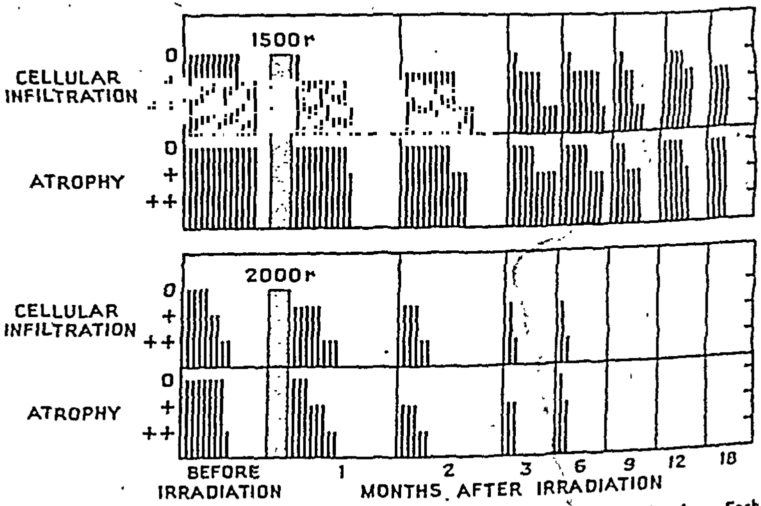

Fig. 2—Effect of irradiation on gastric mucosa shown by serial gastric biopsies. Each vertical line represents a single biopsy result. Reaction of gastric mucosa was judged by cellular infiltration especially in lamina propria, and by atrophy especially of cells secreting acid and pepsin.

It will be noted that with both 1500r and 2000r some general change in biopsy fragments occurred, but change was not severe. Findings suggest that 2000r will cause a greater and more prolonged reponse than will 1500r, but sufficient time has not elapsed to assess this. This improved response to 2000r may have been due in part to improved technique of centring the irradiation over the stomach.

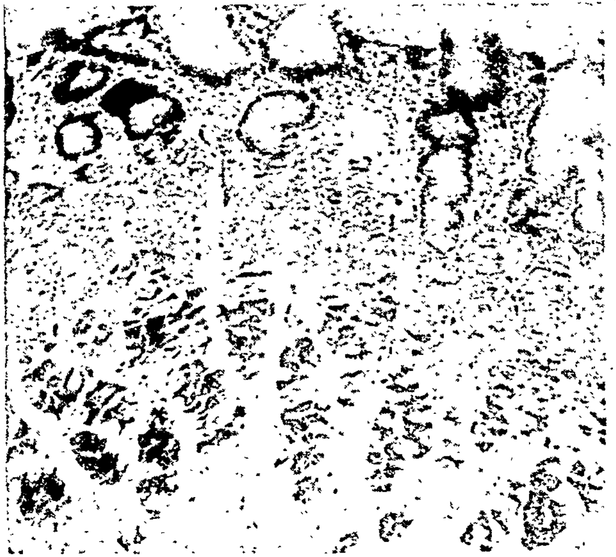

Fig. 3—Fragment of gastric mucosa obtained by biopsy immediately before irradiation in male, aged 51, with chronic duodenal ulcer. Histamine test-meal showed free acid 71 units. Appearances are normal, surface epithelium being regular and cuboidal, gastric pits regular, and acid-secreting and pepsin-secreting cells of tubules staining distinctly dark and being well differentiated. (Motteram's trichrome stain. × 135.)

remission of symptoms. However, these good effects were not always maintained. Of the 10 patients followed up for an average period of seventeen months (range 8–36 months) 4 have remained free from symptoms for eight, nine, twelve, and twenty-two months, and 2 had minor symptoms during twenty-seven and thirty-six months of observation (see table). The remaining 4 had severe relapses after eight, twelve, twelve, and twenty-five months; 1 of these was given a second course of X-ray irradiation (1500r) twelve months after the first, and has been well for a further five months, and the remaining 3 required surgery because of severe and persistent pain (1 case) or pain and vomiting (2 cases, with 1 death after gastro-enterostomy performed for obstruction in a patient with a severe mitral stenosis).

These disappointing results, together with our experience that severe chronic relapsing ulcer of the duodenum rarely showed permanent healing with "medical" treatment, led us to the decision to remove the ulcer by surgical means.

ANTRODUODENECTOMY AND X-RAY IRRADIATION

We were loth, however, to resort once again to the radical operation of subtotal gastrectomy with gastrojejunostomy. It seemed rational to adopt a more physiological and less drastic course by removing only the first part of the duodenum containing the ulcer together with the gastric antrum, and to perform an end-to-end anastomosis (figs. 5 and 6). This left the patient with a larger stomach than is provided by the somewhat similar Billroth-I operation. We call this operation antroduodenectomy to emphasise the limited nature of the gastric resection. We were encouraged to remove the antrum because it is a common site of ulcer formation; moreover Dragstedt et al. (1951) have shown in experiments on animals that, when the stomach is anastomosed to the small bowel, ulceration tends to occur, but this tendency is reduced considerably when the gastric antrum is excised.

As we found that antroduodenectomy per se usually caused no major reduction in the gastric secretion of acid and pepsin, we decided to combine the operation with X-ray irradiation.

Some Surgical Considerations

Consideration of the anatomy of the duodenum led us to realise that duodenal mobilisation is much more practicable than has been generally realised (Ogilvie 1952). It seemed that if most duodenal ulcers are confined to the first part they should be suitable for resection. Further, it was found by examining the duodenum in fresh cadavers that the average distance between the pylorus and the ampulla of Vater was 10 cm. Even if this should be diminished somewhat by scarring, an ample length should be available to allow resection of the ulcer and still leave enough duodenum for an end-to-end anastomosis.

It remained to prove this by operative trial. In the 18 consecutive cases of chronic duodenal ulcer where this has been attempted, including 6 in which the ulcer had completely penetrated into the pancreas, the anastomosis was done and was entirely successful in 16. Complications were encountered, however, in 2 elderly patients.

Case 2.—A man, aged 83, had acute severe duodenal bleeding immediately before and during laparotomy, the common bile-duct having been severed when a hasty resection of a large penetrating ulcer was being performed, but suture of the duct proved successful and the patient was discharged from hospital "fit" three weeks after operation.

Case 3.—A wasted man, aged 73, demanded operation for severe persistent pain caused by a huge ulcer penetrating into the pancreas. An anastomotic ulcer developed, and he died from hæmorrhage ten weeks after operation.

Technique of Antroduodenectomy

Most duodenal ulcers are in the proximal portion of the first part of the duodenum and are easily resected. In those which penetrate, the erosion is on to the anterior surface of the pancreas. This site is usually a safe distance from the common bile-duct and pancreatic duct, but great care must be taken not to damage these structures.

Occasionally, the ulcer lies over the gastroduodenal artery, necessitating dissection further to the right of this vessel. Here there is risk of dissecting near the common bile-duct, which should be identified in the free edge of the lesser omentum and traced down to the duodenum.

Many penetrating ulcers appear irremovable at first, but perseverance will be rewarded by the liberation of a flange of healthy duodenum beyond the ulcer. This somewhat tedious dissection is facilitated by the exposure permitted by modern anæsthesia, and by the fact that

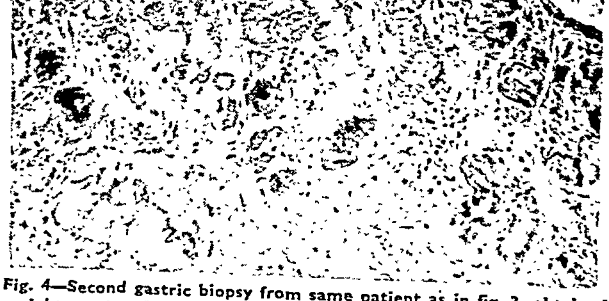

Fig. 4—Second gastric biopsy from same patient as in fig. 3, obtained eight weeks after irradiation 2000r, illustrating typical *irradiation effects*. Cells of epithelium are now irregular, and their cytoplasm stains darkly. Polymorphs are numerous in lamina propria and in dilated pits. Tubules are reduced in number and *most cells secreting acid and pepsin now stain poorly and indefinitely*. Histamine test-meal showed achlorhydria. (Motteram's trichrome stain. × 135.)

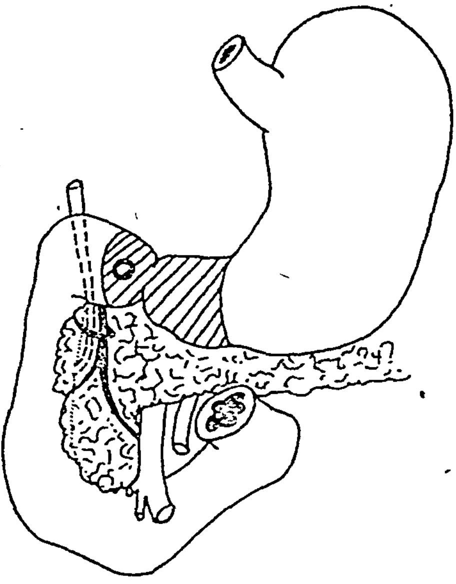

Fig. 5—Relations of ulcer-bearing area of duodenum to pancreas, gastroduodenal blood-vessels, and common bile-duct. Hatched area shows portion excised in antroduodenectomy.

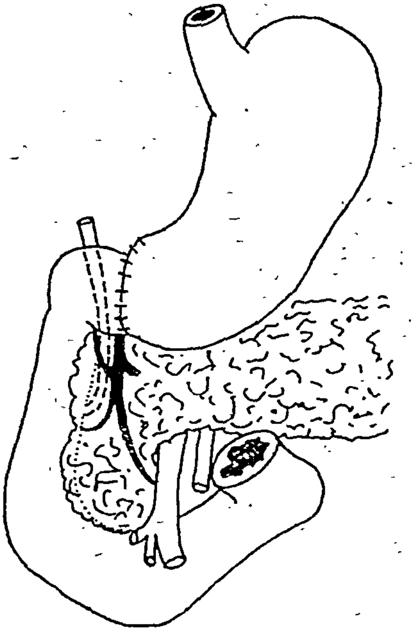

Fig. 6—Appearances following antroduodenectomy and gastroduodenostomy.

only a restricted surgical procedure, gastroduodenostomy, remains to complete the operation.

To aid primary healing it is important to preserve the blood-supply of the cut surfaces of stomach and duodenum to be used in the anastomosis. Healing is also favoured by doing the operation under a cover of penicillin and streptomycin, beginning the day before operation and continuing for at least six days.

Results

Most of our patients suffered little immediate postoperative discomfort. Usually they sat out of bed on the third day after operation, and walked round the ward before the end of a week. Within a month of operation they enjoyed large meals and did not experience any sense of fullness or discomfort.

As previously stated, it was decided to combine X-ray irradiation with antroduodenectomy because this limited resection had little effect on the gastric secretion measured by histamine, insulin, and "all night" test-meals given immediately before and two weeks after operation.

RESULTS OF TREATMENT OF CHRONIC DUODENAL ULCER BY (*a*) X-RAY IRRADIATION ALONE, (*b*) ANTRODUODENECTOMY COMBINED WITH X-RAY IRRADIATION

(a) *Treatment by irradiation alone:*

No. of cases 10 (M 9, F 1); average age 43 (range 17–71).
Reason for irradiation: pain 5; pain and hæmorrhage 5.
Average duration of pain 12 years (range 0–28 years).
[illegible] no symptoms 9; slight hæmorrhage 1.
[illegible] (average 17 months, range 8–36
[illegible] 4; mild relapse 2; moderate or severe relapse 4 (after 8, 12, 12, and 25 months).

(b) *Treatment by antroduodenectomy followed 2 months later by X-ray irradiation:*

No. of cases 10 (M 9, F 1); average age 46 (range 34–73).
Reason for operation: pain and vomiting 6; pain and hæmorrhage 2; pain, hæmorrhage, and vomiting 1; pain only (previous perforation) 1.
Average duration of pain 10 years (range 6–28 years).
Progress during immediate postoperative period good in all cases.
Progress during 2 months between operation and irradiation good in 10.
Progress during irradiation: no symptoms 8; slight or moderate nausea 2.
Progress during follow-up (average 3 months, range 0–7 months): no symptoms 9; slight dyspepsia 1.

Antroduodenectomy was performed in 8 other cases: 2 were preceded by irradiation and have progressed favourably for 3 and 7 months; 3 are about to undergo irradiation 2 months after a successful operation; 2 were considered unsuitable for irradiation owing to old age and low secretion; and 1, aged 73, died from anastomotic ulcer and hæmorrhage ten weeks after operation (no irradiation given).

However, six weeks later, lower concentrations of acid were sometimes recorded.

The ideal plan appeared to be first to reduce the acid by irradiation and then to perform antroduodenectomy two months later, when the secretion of acid was reduced and the inflammation round the ulcer had perhaps subsided. Indeed 2 patients were subjected to this procedure with good results, and we are treating others by this means (see table). Both patients pursued a highly satisfactory course throughout, and are now well four and seven months after operation. After irradiation serial test-meals showed reduced secretion (volume, acid, and pepsin) and serial gastric biopsies moderate irradiation changes. After operation no treatment, either medicinal and dietetic, was ordered or taken. The only restriction was to forbid alcohol, because excessive amounts might reduce the gastric secretion and so impair the significance of the serial test-meals and gastric biopsies (Doig and Wood 1952, Funder and Weidin 1952). The record of one of these patients is as follows:

Case 4.—A male machinist, aged 60, was admitted to hospital in September, 1951, having had severe recurrent ulcer dyspepsia for fifteen years and three major hæmorrhages in the past four years. Barium meal: duodenal ulcer. Histamine test meal: hyperchlorhydria (83 units of free acid). Gastric biopsy: normal. On Sept. 30, 1951, X-ray irradiation 1500r was given without producing any discomfort. There was a decrease in acid secretion to 20 units, and biopsy showed irradiation changes. On Dec. 10 antroduodenectomy was performed for a small chronic ulcer in the first part of the duodenum. Convalescence was good, and the patient remained symptom-free until last seen seven months after operation. Four months after the irradiation the acid was still reduced (48 units) and the biopsy still showed moderate irradiation changes, but during the next five months there was a further increase in acid and resolution of the changes in the mucosa.

However, it seemed unwise to administer deep X-ray irradiation to patients in active relapse, especially when there had been recent hæmorrhage, severe pain, or symptoms of obstruction. So the procedure most often adopted was to perform antroduodenectomy and to follow this two months later by irradiation in a total dose of 2000r given over three weeks.

To reduce the activity of peptic digestion during the period between the antroduodenectomy and the completion of irradiation, a full medical régime was instituted, with powder, belladonna, frequent milk drinks, and diet. At the completion of irradiation this was discontinued.

In this group 16 cases of chronic duodenal ulcer have now been subjected to antroduodenectomy and have progressed as follows (see table): 10 have had both antroduodenectomy and X-ray irradiation from one to eight months ago (average four months) and have enjoyed excellent health free from dyspepsia, taking full unrestricted diet and no antacids or other medical treatment; 3 are about to have their irradiation and are very well; 2 elderly patients with low acid secretion are very well and are being observed by serial test-meals; and 1 died, as previously described.

The following case is representative of this group:

Case 5.—A sorter, aged 61, was admitted to hospital in January, 1952, having had dyspepsia for nine years, together with three severe hæmatemeses. Barium-meal: deformity of duodenal cap. Histamine test-meal: free acid 80 units. Antroduodenectomy revealed a chronic ulcer, 4 × 8 mm., just distal to the pylorus. The postoperative course was uneventful, and after two months the patient was given a course of X-ray irradiation 2000r, during most of which he worked and experienced only slight nausea. A full ulcer régime was observed between the operation and the completion of irradiation. The operation produced no fall in acid secretion (free acid 88 units) or any appreciable change from normal in the gastric mucosa obtained by gastric biopsy. Irradiation caused a fall in acid to achlorhydria, together with cellular infiltration and moderate atrophy in the biopsy fragments.

When last seen six months after operation the patient had remained free from symptoms and had gained 1 st. in weight. He had eaten full unrestricted meals without discomfort and refrained from taking medicinal treatment. Test meal: hypochlorhydria (free acid 20 units). Gastric biopsy: moderate irradiation reaction. Barium meal: normal contours and emptying rate: capacity reduced to about two-thirds of normal.

Barium-meal radiography was done in 5 patients six months after antroduodenectomy, and the results were uniform and most satisfactory. The stomach was of reasonable capacity, appearing to be from half to two-thirds of normal. Emptying was hastened but not excessively rapid. The exact site of the anastomosis was difficult to define, the gastric and duodenal mucosæ fusing imperceptibly. The mucosal pattern was well defined and of normal appearance, there being no suggestion of ulcer.

Gastroscopy was done in 2 patients six months after operation. In both patients the mucosa in the body of the stomach and at the site of the anastomosis appeared normal.

COMMENTS

Antroduodenectomy was rarely difficult, though it demanded a detailed knowledge of the anatomy of the duodenum and meticulous care to provide a successful anastomosis, yet avoiding damage to the surrounding structures, particularly the bile-duct. Assisted by antibiotics and skilled postoperative management, the patients usually recovered rapidly from the immediate effects of the operation and maintained satisfactory progress.

The X-ray irradiation of the stomach to reduce the secretion of acid and pepsin for a period of six to nine months caused little or no discomfort in the dosage recommended, 2000r. After a week of irradiation in hospital the patient received the remainder as an out-patient, the treatment being taken at the end of the day, after work.

Following this scheme of treatment the patients enjoyed a life free from discomfort and pain, free from the irksome demands of "medical treatment" with its strict dietetic régime—powders, belladonna, phenobarbital, endless glasses of milk, and often the fussy dictates of an apprehensive wife and family.

In the present series a comprehensive study was made of gastric secretion and the histology of the gastric mucosa to discover the best dosage of X-ray irradiation. These studies provided valuable data, and it is hoped that a satisfactory régime has now been evolved. Once this has been achieved, gastric biopsy can be discarded entirely, and only an occasional test-meal need be given. Our investigations have placed a considerable burden on our patients, and we are most grateful to them for their cheerful help.

We predict a higher proportion of satisfactory results from this form of treatment than from other methods. For it is reasonable to expect that, with the excision of the vulnerable antrum and first part of the duodenum, and with the depression of acid and pepsin secretion by irradiation for six to twelve months, the body of the stomach and the second part of the duodenum will remain free from ulceration. Experience suggests that those patients who develop ulceration after simple gastro-enterostomy, or subtotal gastrectomy with gastro-jejunostomy, do so during the first year after operation. Our patients are, in part, protected from the action of hyperacidity and high pepsin secretion during this period. Moreover the second part of the duodenum naturally enjoys a high degree of immunity from ulceration, and it may be anticipated that this immunity will continue after antroduodenectomy.

Many years must pass before success can be claimed for the treatment of severe chronic duodenal ulcer by antroduodenectomy and X-ray irradiation; but our hopes have been raised by our early experiences.

SUMMARY

Ten patients with chronic relapsing duodenal ulcer were treated by X-ray irradiation of the stomach, following the work of Palmer and his colleagues (Ricketts et al. 1949). Serial test-meals and gastric biopsies showed a moderate irradiation effect lasting from six to nine months. With return of the secretions and the biopsy findings to their original state 4 of the 10 patients had a severe relapse in their ulcer symptoms, 3 requiring surgery.

Therefore it was decided to combine irradiation to the stomach with local excision of the ulcer-bearing portion of the duodenum and the gastric antrum (antroduodenectomy). In 2 cases irradiation was given before, and in 10 after, the operation. 8 other cases subjected to antroduodenectomy are also reported.

Antroduodenectomy was followed by gastroduodenostomy, thus maintaining the natural continuity of the stomach and the duodenum. Moreover the limited resection left the patient with a stomach of good capacity.

Most of the patients stood the operation very well indeed. The postoperative course was most satisfactory, and the lack of symptoms during the follow-up encouraging. One elderly patient had fatal complications.

Antroduodenectomy per se did not cause a major reduction in the secretion of acid and pepsin.

X-ray irradiation of the stomach using the optimum dosage (2000r) caused little or no inconvenience to the patient. Serial test-meals and gastric biopsies revealed good lowering of the secretion of acid and pepsin, together with pronounced, but not gross, changes in the gastric mucosa.

The early results of the treatment of chronic duodenal ulcer by antroduodenectomy and irradiation are encouraging; but many years must pass before a significant comparison with other methods can be made.

We wish to thank the members of the honorary medical staff of the Royal Melbourne Hospital who have aided us with our study. Our special thanks are due to Mr. Julian Orm Smith and Dr. W. E. King. We are also grateful to Sister M. Hughes for her invaluable help.

O.B.E., T.D., M.D. Edin., F.R.C.P.
PROFESSOR OF PÆDIATRICS AND CHILD HEALTH, UNIVERSITY OF BIRMINGHAM

The condition known as a short œsophagus and partial thoracic stomach has been recognised for some years. Recent advances in thoracic surgery and radiological diagnosis have renewed interest in this abnormality, with the evolution of new ideas concerning its ætiology and clinical characteristics.

So-called congenital stenosis of the œsophagus (Beatty 1928, Sheldon and Ogilvie 1929) was shown to be often associated with a short œsophagus and a partial thoracic stomach (Kelly 1930, Findlay and Kelly 1931, Clerf and Manges 1934). Johnstone (1941, 1943) and Allison et al. (1943) later demonstrated that this type of stricture was not a congenital abnormality but was secondary to œsophagitis induced by reflux of gastric contents. This occurs as a result of incompetence of the gastro-œsophageal valve mechanism. Such an incompetence, associated with hiatus hernia but usually without œsophageal stricture, is now known to be relatively common in adults. It is also becoming increasingly recognised that a similar, if not identical, condition occurs in infancy.

Our present preliminary report is based on a study of 112 children with a short œsophagus and a minor degree of partial thoracic stomach (the thoracic part not exceeding 15% of the whole stomach). Infants and children with a greater proportion of the stomach situated above the diaphragm and those with para-œsophageal pouches, herniæ associated with redundancy of the œsophagus, and chalasia of the cardia (Neuhauser and Berenberg 1947) were excluded from consideration. Of the 112 patients 43 have been followed up for four years or more from the onset of symptoms, and the oldest is now aged 36.

INCIDENCE

In the medical literature of the last twenty-two years we have found reference to only just over 100 cases in children; yet in a single year (1951) 18 infants under the age of 12 months with symptoms demonstrated to be due to a partial thoracic stomach have been observed in the Children's Hospital in Birmingham. This is about a fifth of the number with hypertrophic pyloric stenosis treated in the same period. As only infants with relatively severe clinical manifestations are likely to attend hospital, the true incidence cannot be assessed; but it is probably greater than this figure indicates.

There is no reason to suspect any recent alteration in the incidence of this abnormality, and it is therefore reasonable to presume that in the past many cases in infancy have remained unrecognised. Moreover, despite present-day knowledge of the clinical and radiological features, relatively few cases are diagnosed for the first time in children more than 2 years of age. This further suggests that many affected infants become symptom-free in later childhood. Both these suppositions are supported by the records of the Birmingham Children's Hospital for 1940–50 and by subsequent review and radiography of selected children. This review has brought to light 45 children with a partial thoracic stomach previously undiagnosed. Most of these are now *free from symptoms.*

CLINICAL FEATURES

The medical histories of the 112 children showed that vomiting was the principal and invariable symptom, dating from birth or from the neonatal period in 90%. Under the age of 4–6 months it was often projectile and came on during or immediately after feeds. The vomit consisted of most or all of the feed and always contained much mucus; rarely it was bile-stained. Blood was often present in the vomit, usually only as a few flecks. Obvious hæmatemeses were rare. Except on a few occasions the blood was not bright red but altered in appearance and often not recognised by the parents—an important point to remember in history-taking. Constipation was not a prominent feature, and melæna was seldom recorded. The infants appeared hungry and took their feeds well. *A failure to gain weight was usual, and in severe* cases there was moderate dehydration. Visible gastric peristalsis was occasionally observed.

In later infancy all these symptoms and signs might persist, but the vomiting lacked the original projectile quality and visible gastric peristalsis was not observed. At this age the association of vomiting with such factors as coughing, emotion, and recumbency tended to become more obvious. Later this sometimes constituted the most prominent and characteristic symptom.

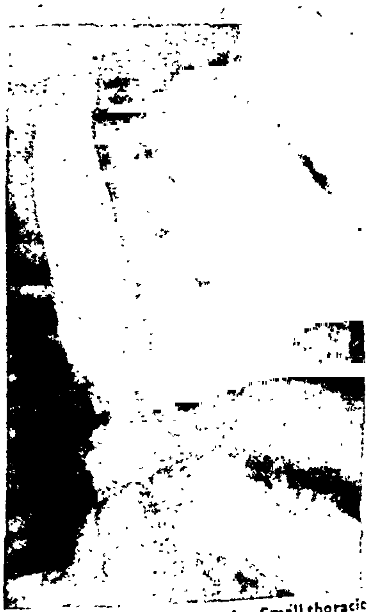

Fig. 1—Infant aged two weeks. Small thoracic loculus of stomach.

According to their clinical course, cases could be divided into three broad groups. In the first group the condition was essentially benign in that the symptoms had ceased or very largely abated by the age of 2 years and later *complications* were not observed. Usually there was clinical improvement on weaning to a mixed diet.

In the second group symptoms persisted longer and there was no significant improvement until the child was 4 years old or more. Even then periodic relapses were occasionally encountered for a *further number of* years. Vomiting when the child was recumbent at night was sometimes a prominent feature; occasionally such night vomiting was the only symptom. In the vast majority of cases vomiting was either not improved, or was aggravated, by the introduction of mixed feeding. Dysphagia was an additional symptom in some children in this group. On occasions food was said *to stick* in the throat or behind the sternum. *Drinking might give* relief; but, failing this, the child would vomit the obstructing fragment and then complete a hearty meal. Other children, even at the age of 2 or 3 years, learned to provoke vomiting to relieve their symptoms by stimulating the back of the throat with the fingers. In a few instances food remained in the gullet for twenty-four hours without causing discomfort except inability to swallow. Such episodes did not necessarily indicate the presence of an organic stricture and might occur after all other symptoms had ceased. Anæmia was apparent in a few children; it was hypochromic and might be explained by chronic blood-loss and dietary insufficiency.

---

* Partly based on a paper presented to the annual meeting of the British Pædiatric Association on May 1, 1952, by I. J. C.

In both the foregoing groups the progress of improvement was similar and characteristic. There were remissions of increasing duration interspersed with decreasing relapses. Many of the children in the second group, as in the first, eventually lost all symptoms, although the time of recovery might be delayed until later childhood. A few were left with a tendency to vomit on such provocation as minor ailments and excitement.

The third group consisted of cases with a complicating œsophageal stricture. Here symptoms were predominantly of dysphagia secondary to the œsophageal obstruction. None of these children showed any symptomatic improvement with the introduction of mixed feeding, and most became worse.

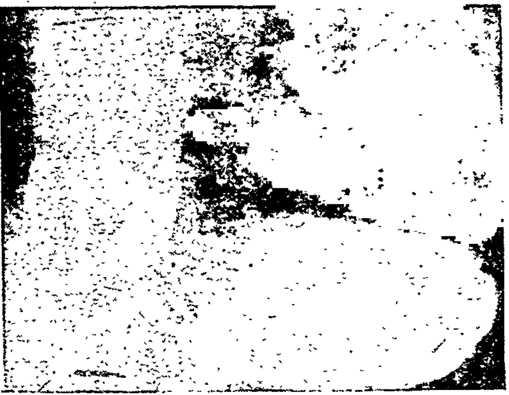

Fig. 2—Child aged 13 months. Showing continuity of gastric mucosal folds through wide diaphragmatic hiatus, and loss of gastro-œsophageal angle.

DIFFERENTIAL DIAGNOSIS

In early infancy the differential diagnosis was chiefly from hypertrophic pyloric stenosis, particularly in view of the projectile vomiting and the visible gastric peristalsis. Important distinguishing features included the history of vomiting from birth, the absence of a palpable pyloric tumour, altered blood in the vomit, and sometimes dramatic response to nursing in a propped-up position. Other conditions to be differentiated at this age included aerography, congenital intestinal obstruction, feeding problems, "pylorospasm," hæmorrhagic disease of the newborn, and cerebral irritation. In later infancy and early childhood renal acidosis, peptic ulceration, cyclical vomiting, and intestinal obstruction might simulate a partial thoracic stomach. During the recovery phase coughing associated with bronchitis or a simple cold might provoke vomiting and so suggest pertussis.

RADIOLOGY

The 112 children here considered received a total of 255 examinations, of which 212 were by one observer (R. A.). Two main features were observed—gastro-œsophageal reflux and a partial thoracic stomach.

If the reflux was severe, barium moved in and out of the stomach synchronously with respiration, but often reflux had to be provoked by manœuvres to raise the intra-abdominal pressure. Occasionally all such tests failed until the child began to cry. Eructation of air could sometimes temporarily mimic the appearances of hiatal incompetence.

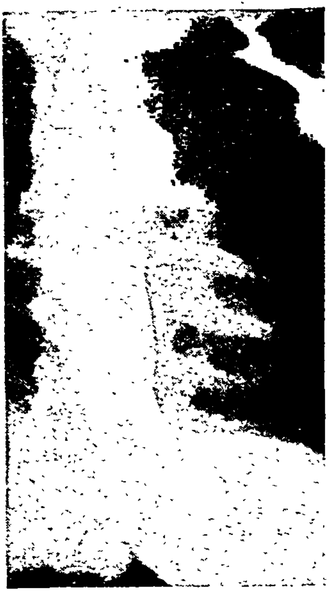

Fig. 3—Infant aged 4 months. Wide hiatus with very free reflux, loss of the gastro-œsophageal angle, and absence of indication of cardia (which at necropsy a few weeks later was found 2 cm. above diaphragm).

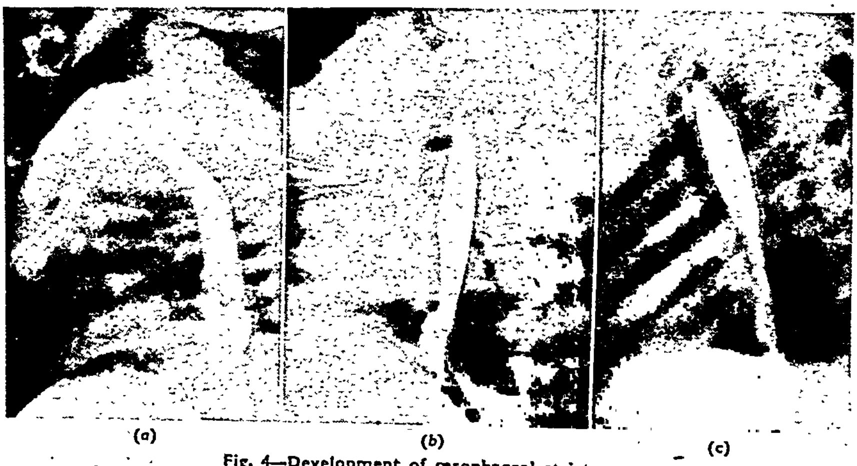
The other pathognomonic radiological feature was that the œsophagus had a normal course, without redundancy, but ended above the diaphragm at the highest point of a small, or very small, thoracic loculus of stomach. In the majority of cases there was a constriction representing the cardia; below this the lumen was expanded, often asymmetrically with respect to the axis of the œsophagus (fig. 1). The gastro-œsophageal angle was reduced, and the gastric mucosal folds converged upwards towards the hiatus, which was wider than usual (fig. 2). These folds could be seen to enter the thoracic loculus of the stomach, where they appeared as rather coarse vertical rugæ, although sometimes irregular folds (greater-curvature type) were also present. At the constriction representing the cardia they were gathered together, to diverge again above as finer œsophageal folds. Sometimes the thoracic part of the stomach was evident at a glance; but often it only filled completely for very fleeting periods, especially when reflux was slight or absent, and not infrequently a correctly timed radiograph was unobtainable. This emphasised the great importance of careful fluoroscopy; occasionally several examinations had to be made before the diagnosis was established.

In a few children reflux appeared at first to be due to a wide incompetent hiatus alone. In such the œsophagus was often dilated but appeared as a tube of even calibre, with no locally expanded portion to indicate the thoracic



(a) (b) (c)

Fig. 4—Development of œsophageal stricture:
(a) Aged 3 months. Shallow constriction above diaphragm at site of cardia.
(b) Aged 15 months. Ulcer-like niche just above cardia.
(c) Aged 2½ years. Stricture

part of the stomach and with no constriction at the cardia, especially when the gullet was well filled. But close observation usually showed a transient yet recurrent slight constriction just above the diaphragm; minimal amounts of barium showed that the mucosal folds were gathered together at this level, diverging below it to pass vertically into the abdomen. Such appearances might mimic chalasia (hiatal incompetence with a normally situated cardia). This point is illustrated by 1 infant in whom the hiatus appeared wide but there was no indication of the cardia (fig. 3), yet subsequent necropsy confirmed that the stomach was partially thoracic. Berenberg and Neuhauser (1950) regarded a supra-diaphragmatic stomach as rare in infancy, which is contrary to our experience. Perhaps some of their cases of "chalasia" were examples of this type of partial thoracic stomach.

When a complicating stricture was present, the exact point of transition from œsophagus to stomach was often ill defined. Only 1 child developed a stricture while under observation: the shallow indentation at the cardia became deeper, and an ulcer-like niche preceded the stricture (fig. 4). Several other infants showed slight irregularities of œsophageal contour, probably due to œsophagitis, but these resolved without stricture.

Until the time of weaning, no radiological difference was demonstrable between the first and second groups. Though in some infants minimal reflux suggested the probability of an early improvement, gross reflux did not necessarily mean a protracted course. After symptomatic improvement the partial thoracic stomach persisted unchanged, although reduced or absent reflux made it much more difficult to demonstrate. Occasionally barium ceased to regurgitate into the œsophagus although it still passed up into the thoracic part of the stomach; more often an effective closure mechanism seemed to develop at the level of the diaphragm, thus preventing or reducing the amount of barium passing into the thorax.

When a stricture had developed, a stationary state seemed more common than progression. Two children treated by repeated dilatation lost all X-ray evidence of stricture.

TREATMENT

Medical treatment often gave very satisfactory results, particularly when begun early in infancy. The essential basis of such therapy was to maintain the baby in as near an upright position as possible, both by night and by day. This was done with the aid of a specially constructed harness, because elevation of the head of the cot was found to be inadequate.

Feeds to meet the infants' full nutritional requirements were introduced cautiously over several days, because too rapid an increase tended to cause diarrhœa. If vomiting persisted despite an upright position, thickening of the feeds with cornflour or 'Benger's Food' was a valuable additional measure. Home treatment was fully satisfactory if the mother was sensible and coöperative.

We shall not discuss surgical treatment. It is, however, our opinion that in the large majority of cases a minor degree of partial thoracic stomach in infancy is a relatively benign condition. Thus both the *indications for surgery and the assessment of its results* should be studied critically.

PROGNOSIS

It is reasonable to suppose that most children with complicating strictures reach hospital practice, and on an average during the last sixteen years 1 case of œsophageal stricture has been admitted each year to the Children's Hospital, Birmingham. When this figure is compared with the total of 18 infants with a partial thoracic stomach admitted in one year (1951) it suggests that only a very small proportion of all affected children eventually develop a stricture—probably less than 10%. This small proportion is contrary to the impression conveyed by a review of the published reports, according to which [illegible] of about 103 children had an œsophageal stricture.

As already indicated, the effect of weaning to solids seems to be a useful prognostic sign. If weaning produces no symptomatic improvement, a prolonged course with vomiting until the age of 4 years or more is likely. Our observations suggest that about a quarter of all untreated cases fall into this group, which includes the relatively few who develop an œsophageal stricture. The other three-quarters have a benign course, with cessation or great relief of symptoms by the age of 2 years and no subsequent relapse in childhood.

DISCUSSION

Whether the basic defect is a congenital disproportion of the œsophagus or a defect of the diaphragmatic hiatus with a secondary sliding hernia, the cause of symptoms is the same—i.e., the incompetence of the gastro-œsophageal valve mechanism, permitting reflux of gastric contents into the œsophagus. Some workers (Allison 1948, Husfeldt et al. 1951, Belsey 1952) have strongly favoured the view that the hiatal defect is nearly always primary, and this is undoubtedly often true of cases where much of the stomach lies in the chest. Where, however, only a small and often tubular loculus of stomach lies above the diaphragm, a primary hiatal defect seems less certain to be the explanation in all instances. Accordingly we have preferred the non-committal term "partial thoracic stomach" to either "congenital short œsophagus" or "hiatus hernia."

It is apparent that the condition is a relatively common cause of vomiting in infancy, and in the past has often masqueraded under various unsatisfactory diagnoses. Increased use of fluoroscopy will be well rewarded, although not uncommonly it requires considerable experience and sometimes several examinations are needed before the diagnosis is established.

The relatively short and benign course in three-quarters of the children, the gradual symptomatic cure in many of those with more prolonged vomiting, and the low incidence of œsophageal stricture are contrary to the impression conveyed by the literature, in which complicated cases predominate. The eventual outcome in adult life is still unknown, and it is interesting to speculate how many of those patients presenting in later years with symptoms attributable to gastro-œsophageal incompetence have a forgotten history of vomiting in infancy.

SUMMARY

From a study of 112 children with minor degrees of partial thoracic stomach an account is given of the clinical picture, radiology, treatment, and prognosis during infancy and childhood.

This condition is a not uncommon cause of vomiting in infancy and has often escaped diagnosis. At this age constant maintenance of an erect posture, by means of a special harness, is often an effective form of treatment.

The infant's reaction to the introduction to a solid diet is a useful guide to prognosis. If vomiting ceases or abates at this time, gradual complete cessation of all symptoms is usual by the age of 2 years, and there is no recurrence during childhood. If weaning does not cause vomiting to decrease, the course is likely to be longer; but, even so, gradual symptomatic cure is still usual. In both instances the partial thoracic stomach persists but the valve mechanism between gullet and stomach becomes more efficient.

Of children with minor degrees of partial thoracic stomach, only a small proportion develop an œsophageal stricture.

We are grateful to Mr. A. L. d'Abreu, Dr. C. G. Te [illegible] and Dr. Frances Braid for helpful criticism and to the consultants of the Children's Hospital, Birmingham, whose patients we examined. A previous study of infantile vomiting

of uncertain origin undertaken by Dr. B. S. B. Wood (1952) made easier the completeness of our review.

DIAZOTISATION OF BILIRUBIN AFTER CHOLELITHIASIS WITHOUT VISIBLE JAUNDICE

L. Schalm

M.D. Utrecht

From the medical department of the Municipal Hospital, Arnhem, Holland

In attacks of upper abdominal pain not followed by visible jaundice or by bilirubinuria the rate of diazotisation of the blood-bilirubin may indicate whether cholelithiasis is responsible or not.

Diaphragmatic pleurisy, coronary occlusion, peptic ulcer, pancreatitis, cholelithiasis, &c., may give a clinical syndrome which is extremely difficult to diagnose correctly. When there is visible jaundice, however slight, there are good grounds for suspecting disease of the gall-bladder and bile-ducts; but where there is no jaundice the most thorough examination may fail to make the diagnosis clear. Though an increased urinary excretion of urobilin may be helpful, in our experience this happens too irregularly, and is not specific enough for it to be absolutely reliable. In attacks of cholelithiasis without visible jaundice the blood-bilirubin level may rise slightly, but this is not always conclusive. On the other hand, the rate of diazotisation of the bilirubin may be much raised and is then highly indicative.

Hence this finding makes a complete examination of the gall-bladder necessary or supports a suspected diagnosis of cholelithiasis.

METHODS

The method of Jendrassik and Cleghorn was followed, and a 'Lumetron' 4–2 colorimeter was used. Besides the total amount of bilirubin, the percentage of bilirubin diazotised in ten minutes was determined (for a detailed description see Schalm and Schulte 1950).

Blood was taken by venepuncture some hours after the beginning of the attack or, when the patient was referred to the clinic after a longer lapse of time, as soon as possible. The rate of diazotisation of the bilirubin was observed if possible for a few days afterwards. The values were determined as soon as possible after the sample of blood had been taken. Normal values were up to 1 mg. of total bilirubin per 100 ml., with a diazotisation-rate of 2–10% in ten minutes (1 mg. = 2 units Hymans van den Bergh).

RESULTS

During this investigation 31 cases of upper abdominal pain due to cholelithiasis, without visible jaundice, were collected. The diagnoses in 24 cases were verified by operation; the rest were clinically beyond doubt. In 16 of these cases the blood-bilirubin level was normal, whereas in the 15 other cases there was a slight transient rise in the blood-bilirubin level which did not exceed 2 mg. per 100 ml. All the cases, however, showed an undeniable acceleration of the rate of diazotisation of the bilirubin up to 30–80%, instead of the normal 2–12%, in ten minutes (see table). Bilirubinuria did not develop.

Not every attack of cholelithiasis is followed by this increase in the rate of diazotisation of bilirubin. Even in the same patient one attack may be followed by a distinct increase and the next attack by none. 3 such cases were observed, 2 of them being verified by operation and the 3rd being clinically certain.

On the other hand, in 8 cases of cholelithiasis proved at operation there was no increase in the rate of diazotisation of bilirubin after a typical severe attack of pain. Therefore, though such an increase points to cholelithiasis, its absence does not rule out cholelithiasis.

To find whether gall-bladder disease not causing attacks of pain was accompanied by an increased rate of diazotisation of bilirubin, similar investigations were made in 14 cases in which, in the course of routine examination or laparotomy for other causes, gall-stones were found which had never caused attacks of pain. The findings were well within normal limits. The same was found in 3 cases of lambliasis.

It must be emphasised that the increased rate of diazotisation of bilirubin and the transient rise of the blood-bilirubin level must be closely linked with an attack of upper abdominal pain for them to be of use in the diagnosis of cholelithiasis. The changes are most pronounced within twenty-four hours from the beginning of the attack and decrease rapidly in the next few days. These conditions have to be kept in mind because a single determination of an increased rate of diazotisation

with a slightly raised blood-bilirubin level is not pathognomonic; this may be found in the course of a developing or decreasing jaundice due to hepatic damage. In the latter case, however, the swift change combined with an attack of pain is lacking.

To discover whether attacks of abdominal pain other than those due to cholelithiasis could cause the same phenomenon, similar investigations were made in cases of appendicitis. In 4 of these, in which a seriously inflamed appendix was found at operation, the results showed a definite acceleration in diazotisation with a slight or moderate rise of the blood-bilirubin level. Though an attack of cholelithiasis without significant cholecystitis will give a different clinical picture from that of acute appendicitis, it may be far more difficult to differentiate between acute cholecystitis and acute appendicitis. In such cases it is impossible to rely on the rate of diazotisation.

In cases of duodenal or gastric ulcer, perforated duodenal ulcer, pancreatitis, renal colic, extra-uterine pregnancy, and Bornholm's disease the blood-bilirubin level and the rate of diazotisation of bilirubin were completely normal.

The cases of acute coronary thrombosis, however, need some further discussion. In the 3 cases in which the blood was examined a day after the attack of pain normal values were found. In a 4th case normal values were found on the sixth day. In the 5th case normal values were found three days after the attack of pain, but in the subsequent weeks a rise and a fall in the rate of diazotisation were noticed—i.e., soon after the attack of pain the rate of diazotisation was not increased, and the subsequent change in its rate lacked the rapid onset so typical of the increased rate after attacks of cholelithiasis. Though the change came on much later after the attack of pain due to coronary thrombosis and was far less rapid than that after cholelithiasis, the increased rate of diazotisation may be found in principle after coronary occlusion.

The increase in the rate of diazotisation a comparatively long time after myocardial infarction may possibly be a consequence of circulatory insufficiency, since it is well known that the blood-bilirubin level very often rises in congestive heart-failure. In such cases we found that this rise in blood-bilirubin level was always accompanied by a definite acceleration of diazotisation (Schalm and Hoogenboom 1952).

DISCUSSION

The results show that after acute attacks of upper abdominal pain due to cholelithiasis a distinct rise in the rate of diazotisation of bilirubin may be found. This rise is of diagnostic value when the attacks are not followed by visible jaundice or bilirubinuria. It is already observable a few hours after the beginning of the attack of pain, is most pronounced within twenty-four hours of it, and in many cases soon returns to normal. Therefore, in looking for this feature it is necessary to determine the rate of diazotisation soon after the attack of pain. To maintain a margin of safety, only an acceleration in diazotisation to 30% or more in ten minutes was considered to be significant. It is important to compare this value, if possible, with a value determined before an attack, and to check whether any increase found in the rate diminishes considerably in the next few days. It has been shown that value can only be attached to a positive finding. The absence of this rise does not exclude the existence of gall-stones, since in several cases of cholelithiasis proved at operation the temporary increase in the rate of diazotisation was not found after an attack of pain.

Where the diagnosis of cholelithiasis is highly probable and no increase in the rate of diazotisation is found after an attack of pain, it is advisable to look for this rise repeatedly, since not every attack of cholelithiasis in the same patient is followed by such a rise. Calculation of the amounts of quick-reacting (direct) bilirubin and slow-reacting (indirect) bilirubin simultaneously present in the blood by the method described by Schalm and Schulte (1950) appears to explain this phenomenon. After the attack a small quantity of quick-reacting bilirubin enters the blood for a short time, thus causing only a slight rise of the blood-bilirubin level, but a pronounced increase in the rate of diazotisation. This amount of quick-reacting bilirubin joins the, at least initially, normal amount of slow-reacting bilirubin physiologically in the blood.

In 22 out of 24 cases, the stones were located either in the gall-bladder or in the cystic duct. In the 2 exceptions the stone was found in the common hepatic duct. The former localisation of the stones might be expected, because a stone in the common hepatic duct usually causes frank jaundice, and cases with a blood-bilirubin level over 2 mg. per 100 ml. were excluded. Most cases with an obstructed gall-bladder containing stones do not cause frank jaundice; in these circumstances the phenomenon described is of great value.

It must be borne in mind that the rate of diazotisation of bilirubin may increase in appendicitis and in myocardial infarction. In such cases the increase takes place later after the attack of pain than it does in cholelithiasis; but the possibility of confusion remains.

SUMMARY

Determination of the rate of diazotisation of the bilirubin soon after an acute attack of upper abdominal pain, not followed by jaundice or bilirubinuria, may give findings indicative of cholelithiasis, thus making a complete examination of the gall-bladder necessary or supporting a tentative diagnosis.

These findings are a considerable increase in the rate of diazotisation of the bilirubin, already a few hours after the attack of pain, even if the blood-bilirubin level is hardly above normal.

Only a positive finding is of any value. A negative finding does *not* rule out cholelithiasis.

An increase in the rate of diazotisation of bilirubin may be found in some cases of serious appendicitis or of myocardial infarction, but usually later after the attack of pain than in cholelithiasis. In principle, however, these diseases may be sources of confusion.

THE final assessment of the value of drugs in the management of peptic ulcer must depend on therapeutic trials; but these are difficult to interpret, whether they are based on relief of symptoms, on relapse-rate, or on rate of healing. It is therefore important to assess the potential therapeutic value of drugs as accurately as possible from their effects on gastric secretion and

*Injection of 100 mg. of C6.

motility. For this purpose the drugs must be tested under the actual conditions in which they are to be used in the treatment of patients with gastric or duodenal ulcers. Some of the tests commonly used are misleading because they reveal pharmacological effects which are not relevant to the clinical evaluation of the drugs. Thus it can be shown that, under certain experimental conditions, antisecretory drugs, such as atropine, hexamethonium, and banthine, will inhibit gastric secretion. but it does not follow that they will produce achlorhydria in patients with duodenal ulcers under the conditions of clinical use.

The conflicting reports of the effect of hexamethonium on gastric acidity illustrate the importance of the method employed for assessing the potential therapeutic value of an antisecretory drug. By continuous gastric aspiration, Kay and Smith (1950, 1951) found that hexamethonium iodide (C6) inhibited the spontaneous secretion of hydrochloric acid, a single injection of 100 mg. producing achlorhydria for as long as three hours; it also inhibited gastric motility. On the other hand, Rowlands and Friedlander (1952) noted that C6 did not raise the pH of small samples of gastric juice aspirated at intervals in the course of short experiments on the effect of C6 on pain in patients with peptic ulcers. Paton and Zaimis (1950) have emphasised the fact that the clinical usefulness of drugs which produce neuromuscular block can be established only by testing them under the conditions in which they are to be used. We have therefore applied the sampling technique to determine whether C6, alone or in combination with alkali, will eliminate free acid in patients with duodenal ulcers undergoing routine medical treatment in hospital.

METHOD

The observations were made on patients with radiologically proven duodenal ulcers; no case showed evidence of pyloric stenosis. The effect of single or repeated injections of C6 on the pH of the intragastric contents was studied under the following conditions: (1) in short experiments on fasting patients, (2) during the night, (3) in patients receiving a gastric diet or a continuous milk drip, and (4) in combination with alkali. Details of procedure are given under individual headings.

Small samples (5–15 ml.) of gastric contents were aspirated, usually hourly, through a Ryle's tube, most of the patients being screened to ensure that the metallic tip was in the body of the stomach. The stomach was not emptied at the beginning of the experiments, and continuous suction was never used. No attempt was made to prevent the swallowing of saliva. In those experiments in which observations were made during administration of a milk drip, the drip was given at a rate of 120 ml. per hour, and samples were aspirated after interrupting the drip and clearing the tube with air. In some cases a double-lumen tube was used so that samples could be aspirated simultaneously from two sites within the body of the stomach $3^1/_2$ in. apart.

The pH of the samples was measured with a sealed glass electrode at room-temperature within forty-eight hours of the collection. Preliminary observations showed that the pH did not change by more than +0·1 during storage at 6°C for forty-eight hours.

Hexamethonium bromide (C6) was injected intramuscularly in doses of 100 mg. In some experiments the gastric contents were neutralised by giving 8 g. of a powder consisting of equal parts of magnesium trisilicate, heavy magnesium carbonate, and calcium carbonate.

RESULTS

Effect of C6 on Gastric Acidity in Fasting Patients

The tests were made on 6 patients who had been fasting for ten hours. Samples of gastric juice were aspirated before, and hourly for four hours after, an injection of 100 mg. of C6. The pH did not rise significantly after the injection; the slight changes observed in the pH were within the range of the spontaneous fluctuations in control experiments without C6. As the stomach was not emptied initially in any of these tests, it seemed possible that a more useful indication of the effect of C6 would be obtained by injecting the drug four-hourly for twenty-four to seventy-two hours before starting the test. In every case the pH was below 2·0 at the beginning of the test, and no significant change took place after the injection of the test dose.

Effect of C6 on Gastric Acidity during the Night

In 15 patients the pH was measured hourly from 8 P.M. to 9 A.M., no food being given after 6 P.M.: 11 patients were given injections of C6 at 10 P.M., 2 A.M., and 6 A.M.; 1 received injections at 10 P.M. and 4 A.M.; and 3 were given a single injection at 10 P.M. All the patients had received injections during the day at 10 A.M. and 4 P.M. Control tests were done on most of the patients, omitting the injections of C6.

The results are summarised in table I. C6 had no significant effect on the pH in cases 1–8. In cases 9 and 10 it may have raised the pH of some of the samples by a fraction of a unit, but most of the readings were below pH 2·0. Free acid was absent (pH>3) in one sample in case 11, in four samples in case 12, and in five samples in case 13; but the pH of most of the other samples was below 2·0. The effect of C6 was studied on two separate occasions in cases 14 and 15. In the first test in case 14 free acid was absent in five samples, all of which were very heavily contaminated with bile; in the second test free acid was absent in only two of the samples, and the pH of the remainder was below 2·0. The effect of C6 was also variable in patient 15, free acid being absent in seven samples during one test but in only three samples during the other.

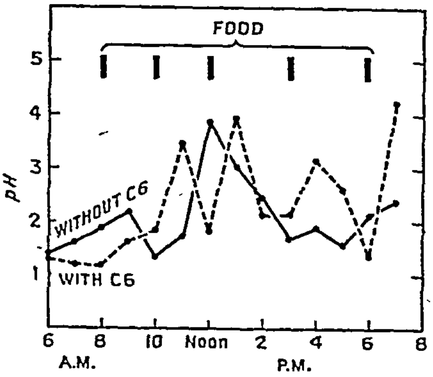

Fig. 1—Effect of C6 on gastric acidity in a patient on a gastric diet. Injections of 100 mg. C6 given at 6 a.m. and 2 p.m.

Thus C6 did not eliminate free acid throughout the night in any of these tests. It produced achlorhydria in 3 patients for from five to seven hours; but, when the test was repeated in 2 of these patients, free acid was absent for only two or three hours. In most of the patients free acid was present in every sample throughout the night, and the pH usually remained below 2·0.

Effect of C6 on Gastric Acidity in Patients on a Gastric Diet

The pH was measured hourly from 7 A.M. to 7 P.M. in 4 patients on a first-stage gastric diet. During the next three days 100 mg. of C6 was given at 6 A.M., 2 P.M., and 10 P.M., and on the third day the pH was again measured hourly. Increases of pH were observed after some of the meals, but there was no evidence that the administration of C6 had any significant effect (see fig. 1).

Effect of C6 in Patients on a Continuous Milk Drip

The pH was measured at short intervals throughout two periods of twenty-four hours in 3 patients receiving continuous milk drips; on the second occasion six-hourly injections of C6 were given in addition. On both occasions the fluctuations of pH were so pronounced that it was impossible to determine from these three tests whether C6 had any significant effect, but the pH often fell below 2·0 despite the administration of the drug. In one of these patients the pH remained above 3 for eight out of twenty-four hours without C6, and for only one out of twenty-four hours while C6 was being administered. In another patient the pH was more than 3·0 for nine out of twenty-four hours without C6, and for thirteen out of twenty-four hours while he was receiving C6. The third patient was kept on the milk drip for four successive periods of twenty-four hours each. During the first three of these he was not given C6 and the pH was above 3·0 for five, fifteen, and eight hours out of twenty-four. During the fourth period of twenty-four hours he was given C6 and the pH remained more than 3·0 for sixteen hours.

Effect of C6 on Gastric Emptying

The following observations show that C6 usually increases the volume of the gastric contents because it delays gastric emptying.

The stomach was emptied as completely as possible at 9 A.M. in 13 patients who had been fasting for fourteen hours, and this was repeated on another occasion after giving C6 at 10 P.M., 2 A.M., and 6 A.M. In 8 of the patients the volume of the resting juice was significantly greater when C6 was given; in the other 5 patients there was no significant difference. The mean volume was 38 ml. without C6 and 127 ml. with C6. The increased volume must have been due to delayed gastric emptying, because Kay and Smith (1950) have shown that C6 reduces the volume of gastric secretion, and there was no evidence of increased regurgitation of duodenal contents, the degree of bile-staining and the pH of the gastric juice being about the same on both occasions.

The delay in emptying was confirmed by the observation that, after the administration of 8 g. of alkaline powder and an injection of C6, a deposit was still present in the gastric samples aspirated three hours later in 4 patients, and five, six, and seven hours later in 3 others.

Effect of C6 and Alkali on Gastric Acidity

As C6 usually failed to produce achlorhydria but delayed gastric emptying, the following observations were made to determine whether it could be used to prolong the effect of alkali. The pH of the gastric contents was raised to more than 4·0 in each of 5 fasting patients by administering 8 g. of alkali, and samples were aspirated hourly or half-hourly until the pH had returned to its initial value. The procedure was repeated on a second occasion, an injection of C6 being given at the same time as the alkali. After the pH had fallen below 4·0, it always returned to its initial value, less than 2·0, during the next hour. C6 prolonged the neutralising effect of the alkali in 4 of the 5 patients by one hour, two hours, three and a half hours, and five hours.

An attempt was made to control the nocturnal acidity in 7 patients by giving injections of C6 at 10 A.M. and 4 P.M., 8 g. of alkali and an injection of C6 at 10 P.M., and further injections of C6 at 2 A.M. and 6 A.M. The results are summarised in table II. In 3 patients (cases 6, 16, and 17) free acid was eliminated for from six to nine hours after the administration of the alkali at 10 P.M., but in the 4 other patients free acid was eliminated for only one hour. The effect of C6 plus alkali also varied in

the same patient at different times. Thus a patient was given alkali and C6 at 10 P.M. on two separate occasions. The pH remained more than 4 for three and a half hours in the first test, but it fell below 2 in less than an hour in the second test.

Effect of C6 on Mixing of Gastric Contents

James and Pickering (1949) have shown that "quite large variations in acidity" sometimes exist at points 3 or 4 in. apart in the body of the stomach, and that systematic differences occur after meals between the acidity in the body of the stomach and the acidity in the pyloric antrum. It seemed possible that C6 might exaggerate such differences by inhibiting motility. If mixing of the gastric contents was inadequate, the pH of small samples might not be representative of the acidity throughout the stomach, particularly after the administration of alkali.

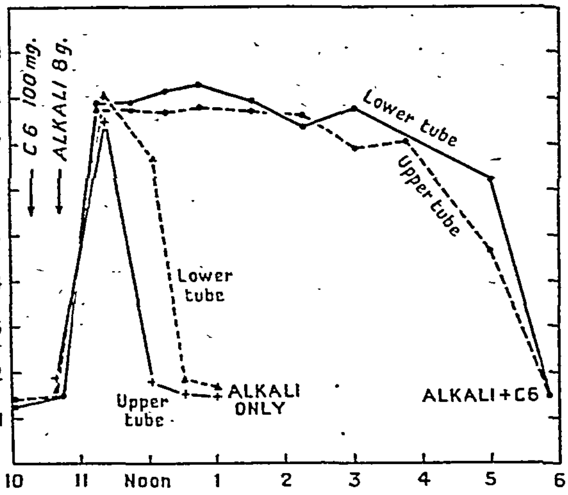

Fig. 2—Effect of alkali alone and of alkali plus C6 on pH of samples of gastric juice aspirated through a double-lumen tube from two sites in the body of the stomach $3^{1}/_{2}$ in. apart.

A double-lumen tube was used in 3 patients to obtain samples of gastric juice from two sites in the body of the stomach $3^{1}/_{2}$ in. apart, after the administration of alkali alone and of alkali plus C6. There was good agreement between the pH of the samples from the two sites in every case (fig. 2), discrepancies occurring only at the end of the tests, when the pH of samples from the upper lumen began to fall a little earlier than those from the lower; but this also happened when alkali was given without C6.

At the end of one of the tests in which both alkali and C6 were given, the stomach was emptied as completely as possible by aspirating its contents in separate fractions of 10–20 ml. after the pH of samples from both tubes had returned to below 2·0. The pH of the first five fractions ranged from 1·70 to 2·13, but the last two fractions had values of 6·7 and 7·2, and both contained heavy deposits. Similar discrepancies in the acidities of different fractions of the gastric residue were observed in other patients, and heavy deposits were present in some of the fractions. The pH of some of the fractions which contained deposits was below 2·0 when measured at the bedside immediately after aspiration; but when measured again, after the specimen had been shaken, the pH was often very much higher. In some cases the pH continued to rise while it was being measured, if the specimen was shaken vigorously. These deposits must have contained some of the alkaline powder which had been given at the beginning of the tests and had not reacted with the hydrochloric acid secreted in the stomach. If alkaline powder is dropped into a beaker containing N/10 hydrochloric acid at 37°C, most of it deposits as a sediment, and little or no reaction takes place until the beaker is shaken vigorously. By inhibiting motility, C6 prevents adequate mixing of the gastric contents, and a variable proportion of a dose of alkaline powder may remain in the stomach for many hours as a sediment without reacting with the acid secretion. To obtain a correct estimate of the acidity within the stomach after the administration of alkali with C6, the samples should not be shaken before the pH is measured. This was not appreciated at first, and some of the pH readings recorded here may be too high because in some of the earlier experiments the specimens were shaken vigorously before the pH was measured.

DISCUSSION

Hexamethonium has been used in the treatment of peptic ulcer since Kay and Smith (1950) reported that it inhibited the spontaneous secretion of hydrochloric acid. They found that a single injection of 100 mg. produced achlorhydria for as long as three hours, and Riddell (1951) confirmed their finding that repeated doses cause "a substantial reduction in the volume and acidity of the night secretion" in patients with duodenal ulcers. *These observations were made by emptying the stomach* at the beginning of the test and then aspirating continuously after giving the drug. On the other hand, the results reported here show that the volume of the gastric contents usually increases after the administration of C6, and the acidity does not change significantly, the pH remaining below 2·0 in most cases. Very few patients showed achlorhydria for even a few hours during the night despite four-hourly injections of C6. Our findings, however, are not incompatible with the pharmacological effects observed by Kay and Smith, but the therapeutic implications are entirely different, if the object of treatment is to eliminate free acid and peptic activity.

The effect of antisecretory drugs, such as atropine, hexamethonium, and banthine, on the volume and acidity of the intragastric contents is determined not only by their action on gastric secretion but also by the fact that they inhibit gastroduodenal motility and thus prolong the emptying-time of the stomach. By aspirating the stomach continuously, Kay and Smith showed that C6 depresses gastric secretion; but this technique masks the effect of the delay in gastric emptying. Thus C6 may cause a statistically significant reduction in the volume and acidity of the gastric secretion, but the volume of the intragastric contents may actually increase, and the pH may not rise significantly. Using the sampling technique we tried to study the effect of hexamethonium under the actual conditions in which it would be used clinically. Continuous aspiration provides important information about the effect of drugs on the spontaneous secretion of gastric juice and on the secretory response to insulin and histamine, but the findings may be misleading if interpreted in terms of the clinical usefulness of the drugs. This also applies to the method employed for measuring acidity and for expressing the results. The titration method, which was used by Kay and Smith,

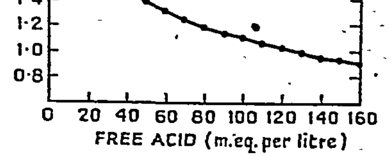

Fig. 3—Relation between pH and titratable free acid.

The results are summarised in table I. C6 had no significant effect on the pH in cases 1–8. In cases 9 and 10 it may have raised the pH of some of the samples by a fraction of a unit, but most of the readings were below pH 2·0. Free acid was absent (pH>3) in one sample in case 11, in four samples in case 12, and in five samples in case 13; but the pH of most of the other samples was below 2·0. The effect of C6 was studied on two separate occasions in cases 14 and 15. In the first test in case 14 free acid was absent in five samples, all of which were very heavily contaminated with bile; in the second test free acid was absent in only two of the samples, and the pH of the remainder was below 2·0. The effect of C6 was also variable in patient 15, free acid being absent in seven samples during one test but in only three samples during the other.

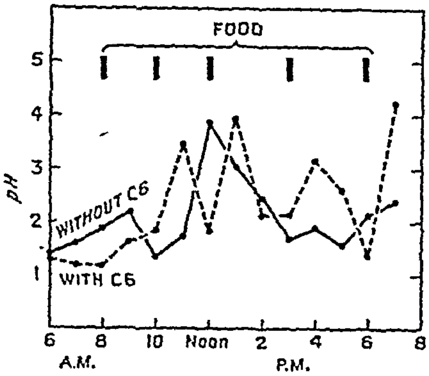

Fig. 1—Effect of C6 on gastric acidity in a patient on a gastric diet. Injections of 100 mg. C6 given at 6 a.m. and 2 p.m.

Thus C6 did not eliminate free acid throughout the night in any of these tests. It produced achlorhydria in 3 patients for from five to seven hours; but, when the test was repeated in 2 of these patients, free acid was absent for only two or three hours. In most of the patients free acid was present in every sample throughout the night, and the pH usually remained below 2·0.

Effect of C6 on Gastric Acidity in Patients on a Gastric Diet

The pH was measured hourly from 7 A.M. to 7 P.M. in 4 patients on a first-stage gastric diet. During the next three days 100 mg. of C6 was given at 6 A.M., 2 P.M., and 10 P.M., and on the third day the pH was again measured hourly. Increases of pH were observed after some of the meals, but there was no evidence that the administration of C6 had any significant effect (see fig. 1).

Effect of C6 in Patients on a Continuous Milk Drip

The pH was measured at short intervals throughout two periods of twenty-four hours in 3 patients receiving continuous milk drips; on the second occasion six-hourly injections of C6 were given in addition. On both occasions the fluctuations of pH were so pronounced that it was impossible to determine from these three tests whether C6 had any significant effect, but the pH often fell below 2·0 despite the administration of the drug. In one of these patients the pH remained above 3 for eight out of twenty-four hours without C6, and for only one out of twenty-four hours while C6 was being administered. In another patient the pH was more than 3·0 for nine out of twenty-four hours without C6, and for thirteen out of twenty-four hours while he was receiving C6. The third patient was kept on the milk drip for four successive periods of twenty-four hours each. During the first three of these he was *not given C6 and the pH* was above 3·0 for five, fifteen, and eight hours out of twenty-four. During the fourth period of twenty-four hours he was given C6 and the pH remained more than 3·0 for sixteen hours.

Effect of C6 on Gastric Emptying

The following observations show that C6 usually increases the volume of the gastric contents because it delays gastric emptying.

The stomach was emptied as completely as possible at 9 A.M. in 13 patients who had been fasting for fourteen hours, and this was repeated on another occasion after giving C6 at 10 P.M., 2 A.M., and 6 A.M. In 8 of the patients the volume of the resting juice was significantly greater when C6 was given; in the other 5 patients there was no significant difference. The mean volume was 38 ml. without C6 and 127 ml. with C6. The increased volume must have been due to delayed gastric emptying, because Kay and Smith (1950) have shown that C6 reduces the volume of gastric secretion, and there was no evidence of increased regurgitation of duodenal contents, the degree of bile-staining and the pH of the gastric juice being about the same on both occasions.

The delay in emptying was confirmed by the observation that, after the administration of 8 g. of alkaline powder and an injection of C6, a deposit was still present in the gastric samples aspirated three hours later in 4 patients, and five, six, and seven hours later in 3 others.

Effect of C6 and Alkali on Gastric Acidity

As C6 usually failed to produce achlorhydria but delayed gastric emptying, the following observations were made to determine whether it could be used to prolong the effect of alkali. The pH of the gastric contents was raised to more than 4·0 in each of 5 fasting patients by administering 8 g. of alkali, and samples were aspirated hourly or half-hourly until the pH had returned to its initial value. The procedure was repeated on a second occasion, an injection of C6 being given at the same time as the alkali. After the pH had fallen below 4·0, it always returned to its initial value, less than 2·0, during the next hour. C6 prolonged the neutralising effect of the alkali in 4 of the 5 patients by one hour, two hours, three and a half hours, and five hours.

An attempt was made to control the nocturnal acidity in 7 patients by giving injections of C6 at 10 A.M. and 4 P.M., 8 g. of alkali and an injection of C6 at 10 P.M., and further injections of C6 at 2 A.M. and 6 A.M. The results are summarised in table II. In 3 patients (cases 6, 16, and 17) free acid was eliminated for from six to nine hours after the administration of the alkali at 10 P.M., but in the 4 other patients free acid was eliminated for only one hour. The effect of C6 plus alkali also varied in

or easily irritated ears, a fact they do not always appreciate." There are many deaf persons in whom the greatest efficiency which might be obtained from an aid is reduced considerably because of discharging ears. I report here an investigation of the effect of the insert in active chronic otitis media.

INVESTIGATION

From a large number of patients with chronic otitis media for whom an aid was prescribed or who already used a medresco external aid 22 were selected and examined at the audiology unit of the Royal National Throat, Nose, and Ear Hospital from April to October, 1951, and re-examined on subsequent occasions.

Each patient had the ears, nose, and throat examined thoroughly. The aural discharge was examined bacteriologically; the hearing tests consisted of voice tests in an ordinary hearing environment, amplified speech tests (both unaided and with external and insert hearing-aids), and a pure-tone threshold audiogram by bone and air conduction. Eventually an individually moulded insert was fitted, and an insert type of medresco aid issued. The patients were instructed in maintaining a careful aural toilet and in cleaning the insert (daily with soap and water, afterwards drying it carefully).

Besides the small controlled series we began to prescribe insert aids to patients with discharging ears (from chronic otitis media) who attended at this clinic, as soon as it became apparent that this was not harmful. Further, whenever a patient with an external aid returned with various complaints (discomfort, headache, very conspicuous, hearing not very good), and when the only reason for prescribing an external aid was a discharging ear due to chronic otitis media, the external aid was changed for an insert type. The patients were seen several weeks later at a routine check clinic.

RESULTS

The ages of the patients ranged from 26 to 73 years. In all cases the deafness was of long duration. In 13 it was moderate, conductive; in 6 severe, conductive; and in 3 severe, mixed, predominantly conductive. In all cases the prescription of a hearing-aid was justified because of social disability, and in 9 cases there was also some disability at work. In all cases the hearing-aid helped to restore the ability of auditory communication. 11 patients had had an external aid before, and all of these appreciated the change to the insert type. All the patients had bilateral chronic otitis media, and 8 of them had undergone radical mastoidectomy. In 3 of these cases the insert was fitted in the cavity left by the operation.

In order of frequency the organisms found were *Staphylococcus albus* (9 cases), diphtheroids (8 cases), proteus (7 cases), gram-negative bacilli (5 cases), *Staph. aureus* (3 cases), *Neisseria catarrhalis* (1 case). In 6 cases no pathogenic organisms were detected.

The insert was fitted in 20 moist ears and 2 dry ones (chronic otitis media in a quiescent stage). The 2 dry ears remained dry, 1 after four months' observation and 1 after six months', and no ill effect was observed. Of the 20 moist ears 7 dried up at various periods after inserts were worn, and were still dry after five months' observation. In 1 case traces of discharge were observed and in 1 case the discharge diminished after six months. In 1 case there was more profuse discharge. In the rest of the cases no change was observed after ten months' observation. In none of the cases did the insert cause irritation, discomfort, or inflammation.

In 1 case one ear was moist and the other dry, but the discharging ear could hear better. Therefore the insert was fitted to that ear, with a satisfactory result from the functional point of view and no ill effect from the insert. In 1 case the ear subjected to radical mastoidectomy was moist but could hear better than the other ear, which was dry. The insert was fitted in the radical mastoid ear with good results.

Amplified speech tests were made to ascertain how much hearing was gained with the insert and the external aid. The average unaided hearing loss (at 40% word articulation level) was 53 decibels. The average gain with the insert type was 33 decibels, and with the external type 25 decibels.

DISCUSSION

The insert is made from an acrylic plastic material which is inert to the healthy skin. Allergic contact dermatitis or otitis externa is rare. A badly made insert, however, may have some ill effects. A good insert should be clear and smooth and should fit perfectly. Faulty processing may cause cloudiness or porosity (Denison et al. 1949); the insert then contains bubbles of free monomeric vapour produced by overheating the acrylic material, and this vapour is toxic. There is a theoretical possibility that the gas from the bubbles near the surface may have some ill effect. The rough surface of imperfectly polished inserts may cause irritation. Occasionally a decubitus sore on the auricle can be detected as a result of the pressure of a badly fitting insert. An insert which is not smooth, clear, and well fitting should be rejected.

The observation of the 22 cases, and of a much larger number of patients who attended a routine check, showed no ill effect from wearing an insert in an ear discharging because of chronic otitis media. A combination of discharge and insert does not irritate the skin of the meatus more than the discharge does by itself. The bacteriology of the discharge does not make any difference from this point of view. Patients soon learn that a comparatively dry ear hears better, and the use of the insert aid usually gives them a new impetus to take care of their discharging ears.

It has been argued that profuse discharge may block the insert; but such an ear is unfit for any kind of aid. Profuse discharge itself causes an additional impairment of hearing. The effect of the discharge on the external ear-piece is worse than on the insert. When soiled it is difficult to clean and it may be damaged in the cleaning. Thus a profusely discharging ear should be treated before an aid is prescribed. Almost all cases can be improved with regular aural toilet. If a patient is indolent towards his discharging ear and unwilling to maintain a reasonable aural hygiene, it is very unlikely that he will make a good use of his aid or look after it properly. It is not advisable to give a patient an aid and to neglect the treatment of a chronic otitis media.

When one ear is dry and the other is discharging, the decision about which side should have an insert fitted should be made from the functional point of view. If the hearing is appreciably better in the wet ear, one should not hesitate to prescribe the aid for that ear.

There are obvious indications for the use of an external aid—e.g., various types of chronic otitis externa, anatomical disfigurement of the meatus, stenosis of the meatal orifice, &c. In these cases, too, the bone-conduction aid is an alternative. It is important, however, to remember that the bone-conduction type of aid is less efficient than the air-conduction type as regards both its heavy battery consumption and its very restricted bandwidth of sound frequency. The battery consumption of the more powerful bone-conduction aids is roughly the same as that of the medresco external air-conduction aid, but the external aid scores over the bone-conduction aid on its better frequency characteristic. When a medresco bone-conduction aid becomes available for general use, a tendency may arise to prescribe it for all discharging ears. That would be unfortunate.

The indications for the various types of aid are not difficult to define. The decision must be made from the functional standpoint first of all. Modifying factors may be present, and accordingly a less efficient, but for the individual as a whole a more suitable, aid will have to be is more accurate than pH measurements because, at the high acidities which occur in duodenal ulcer, a small change in pH represents a large change in hydrogen-ion concentration (see fig. 3). Thus C6 may cause a "substantial reduction" in the output of free acid expressed in milli-equivalents per litre, but the change in pH may be very small. However, the pH unit is the more useful for assessing the clinical value of an antisecretory drug, since there is no evidence that a reduction in the output of acid would have any therapeutic significance unless the acid-pepsin factor was eliminated by increasing the pH to 3 or preferably 4. Moreover it can be calculated from Riddell's data that the effect of C6 on gastric secretion is less impressive when expressed in terms of the concentration rather than the total output of free acid. Indeed in one of Riddell's 5 cases C6 reduced the output of free acid during the night by 47·7%, but the concentration actually increased from 69·5 to 82 m.eq. per litre, which corresponds to a decrease in pH from 1·24 to 1·18. The effect on the concentration is the more reliable index in the clinical evaluation of hexamethonium, partly because continuous aspiration obscures the effect of the delay in gastric emptying, and partly because gastric secretion cannot be collected quantitatively in man, because the amount lost through the pylorus is unknown.

Moreover, our results show that hexamethonium, like atropine (Levin et al. 1951) and banthine (Atkinson 1952), produces variable and unpredictable results in different patients, and even in the same patient at different times. C6 is unlikely to raise the pH in a patient with a high rate of secretion, particularly if it causes a pronounced delay in gastric emptying. Thus, one of our patients showed a slight delay in the rate of emptying of a barium meal; C6 had no effect on the nocturnal pH, but the volume of the gastric residue next morning was 800 ml., compared with 100 ml. when no C6 was given. In our series of cases C6 was most effective in an elderly patient whose rate of secretion was so low that it was difficult to aspirate 10 ml. of gastric juice every hour during the night, even when C6 was not given; the presence of a duodenal ulcer was confirmed at operation. Even in this patient the effect of C6 on the nocturnal pH was variable. The clinical value of antisecretory drugs—e.g., banthine—in the treatment of duodenal ulcer is sometimes assessed by studying their effects in normal people. Such an assessment is not valid, because their effects in the presence of normal or low rates of secretion give little or no indication of their value for controlling gastric acidity in patients with duodenal ulcers, most of whom have a very high output of gastric juice.

The variable effect of C6 on the output of acid and on gastric emptying is also illustrated by the tests in which it was given in combination with alkali. Moreover, a drug which inhibits motility may prevent adequate mixing of the gastric contents, and alkaline powder may remain in the stomach for many hours without reacting with the acid secretion. The powder probably sediments in an alkaline pool in the most dependent part of the stomach, and the gastric juice forms a layer above it and flows through the pylorus without mixing. The fact that C6 had no significant effect on gastric acidity during the administration of a gastric diet or a milk drip is in keeping with the observation that it does not affect the secretory response to histamine, meat extracts (Kay and Smith 1951), or test-meals (Douthwaite and Thorne 1951).

It is possible, however, that hexamethonium may facilitate the neutralisation of hydrochloric acid in the duodenum by retarding the flow of gastric juice from the stomach—assuming that it does not depress the alkaline duodenal secretions. This hypothesis could only be tested by aspirating samples of fluid from the duodenal bulb, but there is indirect evidence that the pH of this fluid follows that of the gastric juice very closely. Rowlands and Friedlander (1952) found that C6 did not relieve attacks of pain in patients with duodenal ulcers although it inhibited gastroduodenal motility, but neutralisation with alkali gave prompt relief whether C6 had been administered or not.

Thus, although C6 depresses the spontaneous secretion of hydrochloric acid, it is unlikely to be useful in the treatment of duodenal ulcer, because it has little or no effect on the pH of the gastric contents in most patients. It will eliminate free acid for a few hours during the night in some patients, but its effect is variable and unpredictable, even when the drug is given by injection four-hourly, and its side-effects are unpleasant and may be dangerous.

SUMMARY

The effect of hexamethonium on gastric acidity has been studied in patients with duodenal ulcers by aspirating small samples of gastric juice at hourly intervals.

Its effect was variable and unpredictable. Single injections did not raise the pH significantly in fasting patients, and four-hourly injections eliminated free acid during the night in only a small proportion of patients and for only a few hours. C6 prolonged the neutralising effect of antacids in about half the patients; it had no significant effect on the pH in patients on a gastric diet or milk drip.

The assessment of the potential therapeutic value of antisecretory drugs—e.g., hexamethonium, atropine, and banthine—is discussed. Their effect on gastric acidity must be studied under the actual conditions in which they are to be used in clinical practice. Although hexamethonium reduces the volume and acidity of the gastric secretion, it is unlikely to be useful in the treatment of duodenal ulcer, because it usually increases the volume of the intragastric contents without raising the pH significantly.

We wish to thank Dr. J. B. Harman, Dr. J. C. Hawksley, Dr. Avery Jones, and Dr. E. E. Pochin for allowing us to make observations on patients under their care; and the sisters and nurses at St. Helier, the Central Middlesex, and University *College Hospitals for their kind coöperation.*

THE INSERT HEARING-AID IN A DISCHARGING EAR

L. FISCH
M.D. Brno, D.L.O.
RESEARCH ASSISTANT, AUDIOLOGY UNIT, ROYAL NATIONAL THROAT, NOSE, AND EAR HOSPITAL, LONDON

THE main advantages of the insert type of hearing-aid are its greater acoustic efficiency, its economical battery consumption, and the ease with which a good acoustic seal can be maintained between the insert and the meatus by using an individually made ear-mould. The insert is more comfortable and easier to conceal. Concealment of the aid is important for a great majority of hearing-aid users. Nobody likes to advertise a disability. It has been generally accepted that the insert aid is the one of choice, and the external type is for exceptional cases.

Opinions differ, however, about the insert in discharging ears. Some believe that, in a discharging ear because of a chronic otitis media, it is inadvisable to wear an insert. Gray and Cartwright (1951) said of the 'Medresco' aid: "The insert cannot be worn by patients with discharging or easily irritated ears, a fact they do not always appreciate." There are many deaf persons in whom the greatest efficiency which might be obtained from an aid is reduced considerably because of discharging ears. I report here an investigation of the effect of the insert in active chronic otitis media.

INVESTIGATION

From a large number of patients with chronic otitis media for whom an aid was prescribed or who already used a medresco external aid 22 were selected and examined at the audiology unit of the Royal National Throat, Nose, and Ear Hospital from April to October, 1951, and re-examined on subsequent occasions.

Each patient had the ears, nose, and throat examined thoroughly. The aural discharge was examined bacteriologically; the hearing tests consisted of voice tests in an ordinary hearing environment, amplified speech tests (both unaided and with external and insert hearing-aids), and a pure-tone threshold audiogram by bone and air conduction. Eventually an individually moulded insert was fitted, and an insert type of medresco aid issued. The patients were instructed in maintaining a careful aural toilet and in cleaning the insert (daily with soap and water, afterwards drying it carefully).

Besides the small controlled series we began to prescribe insert aids to patients with discharging ears (from chronic otitis media) who attended at this clinic, as soon as it became apparent that this was not harmful. Further, whenever a patient with an external aid returned with various complaints (discomfort, headache, very conspicuous, hearing not very good), and when the only reason for prescribing an external aid was a discharging ear due to chronic otitis media, the external aid was changed for an insert type. The patients were seen several weeks later at a routine check clinic.

RESULTS

The ages of the patients ranged from 26 to 73 years. In all cases the deafness was of long duration. In 13 it was moderate, conductive; in 6 severe, conductive; and in 3 severe, mixed, predominantly conductive. In all cases the prescription of a hearing-aid was justified because of social disability, and in 9 cases there was also some disability at work. In all cases the hearing-aid helped to restore the ability of auditory communication. 11 patients had had an external aid before, and all of these appreciated the change to the insert type. All the patients had bilateral chronic otitis media, and 8 of them had undergone radical mastoidectomy. In 3 of these cases the insert was fitted in the cavity left by the operation.

In order of frequency the organisms found were *Staphylococcus albus* (9 cases), diphtheroids (8 cases), proteus (7 cases), gram-negative bacilli (5 cases), *Staph. aureus* (3 cases), *Neisseria catarrhalis* (1 case). In 6 cases no pathogenic organisms were detected.

The insert was fitted in 20 moist ears and 2 dry ones (chronic otitis media in a quiescent stage). The 2 dry ears remained dry, 1 after four months' observation and 1 after six months', and no ill effect was observed. Of the 20 moist ears 7 dried up at various periods after inserts were worn, and were still dry after five months' observation. In 1 case traces of discharge were observed and in 1 case the discharge diminished after six months. In 1 case there was more profuse discharge. In the rest of the cases no change was observed after ten months' observation. In none of the cases did the insert cause irritation, discomfort, or inflammation.

In 1 case one ear was moist and the other dry, but the discharging ear could hear better. Therefore the insert was fitted to that ear, with a satisfactory result from the functional point of view and no ill effect from the insert. In 1 case the ear subjected to radical mastoidectomy was moist but could hear better than the other ear, which was dry. The insert was fitted in the radical mastoid ear with good results.

Amplified speech tests were made to ascertain how much hearing was gained with the insert and the external aid. The average unaided hearing loss (at 40% word articulation level) was 53 decibels. The average gain with the insert type was 33 decibels, and with the external type 25 decibels.

DISCUSSION

The insert is made from an acrylic plastic material which is inert to the healthy skin. Allergic contact dermatitis or otitis externa is rare. A badly made insert, however, may have some ill effects. A good insert should be clear and smooth and should fit perfectly. Faulty processing may cause cloudiness or porosity (Denison et al. 1949); the insert then contains bubbles of free monomeric vapour produced by overheating the acrylic material, and this vapour is toxic. There is a theoretical possibility that the gas from the bubbles near the surface may have some ill effect. The rough surface of imperfectly polished inserts may cause irritation. Occasionally a decubitus sore on the auricle can be detected as a result of the pressure of a badly fitting insert. An insert which is not smooth, clear, and well fitting should be rejected.

The observation of the 22 cases, and of a much larger number of patients who attended a routine check, showed no ill effect from wearing an insert in an ear discharging because of chronic otitis media. A combination of discharge and insert does not irritate the skin of the meatus more than the discharge does by itself. The bacteriology of the discharge does not make any difference from this point of view. Patients soon learn that a comparatively dry ear hears better, and the use of the insert aid usually gives them a new impetus to take care of their discharging ears.

It has been argued that profuse discharge may block the insert; but such an ear is unfit for any kind of aid. *Profuse discharge itself causes an additional impairment* of hearing. The effect of the discharge on the external ear-piece is worse than on the insert. When soiled it is difficult to clean and it may be damaged in the cleaning. Thus a profusely discharging ear should be treated before an aid is prescribed. Almost all cases can be improved with regular aural toilet. If a patient is indolent towards his discharging ear and unwilling to maintain a reasonable aural hygiene, it is very unlikely that he will make a good use of his aid or look after it properly. It is not advisable to give a patient an aid and to neglect the treatment of a chronic otitis media.

When one ear is dry and the other is discharging, the decision about which side should have an insert fitted should be made from the functional point of view. If the hearing is appreciably better in the wet ear, one should not hesitate to prescribe the aid for that ear.

There are obvious indications for the use of an external aid—e.g., various types of chronic otitis externa, anatomical disfigurement of the meatus, stenosis of the meatal orifice, &c. In these cases, too, the bone-conduction aid is an alternative. It is important, however, to remember that the bone-conduction type of aid is less efficient than the air-conduction type as regards both its heavy battery consumption and its very restricted bandwidth of sound frequency. The battery consumption of the more powerful bone-conduction aids is roughly the same as that of the medresco external air-conduction aid, but the external aid scores over the bone-conduction aid on its better frequency characteristic. When a medresco bone-conduction aid becomes available for general use, a tendency may arise to prescribe it for all discharging ears. That would be unfortunate.

The indications for the various types of aid are not difficult to define. The decision must be made from the functional standpoint first of all. Modifying factors may be present, and accordingly a less efficient, but for the individual as a whole a more suitable, aid will have to be prescribed. However, as I have tried to prove here, the fact that an ear is discharging because of chronic otitis media should not be an obstacle to the prescription of the most efficient (insert type) hearing-aid.

This investigation was started by Dr. J. H. Sherrey, former assistant at the audiology unit, who made the initial examination of the first 22 patients. The amplified speech tests were made by Mr. G. A. Vale, technical assistant. I wish to thank Mr. J. J. Knight, physicist at the Wernher Research Unit, for his valuable coöperation and advice, and Dr. A. S. Smith-Walker, first assistant at the audiology unit, for reading and discussing this paper.

SARCOIDOSIS TREATED WITH CORTISONE

REPORT OF A CASE

A. Dolphin
M.D. Dubl., M.R.C.P.
PHYSICIAN, MILE END HOSPITAL, LONDON

K. W. G. Heathfield
M.D. Lond., M.R.C.P.
NEUROLOGIST, BETHNAL GREEN AND MILE END HOSPITALS;
SENIOR REGISTRAR, NEUROLOGICAL DEPARTMENT,
ST. BARTHOLOMEW'S HOSPITAL, LONDON

MUCH has been written on Boeck's sarcoid, which is increasingly recognised as a cause of symptoms due to involvement of any of the body systems. The case reported here is interesting because of the severity of the ocular condition leading to blindness, the involvement of the peripheral and central nervous systems, the establishment of the diagnosis by aspiration liver biopsy, and the use of cortisone in therapy.

CASE-RECORD

A housewife, aged 43, was first seen in the surgical outpatient department at Mile End Hospital on Dec. 27, 1950, with three weeks' bilateral swelling of the parotid glands and a week's loss of taste on both sides of the tongue. There was also a complete right facial paralysis with diminution of hearing in the right ear. The patient was subsequently seen at weekly intervals, the parotid enlargement subsided, and the facial paralysis recovered; but her general condition deteriorated and she was referred to one of us (A. D.), who admitted her on Feb. 6, 1951.

First admission.—Until April 4, 1951, she had low-grade pyrexia between 99° and 100°F. She was sallow, wasted, and slightly icteric. Her superior cervical lymph-glands were enlarged, and small discrete glands were palpable in each parotid region. Her cardiovascular system was normal, and blood-pressure 140/80 mm. Hg. Apart from scattered râles in the left mid-zone anteriorly, there were no abnormal signs in the chest. The left pupil was slightly larger than the right, but otherwise the nervous system showed no abnormality. Radiography of the chest showed calcified enlarged hilar glands and calcified foci in the upper and mid-zone regions of the right lung. A Mantoux test was positive at 1/100, and negative at 1/1000. A direct van den Bergh test was weakly positive in 10 minutes. The serum-bilirubin level was 1·3 mg. per 100 ml., alkaline phosphatase 3 units, colloidal gold 0, thymol turbidity 2, and flocculation 0. Total and differential leucocyte and erythrocyte counts were normal. The patient refused biopsy of an enlarged lymph-gland and lumbar puncture, and before her discharge as an inpatient the lymph-glands were no longer palpable.

Readmission.—Two weeks after leaving hospital she developed sudden painless dimness of vision in her right eye and soon afterwards in her left eye, and was referred by her private doctor to the ophthalmological outpatient department, from which she was admitted for the eye condition. Her pupils were widely dilated and non-reacting, with bilateral vitreous haze and œdema of the choroid and retina. There were no other abnormal findings clinically and no change in the chest radiograph. Cerebrospinal fluid (C.S.F.) was examined on April 23 and thereafter at about monthly intervals (see table) and showed a lymphocytic pleocytosis with increased protein and globulin; the chloride was somewhat low.

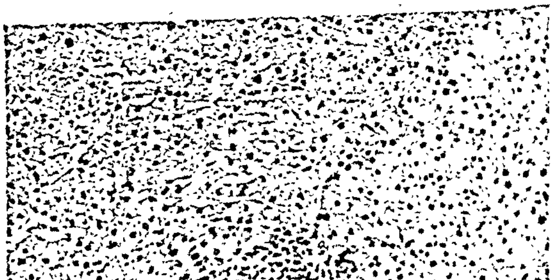
C.S.F. FINDINGS

Date	No. of lymphocytes per c.mm.	Protein (mg. per 100 ml.)	Globulin	Chloride (mg. per 100 ml.)	Sugar (mg. per 100 ml.)	Lange
April 23, 1951	18	110	Excess +	680	62	0001110000
May 11, ,,	53	100	Excess +	..	60	000112100
June 13, ,,	12	78	Slight +	580	57	0011100000
June 28, ,,	11	50	Slight +	690	65	..
July 19, ,,	8	60	..	..	..	..
July 30, ,,	4	70	..	720	..	..
Oct. 9, ,,	4	60	..	730	53	..

Cortisone therapy was given from July 20 to 30.

Progress.—During subsequent weeks there was no change in vision. The patient was somewhat drowsy and insidiously developed bilateral deafness. She had complete amenorrhœa from the onset of the illness, and during this time she lost 3 st. in weight. She did not menstruate again until November, 1951. There was nothing relevant in her past or family history. At this stage sarcoidosis was considered the most probable diagnosis. To exclude toxoplasmosis, considered as unlikely, a complement-fixation test was done by Dr. J. A. Dudgeon, and the result was negative.

Transfer.—The patient was transferred to St. Bartholomew's Hospital on June 30, 1951, and was found to be thin and sallow but not icteric. The cardiovascular system was normal apart from some hypotension, the blood-pressure being 100/60 mm. Hg. The lungs showed only a few scattered rhonchi; there were no enlarged lymph-glands in the neck, axillæ, or groins; the spleen was not palpable; but the liver was slightly enlarged (1 finger-breadth). Apart from the ocular condition the chief finding in the cranial nerves was a bilateral severe nerve deafness. The limbs were thin, but there was no focal wasting. Tone was normal in the arms but was somewhat increased in the legs. Power and coördination were normal, the tendon-reflexes were all brisk, there was bilateral ankle clonus, but the plantar responses were flexor. Sensation was normal. Mr. H. Stallard saw her on July 3, 1951, and found that the visual acuity was diminished to counting fingers on both sides and was not improved by correcting the refractive error. Secondary glaucoma was confirmed in both eyes by tonometry readings; and paracentesis, with daily reopening with iris repositor, was begun. Otological tests showed an old inactive chronic suppurative otitis media on the right side, with a mixed middle-ear and perceptive deafness, and a severe perceptive deafness on the left. Tomograms of the hilar region showed glandular enlargement on both sides with calcification in some of the glands; there was no evidence of an active lung lesion. Dr. R. Terry did an aspiration liver



Photomicrograph of liver-biopsy specimen in sarcoidosis showing occasional follicles of epithelioid cells surrounded by lymphocytes and multinucleated giant cells.

biopsy on July 11. A section (see figure) showed occasional follicles of epithelioid cells surrounded by lymphocytes and multinucleated giant cells; no tubercle bacilli were seen with the Ziehl-Neelsen stain. The appearances confirmed the clinical diagnosis of sarcoidosis.

Treatment and progress.—The eyes were treated with subconjunctival cortisone 0·4 ml. in each eye, homatropine and cocaine, and daily reopening of the paracentesis. The ocular pressure slowly fell to normal over a period of two weeks. Despite the improvement in the appearance of the eyes and the elimination of the ocular hypertension there was little return of vision. Parenteral cortisone 100 mg. was given twice daily from July 20 to 30, and during this period there was striking improvement in her appearance and sense of well-being. She gained 6 lb. in weight, and her blood-pressure returned to normal (from 110/60 to 120/70 mm. Hg). Her erythrocyte-sedimentation rate fell from 22 to 4 mm. in 1 hr. (Westergren). Her hearing also improved; she became able to hear ordinary conversational tones (this clinical improvement was confirmed by audiometry). The C.S.F., however, showed little significant change. In this period, which overlapped with that of local therapy to the eyes, the most dramatic changes took place in the ocular condition; the corneal and vitreous haze cleared completely, and the fundi could now be clearly seen. There was unfortunately still no return of visual acuity.

DISCUSSION

According to Bodley Scott (1938), Jonathan Hutchinson, in 1875, was the first to recognise the condition, although priority is usually given to others. Regarding the frequency of the disease Bodley Scott stated that in histological examinations of lymph-glands excised to establish a diagnosis of Hodgkin's disease, sarcoidosis was found once to every 11 cases of lymphadenoma. He reported 8 cases which occurred within a year. The disease has been reviewed by Longcope and Freiman (1952).

In the present case aspiration liver biopsy established the diagnosis. Although this method has been used for several years in the diagnosis of sarcoidosis, it has not perhaps in this country received the attention it deserves. According to Scadding and Sherlock (1948), van Beek and Haex (1943) were the first to use liver biopsy and obtained positive results in 2 out of 4 cases, although in none of the cases was there clinical evidence of liver involvement. van Buchem (1946) described the results of liver biopsy in 14 cases, of which 11 showed sarcoid lesions in the liver substance. Similar results were reported by Scadding and Sherlock (1948) in this country and by Schiff (1951) in the U.S.A. R. B. Terry, working at St. Bartholomew's Hospital, has had positive liver biopsies in several cases of sarcoidosis in the past year.

Although commonly benign in its course sarcoidosis may produce crippling disability, particularly if the eyes, central nervous system, or lungs are affected. Woods (1949) stated that the eyes are affected in 50% of cases, the commonest lesion being uveitis. Choroiditis and retinitis are comparatively rare, the first recorded cases of retinitis being by Rabut and Hudelo (1925). The eye lesions were comprehensively reviewed by Levitt (1941), Woods (1949), and Hogan (1951). Bodley Scott's (1938) third patient was blind four years after the onset of the eye lesions, by which time myxœdema, which responded to thyroid therapy, had developed. As in the present case, Lewis's (1941) patient had at one stage absent tendon-jerks and Adie's pupil.

Involvement of the central and peripheral nervous systems in sarcoidosis has been reported many times, and recent reviews have been made by Colover (1948) and Pennell (1951). The symptoms and signs are protean, and no part of the nervous system is exempt, although certain syndromes are more commonly encountered than others. Peripheral neuritis, with special affection of the facial nerves, is common. Involvement of the pars intermedia of the pituitary, with diabetes insipidus, is also characteristic. A chronic meningo-encephalitis with lymphocytic pleocytosis in the C.S.F. and hydrocephalus from arachnoiditis around the foramina of exit of the 4th ventricle has also been reported on several occasions. Although the condition is extremely chronic, a tendency to spontaneous improvement is in most cases manifest.

In this patient the signs of involvement of the central nervous system were the initial facial paralysis at the time of parotid swelling and, later, the onset of mental confusion, bilateral nerve deafness, pyramidal signs in the legs, and lymphocytic pleocytosis in the C.S.F. The facial paralysis cleared spontaneously before the diagnosis was established, but the other symptoms persisted for several months. Apart from unequal pupils in the early stage of the illness, there was no ocular involvement until, after five months, the patient returned to hospital because dimness of vision had developed painlessly and suddenly in each eye and examination showed widely dilated pupils, bilateral vitreous haze, and choroidoretinal œdema.

A.C.T.H. and Cortisone Therapy

Apart from the report by Duke-Elder (1951) we have found no other in this country on the therapeutic use of A.C.T.H. and cortisone in sarcoidosis; most of them are American.

Olson et al. (1950) reported two cases of plastic iritis in which there was rapid clearing, within a few hours, of the plastic exudate with A.C.T.H. therapy.

Topical cortisone produced complete remission of iridocyclitis in one case (Steffensen et al. 1951).

Sones et al. (1951) reported two cases treated with systemic cortisone. In one there was clearing of the skin and eye lesions and chest X-ray appearances and diminution in the size of lymph-glands, but no change in the size of the liver and spleen. In the other patient the chest radiograph was normal after nine days' therapy. Sones et al. thought cortisone was most effective in the treatment of acute lesions.

Galdston et al. (1951) reported a case with complete subsidence of polyarthritis after three days' treatment.

West et al. (1951) reported a case where cortisone therapy led to clearing of lung infiltration and lessening of dyspnœa.

Leopold et al. (1951) found no response to subconjunctival cortisone in three cases of anterior uveitis.

The experience of Siltzbach (1952) in the treatment of 13 cases confirms that cortisone exerts a suppressive action on the lesions of sarcoid.

Duke-Elder (1951), in an extensive review of the use of cortisone in ophthalmology, recorded a case of sarcoid in which one eye had been excised three years previously and the remaining eye was beginning a similar granulomatous iridocyclitis. The inflammation subsided and vision was 6/9 within four weeks of the start of cortisone therapy, and there was no relapse after ten months. Duke-Elder contrasted the good results in secondary glaucoma associated with iridocyclitis with the failure to respond in primary glaucoma and secondary glaucoma due to mechanical causes such as hypermature and dislocated lens. He also mentioned the development of ocular hypertension as a complication of the treatment of iridocyclitis by systemic cortisone, and stated that McLean et al. (1951) had found that secondary glaucoma might be precipitated in this way. This complication of therapy is much less likely to develop with topical therapy, but this method of treatment would not, on the other hand, benefit systemic disease.

From these reports and our experience in the treatment of the present case it seems that cortisone is of definite value in the treatment of sarcoidosis. There was no doubt about the great improvement in the general condition of our patient although, owing to shortage of supply, cortisone treatment could not be continued for longer than two weeks. The ocular condition improved dramatically, but unfortunately it was too late to save vision. In view of Duke-Elder's experience it seems it may be of great value in saving vision if used early enough. The relationship between sarcoidosis and tuberculosis has not yet been clarified, but many think that sarcoidosis represents tuberculosis in an anergic person. Because of the dangers of giving cortisone in latent or active tuberculosis its use in sarcoid may not be without danger, and further experience in the use of cortisone will be needed before its therapeutic value can be fully assessed. Possibly a combination of streptomycin and cortisone might be the treatment of choice in carefully selected cases of sarcoidosis.

SUMMARY

A case of sarcoidosis presenting with bilateral parotid swellings and facial paralysis is described.

C.S.F. examination early in the illness showed lymphocytic pleocytosis, which was followed by severe nerve deafness and a confusional state. Secondary glaucoma and blindness developed.

The diagnosis was confirmed by aspiration liver biopsy.

Cortisone was given locally and systemically, with improvement of the general condition and clearing of the ocular exudate. There was, however, no recovery of vision, and chronic glaucoma is present.

We wish to thank Dr. J. W. Aldren Turner and Mr. H. B. Stallard, of St. Bartholomew's Hospital; Dr. R. B. Terry, of St. Bartholomew's Hospital, for the liver biopsy; Mr. G. Ebbage, consultant ophthalmologist, Mile End Hospital; Dr. E. Hardy, consultant pathologist, Mile End Hospital; Dr. J. A. Dudgeon, of the Virus Research Laboratories, Great Ormond Street, for the toxoplasmosis complement-fixation test; and Prof. J. W. S. Blacklock, of St. Bartholomew's Hospital.

Medical Societies

ROYAL SOCIETY OF MEDICINE

Treatment of Non-tuberculous Meningitis

ON NOV. 25 the section of medicine of the Royal Society of Medicine met, under the chairmanship of Sir ALUN ROWLANDS, president of the section, to discuss non-tuberculous meningitis.

Dr. STANLEY BANKS remarked that meningitis was preceded by bacteræmia or septicæmia arising from a primary focus, and associated metastases might require special treatment. The basic pathological lesion was an endarteritis. Capillaries were found stuffed with organisms; and thrombosis infarction, and hæmorrhage might occur.

Dr. Banks emphasised the importance of early diagnosis. Diagnosis was, however, often very difficult in infants, especially in the neonatal period when the only manifestations might be mild fever and refusal to feed. Mild cases could easily be missed in adults.

Treatment consisted in a short course of antibiotics in maximal dosage. Laboratory reports on sensitivity of organisms to antibiotics were essential; and if there was any doubt about sensitivity an adjuvant drug should be given. Because intrathecal administration might give rise to meningeal irritation and to secondary infections, this should be avoided whenever possible. Chloramphenicol and sulphadiazine by mouth gave an adequate concentration in the cerebrospinal fluid (C.S.F.). An effective C.S.F. concentration of penicillin could be achieved by giving enormous doses intramuscularly, such as 1 million units two-hourly; but such a concentration was not reached for eight hours. Systemic administration of streptomycin gave a very poor concentration in the C.S.F., and systemic administration of terramycin gave hardly any. Aureomycin gave a variable concentration, and its appearance in the C.S.F. was delayed for up to forty-eight hours after administration was started. Both aureomycin and terramycin were acid and thus unsuitable for intrathecal injection except in special solutes.

Dr. Banks said that 24–30% of notified cases of meningococcal disease still died; the death-rate had decreased no further since the fall occasioned by the introduction of sulphonamides. Mortality was highest at the extremes of life. Sulphadiazine was still the drug of choice in the treatment of meningococcal meningitis, and as yet the organism was not resistant. Maximal doses must be given; infants should receive not less than 3 g. per day. If the diagnosis was uncertain when the first lumbar puncture was done, up to 20,000 units of penicillin might be given intrathecally. When there was evidence of adrenal damage, cortisone 50–100 mg. daily was given; and if cortisone was not available large doses of adrenal cortical extract should be given instead—e.g., 20–40 ml. intravenously and then 10 ml. hourly for six hours, followed by 10 ml. three-hourly for several days. The eosinophil-count should be kept below 15 per c.mm. Where the patient was comatose from encephalitis the prognosis was grave; but improvement and cure sometimes followed repeated infusion of 50% glucose intravenously.

Pneumococcal meningitis still caused death in one-third of the cases; early diagnosis was imperative. 200,000 units of penicillin should be given four-hourly together with sulphadiazine; and 20,000 units of penicillin should be given intrathecally every day for four or five days. The combination of penicillin with aureomycin was unsatisfactory, the results being worse than with penicillin alone. Better results might be obtained with a combination of chloramphenicol with sulphathiazole, but this had not yet been tried.

In *Hæmophilus influenzæ* meningitis chloramphenicol in a dosage of 250 mg. four-hourly for eight to ten days gave excellent results, which were analogous to those obtained with sulphadiazine in meningococcal meningitis. The C.S.F. usually became sterile in seventy-two hours. There was still no sign of the organism becoming insensitive to chloramphenicol. A combination of streptomycin intramuscularly and intrathecally with sulphadiazine was also effective. It was found that penicillin might be added with advantage even though the organism was resistant in vitro.

Meningitis caused by *Bacterium coli*, proteus, *Streptococcus fæcalis*, or *Pseudomonas pyocyanea* was difficult to treat, and large doses of antibiotics were needed. It was of course essential to know to which drug the organism was sensitive. A combination of streptomycin and sulphadiazine might be used at first, and after twenty-four hours chloramphenicol should be substituted for the streptomycin. In resistant cases all three drugs should be used. In intractable meningitis due to *Ps. pyocyanea* polymyxin B might be given in daily doses of 5 mg. per kg. body-weight systemically and 4 mg. intrathecally.

Recent work had shown that subdural collections of fluid were more common in meningitis than had been suspected. These were usually sterile; rarely collections of encapsulated pus were found. The presence of subdural fluid was suggested by the recurrence, in adequately treated cases, of fever and perhaps by convulsions; in infants the fontanelle might bulge after forty-eight hours of adequate treatment. Dr. Banks said that such collections of fluid often subsided by themselves; surgical interference was only rarely needed.

Dr. J. C. **Broom** spoke about leptospiral meningitis. *Leptospira icterohæmorrhagiæ* and *L. canicola* were the only types met with in this country. The organism might affect the meninges alone, or also the kidneys and liver. The onset was usually sudden with headache, fever, nausea, photophobia, and great prostration; and mental confusion, vertigo, and even paresis of muscles could occur. Sometimes the initial fever subsided, and signs of meningeal involvement and renewed fever developed after an interval of a day or two. Lumbar puncture relieved the severe headache, which was a prominent symptom. The death-rate in leptospiral meningitis was negligible.

Dr. Broom showed that penicillin had no effect on the course of the disease. Experimental work on hamsters indicated that aureomycin and terramycin might be of value, but there was insufficient evidence of their effectiveness in treating this disease in man. There was also the possible disadvantage that aureomycin and terramycin did not enter the C.S.F. in sufficient concentration.

Mr. J. V. **Crawford** discussed surgery in the treatment of meningitis. Prompt and adequate treatment of head injuries was essential if meningeal infection was to be prevented; and he emphasised the importance of closing dural tears. Cases of cerebrospinal rhinorrhœa were often difficult to treat, and before the gap was closed lumbar puncture might have to be repeated several times daily. In patients with a closed fracture of the middle fossa, the dural tear usually healed without surgical interference, but operation was often necessary in open fractures due to gunshot wounds. Herniation of the temporal lobe or the cerebellar tonsil could follow lumbar puncture when a space-occupying lesion was present—a danger that should never be overlooked. Streptococcal infections were particularly dangerous in this respect. When a space-occupying lesion was suspected, percutaneous angiography was often safer than ventriculography; and it was especially valuable in temporal-lobe lesions. However, ventriculography was often necessary to establish the position of a subdural collection of fluid, and it was a useful method of obtaining fluid for culture. In the acute phase of meningitis an exudate might cause obstruction and signs of raised intracranial pressure. Ventricular drainage should then be performed by catheters introduced into the ventricles through frontal burr-holes. This was a simpler approach than the posterior route when neck retraction was present, and it was safer than cisternal puncture. In infants needles were introduced into the subdural spaces or ventricles through the lateral angles of the fontanelle; but in infancy there was a danger of a cerebrospinal fistula after ventricular drainage.

After the acute phase was over, adhesions might produce either an obstructive or a communicating hydrocephalus, and operation was then required. The results from the surgical treatment of obstructive hydrocephalus were quite good, but the relief of communicating hydrocephalus by operation was unsatisfactory.

In the discussion, Mr. D. W. C. **Northfield** drew attention to the importance of a correct technique in performing lumbar puncture. The best agent for sterilising the skin was a 2% solution of iodine in spirit. A small-bore lumbar-puncture needle should be used, and it should be held in several folds of a sterile towel.

LIVERPOOL MEDICAL INSTITUTION

Epidemiology of Salmonella typhi-murium Infection

At a pathology meeting of the Liverpool Medical Institution on Nov. 21, with Dr. R. J. **Minnitt**, vice-president, in the chair, the epidemiology of *Salmonella typhi-murium* infection was discussed.

Brigadier J. S. K. **Boyd**, F.R.S., said that certain bacteria—e.g. *Salmonella typhi* and *S. paratyphi-B*—could be divided into a series of "types" by means of conditioned bacteriophages, each of which had a specific lytic action on a particular type of bacterium. Recent work strongly suggested that the type-specificity of the bacteria was attributable to the resistance they acquired from the "natural" or "symbiotic" bacteriophages which they carried. In a study of the symbiotic phages found in *S. typhi-murium*, it had been confirmed that these were transmitted hereditarily, that the infection of the bacterial strain was virtually permanent, and that most, if not all, strains of *S. typhi-murium* contained such phages. A technique had been devised for isolating and identifying these phages. These fell into two distinct groups, and at present 12 phages had been described: a few more were in the offing. Two different phages were often found in the same strain of bacteria. There were thus a large number of different "marks"—i.e., strains—of *S. typhi-murium* labelled by the symbiotic phage they carried.

Dr. M. T. **Parker** said that in the last two and a half years 446 strains of *S. typhi-murium* isolated from man in the Manchester district had been submitted to Brigadier Boyd for identification of their symbioticphages. The "marking" results agreed almost completely with the suspected epidemiological relationships between the cases.

About one-third of all infections diagnosed in the area were "cross-infections" of infants in hospital. Brigadier Boyd's findings had been extremely useful in demonstrating the persistence of infection in one hospital for eighteen months, and had made it possible to detect spread to three other hospitals and to the family contacts of a number of discharged patients. Inter-ward spread occurred easily, and often was not associated with the transfer of infected patients. Hospital infection could take place at all seasons of the year, but the worst outbreaks had been in the cold weather. Presumably infection of the very young could occur without preliminary multiplication of the organism in food.

Rather less than one-third of all the infections had been in food-poisoning outbreaks, which had followed the familiar pattern. The remainder of the infections had nearly all been single cases in families. These cases were largely confined to the warm weather, presumably because the organism had to multiply before infection occurred. This suggested that the infection was due to "food poisoning," and not to contact infection as in the hospital cases. Analysis of the "marking" results showed that the summer peak of sporadic cases was mainly due to the prevalence of one, or a small number, of "marks" which differed in distribution from year to year and from district to district. These "single-mark prevalences" were spread over several weeks and suggest intermittent contamination of a small part of some widely distributed food, probably in the late stages of preparation.

Dr. R. E. **Rewell** pointed out that *S. typhi-murium* could infect many different species of animals. Some, such as mice, were commonly in association with man, while others—e.g., penguins—were not. In most of them the organism's behaviour resembled that of typhoid fever in man, with alternate alimentary and systemic infection. Mice commonly migrated among buildings for quite long distances and might be a reservoir of infection for sporadic cases in man.

Reviews of Books

Britain's Food Supplies

K. G. FENELON, M.A., PH.D. London: Methuen. 1952. Pp. 212. 15*s.*

THE experienced nutritionist will appreciate the appendix of this book, where 31 tables, beautifully set out and printed, supply the fundamental data concerning the changes year by year, since 1939, in our food-supplies. Livestock population, crop production, home-produced food, annual consumption of main foods, nutrient equivalents of supplies per head per day, food expenditure in the home, food subsidies, comparison of retail prices, supply of milk to school-children, annual expenditure of the Ministry of Food—these and other tables provide a mass of information which previously has never been assembled in so convenient a form. The author, formerly director of statistics and intelligence at the Ministry of Food, naturally handles figures with ease, but he also writes well. The main body of the book, written for the general reader, gives an elegant account of Britain's food problems, past, present, and future. Since so much of our food is imported, there is properly a chapter on the world's food supplies and another on international organisations. The Colombo plan, the Overseas Food Corporation, and the Colonial Development Corporation are also described. Since he is no longer a British civil servant Dr. Fenelon can write critically about such disputed subjects as food subsidies. An informative gastronomic map of England and Wales forms the end papers, enclosing a book which can be recommended to all interested in our food problems.

Human Actinomycosis

V. ZACHARY COPE, M.S., F.R.C.S., consulting surgeon, St. Mary's Hospital and the Bolingbroke Hospital. London: Heinemann Medical Books. 1952. Pp. 80. 12*s.* 6*d.*

FOR the general practitioner this is a timely monograph, because of the new conception of actinomycosis as essentially an autogenous infection by the anaerobic *Actinomyces israeli*, a frequent commensal or semi-parasite in the mouth, and also because of the evidence, from recent studies, that the disease is often overlooked or incorrectly diagnosed and is in fact much more prevalent than was formerly believed. Happily the new revelation of the greater frequency of actinomycotic infections synchronised with the discovery that the disease could be cured by suitable doses of penicillin and some other antibiotics. This lucid account of the disease—its history, ætiology, clinical and pathological features, its various anatomical types, and the methods of diagnosis and treatment—offers the practitioner all he needs to know without burdensome academic details. The use of rhymes to impress vital facts on the memory is an effective, and sometimes amusing, innovation.

Surgical Forum

Proceedings of the Forum Sessions Thirty-seventh Clinical Congress of the American College of Surgeons, San Francisco, California. November 1951. Chairman, Surgical Forum Committee: Owen H. Wangensteen, M.D., F.A.C.S. Philadelphia and London: W. B. Saunders. 1952. Pp. 667. 50*s.*

As would be expected, the papers which make up this volume deal with subjects in the very forefront of surgical thought. In comparison with similar collections of a decade or two ago there is a very striking change. So much of surgery of the human body has been standardised, in the practical sense, that we now find surgeons searching the physical and chemical sciences for assistance in elucidating their problems.

This work deals with electrolytes and body-fluids in normal and shocked persons, the effect of long-continued hormone administration, the action of antibiotics, the elaborate experiments on short-circuiting the heart, arterial grafts, and many other subjects. A careful analytical study of the papers on the blood-fluids is necessary in order to see what bearing they have on current surgical problems, though many of the results, of course, are at present rather inconclusive. The effect of cortisone on the healing of wounds and the formation of adhesions, has been studied, but with no very striking results. Of much interest is the work done on stimulating the growth of bones by an electrolytic couple (constantan-copper) placed near the epiphysis: and this has immediate practical importance. The open treatment of burns forms the subject of another practical paper, and a great deal of experimental work on the heart and blood-vessels is reported.

Ciba Foundation Colloquia on Endocrinology

Vol. 2. *Steroid Metabolism and Estimation.* Editors: G. E. W. WOLSTENHOLME, O.B.E., M.A., M.B., and MARGARET P. CAMERON, M.A., A.B.L.S. London: J. & A. Churchill. 1952. Pp. 429. 35*s.*

THE Ciba Foundation is doing an outstanding service to medical science in Britain by organising small intimate colloquia, each composed of a restricted number of experts from various countries. The papers read at these meetings, with transcripts of much of the discussions, are just beginning to appear; and the volume under review, the second in the series, contains papers given at two successive conferences in 1950. It is unfortunate that publishing delays are still so great, for the subject of steroid metabolism is moving fast.

This volume contains contributions on the estimation in the body-fluids of progesterone and its metabolites, of œstrogens, 17-ketosteroids, and, of course, corticoids. The shift from the biological assay methods, characteristic of pre-war endocrinology, to methods based on physical and chemical techniques such as infra-red spectrometry, chromatography, fluorimetry, and polarography was, at the time of the meeting, a striking foretaste of things to come. The metabolic breakdown of steroids in the body was also discussed. The adrenal corticoids occupied a place of special prominence in these discussions, and it is interesting to see how far this particular aspect has advanced in the two years since the papers were read.

The meetings gave British workers the opportunity of meeting the late Konrad Dobriner, and hearing at first hand an account of his outstanding work on the application of infra-red spectroscopy to steroid biochemistry.

Fluid Balance

A Clinical Manual. CARL A. MOYER, M.D., professor of surgery, Washington University School of Medicine, St. Louis. Chicago: Year Book Publishers. London: Interscience Publishers. 1952. Pp. 191. 28*s.*

IN this useful pocket manual Professor Moyer covers all the important aspects of fluid balance. After a brief historical survey he summarises basic physiological principles before discussing disturbances of body-fluid equilibrium in terms of volume, osmolar concentration, ionic composition, distribution, and rate of internal exchange of the fluid compartments. He skilfully backs clinical points with laboratory data and illustrative case-reports. His descriptions of therapy and—equally important—complications of therapy are adequate. Neither his subject matter nor his style makes for easy reading. Nevertheless, this manual should find its way into all hospital libraries, and it can be recommended to all surgeons and physicians who are concerned about the morbidity and mortality due to ignorance of, or indifference to, this important subject.

Diseases of the Ear, Nose and Throat (2nd ed. London: H. K. Lewis. 1952. Pp. 438. 37*s.* 6*d.*).—Mr. J. Douglas McLaggan, the original author of this good book, has been joined by Miss Josephine Collier, a colleague at the Royal Free Hospital, in producing a second edition. The several parts are well apportioned, and the approach is essentially practical, emphasis being laid on principles. Applied anatomy and physiology are described clearly and accurately as the basis of clinical practice; and the illustrations include some very good drawings and several radiographs of an unusually high standard. A facile style makes for pleasant reading, and a good index ensures easy reference. Despite the absence of a bibliography, much recent work has clearly been incorporated in the pages of this new edition, which covers the subject amply for the undergraduate, and should also be a popular and convenient source of information for the busy general practitioner.

THE LANCET

LONDON: SATURDAY, DEC. 13, 1952

A Dangerous Trade?

In the churchyard at Aldenham in Hertfordshire the observant visitor will find a monument commemorating a young bacteriologist who died of plague in 1914 while working at the Lister Institute. His was probably the first death in the parish from this cause since 1665. The story of some similar sad accident, not always fatal and sometimes merged in folklore, probably attaches to every bacteriological laboratory. No statistics are available for this country, but a questionary circulated two years ago to about 5000 laboratories in the U.S.A. showed that among their staffs there had been since 1930 at least 1275 infections reasonably attributable to employment[1]; and 39 of these were fatal. Most occurred among those working at the bench; but doorkeepers, typists, and visitors had their share of infections. Certain micro-organisms have had an ill repute for many years. We know of only one man who has worked with *Pasteurella tularensis* and escaped infection; and the American figures confirm the dangers attached to handling brucella. The risk of tuberculous infection seems to be as great from the post-mortem table as from the bench.[2] [3] In the American series *Bacillus anthracis* caused 30 laboratory infections; and this is perhaps not surprising now that we know that the spores retain life despite fixing and staining. No-one would have expected a microscopic preparation to be any more dangerous than a stuffed tiger. With regard to virus diseases, yellow fever has robbed us of many distinguished colleagues; but, considering how tentative are our methods of handling material infected with viruses, these have caused few laboratory infections. The rickettsiæ, however, have done their share of damage and more, and in the U.S.A. the first recognised natural infection with Q fever occurred in a visitor to a laboratory where the disease was being investigated. Among the fungi *Coccidioides immitis* has given rise to many laboratory infections—the more alarming because few outside the areas where coccidiomycosis is endemic have experience of this disease.

Anderson et al.[4] have tried to appraise the risk of spreading infectious matter in the course of everyday laboratory practice. A battery of suction-pumps placed round the field of operations led continuous samples of air to traps from which straying organisms could be recovered; a harmless species of serratia was used as the test organism. The results were alarming. A drop of fluid culture falling 12 in. diffused organisms in the surrounding air. The effect was greatest, as might be expected, when the drop fell on a hard smooth surface, but a few serratiæ could be detected in the air when the drop fell in a pan of phenol. Opening a stoppered bottle which had been shaken, or removing a cotton-wool plug moistened with the culture, had the same effect. The dangers incurred by removing fluid from a vaccine bottle with a syringe and needle seemed about equal whether the contents of the bottle were under positive or negative pressure, but were much diminished if the needle was shrouded with a pledget of cotton wool soaked in alcohol. The risk of flaming a platinum loop charged with too much material is taught to every student, but we are surprised to learn that in the most careful hands large numbers of organisms are dispersed by this device; the springy loop, so pleasant to handle, seems to be the most risky. The dangers proved to be greatest with procedures involving splashing and bubbling; and apparently the surest device for infecting the entire air space is the high-speed mixer often used for disintegrating tissues.

Prevention is not easy. Students will suffer no loss if they limit their attention to organisms of low infectivity. All who work in laboratories should be persuaded to accept such immunising procedures as are available. These are not many, but they apply to some of the more lethal diseases. Directors of laboratories must insist on the duty of reporting not only infections but errors and accidents which may lead to infections. Smadel[5] has set out rules directed at preventing infection by viruses and rickettsiæ; and these can be largely applied to bacteriological technique. The value of face-masks is difficult to judge; there are good masks and bad, and they may be worn sensibly or carelessly. Inoculation hoods should probably be used more widely; and those who work with mixers must remember their habit of distributing a sample of their contents over a wide area. Specialised laboratories have a better chance of devising safe working methods than those dealing with all varieties of infectious material. An intelligent understanding of laboratory dangers by all who work in the building will always be one of the chief safeguards. Many laboratory infections are seen in retrospect to have been avoidable. No risk should be taken knowingly: in the laboratory bravery and foolhardiness are almost synonymous. Anyone who calls on bacteriologists will prefer him who washes his hands three times (soap and water, alcohol, and soap and water) before greeting his visitor to the gallant fellow whose only preparation before shaking hands is to wipe his own on the tail of his overall.

Vitamin B_{12} in Practice

Vitamin B_{12} was discovered during a search for the factor in liver extracts that causes a remission of pernicious anæmia. The further discovery that the vitamin could be extracted from the mother liquor in which *Streptomyces griseus* was grown provided a plentiful and relatively cheap supply, so that preparations of vitamin B_{12} became available for general use. It was soon found that microgramme doses caused a full remission in pernicious anæmia, and sufficient time has now elapsed for us to be able to judge its value in this disease and for reports to have appeared on its action in other anæmias and in other diseases. Conley

and his colleagues[1] at the Johns Hopkins Hospital have published details about 54 patients maintained on vitamin B_{12} alone for one year or more. They found, as others have done, that though an initial response could be obtained with as little as 12·5 μg. intramuscularly, doses of 100 μg. gave a much more satisfactory response. Most patients received maintenance doses of 45 μg. intramuscularly every six weeks; and a few had more—up to 150 μg. every four weeks. CONLEY et al. considered the results satisfactory; they found that there were no relapses and that symptoms, including soreness of the tongue, were quickly relieved and did not recur. The neurological complications of pernicious anæmia seemed to respond to B_{12} in much the same way as they do to liver extracts; that is to say, some patients showed remarkable improvement, while others were hardly affected. To those who did not improve, larger doses were given more often, but without effect. However, no patient was made worse by B_{12}, and there was no sudden onset of neurological symptoms, such as is seen with folic-acid treatment. The figures given in this paper suggest, however, that maintenance treatment with vitamin B_{12} could be better; no less than 16 out of their 54 patients had hæmoglobin levels of under 13·0 g. per 100 ml. after twenty or more months' treatment, and it seems probable that the maintenance dose was too small in these patients. OWREN[2] claimed that liver extracts produced a more complete remission than B_{12}, but CONLEY et al. were unable to confirm his findings. They also attempted to treat and maintain a small group of patients with pernicious anæmia on vitamin B_{12} by mouth: it could be done, but it was expensive, for an initial dose of 5 mg. (5000 μg.), followed by 1–2 mg. every month, was needed. In this country BLACKBURN et al.[3] in Sheffield have described their results with 22 patients who had previously been treated with liver extracts. They were transferred to vitamin-B_{12} treatment, and maintained on it for at least two years. They had larger doses than those given by the Johns Hopkins workers—50 μg. every two weeks for most patients—and the results, as judged by hæmoglobin levels, were on the whole better. But BLACKBURN et al. noticed that in the penultimate six months of B_{12} treatment hæmoglobin levels tended to fall. BREWERTON and ASHER[4] discussed B_{12} treatment from the patient's point of view, and there seems no doubt that their patients preferred it to liver injections. WALKER and HUNTER[5] tried to produce a remission or to maintain patients with single parenteral doses of 1000 μg. repeated at long intervals. Such a dose given to previously untreated patients did in fact produce a remission lasting from four months to as long as a year in one case, but they found that signs of reversion in the bone-marrow could be detected after forty to fifty days, and a patient with involvement of the spinal-cord tracts relapsed in six weeks. They concluded therefore that the technique was not practicable. In the treatment of the other megaloblastic anæmias, vitamin B_{12} does not seem as efficient as folic acid. It was soon reported[6] that vitamin B_{12} was ineffective in the megaloblastic anæmia of pregnancy, and later work in Europe and America has, on the whole, confirmed this view. However, NIEWEG[7] drew attention to 2 patients in Holland who did respond satisfactorily, and in India CHAUDHURI[8] found B_{12} effective in 16 patients who were given only ordinary doses. In the tropical megaloblastic anæmia of non-pregnant patients B_{12} was effective in 4 cases, but folic acid was better in another.[8] At the moment there is no way of distinguishing before treatment the patient who has a vitamin-B_{12} deficiency from one who has a folic-acid deficiency. With an anæmic patient who is well advanced in pregnancy or who has just given birth to a child, time is often too short to allow comparisons to be made, when we know that folic acid is effective.

Vitamin B_{12} is also a growth factor,[9] and WETZEL et al.[10] said that 10 μg. *by mouth* accelerated the rate of growth of children who were undersized because of long sickness or simple malnutrition. Similar results were reported by CHOW.[11] But in this country BENJAMIN and PIRRIE[12] carried out a large controlled survey of the effects of the vitamin in poorly nourished school-children, and they failed to confirm these findings. In fact YUDKIN,[13] who described the stimulating effect of a liver preparation, claimed that the factor responsible was not vitamin B_{12} at all. There certainly seems to be little reason to give vitamin B_{12} as a dietary supplement in convalescence. Good results have also been claimed for B_{12} in the treatment of peripheral neuritis, especially the forms associated with diabetes and alcoholism. MENOT[14] in South Africa found that daily doses of 60–300 μg. intramuscularly rapidly relieved the pains and cramps of this condition; and hyperæsthesia disappeared after about a week's treatment, though absent reflexes did not return. He also discovered that the enlarged and tender livers sometimes found in these patients were relieved by treatment with vitamin B_{12}. SANCETTA et al.[15] gave 12 patients with diabetic neuritis doses of 15–30 μg. daily for seven to fourteen days, followed by a maintenance dose of 15–30 μg. once or twice weekly; 3 of the patients showed complete remission, 3 "almost complete" remission, and 3 were improved. They found that massive doses did not help, and they thought that the degree of vascular damage influenced the response. It is interesting that RABINOWITCH[16] found that an extract of pregnant mammal's liver also relieved diabetic neuropathy, though it contains only traces of vitamin B_{12}. Success has also been achieved in the treatment of ulcerative colitis with B_{12}. RALL[17] had 2 patients who responded to the usual therapeutic doses; both these patients had hyperchromic anæmia, but unfortunately we do not know whether the marrow was megaloblastic or not. Vitamin B_{12} has

been singularly free from unpleasant side-effects. Young et al.[18] and Bedford[19] reported allergic types of reaction after injection, but Bedford produced good evidence to show that some factor other than B_{12} in the medium was responsible.

Clearly, the vitamin has an important place in practical therapeutics, and its popularity is no passing fashion. For the treatment of pernicious anæmia in relapse and for maintenance it has already won its place, and all that remains to be settled is the optimum range of dosage. The evidence suggests that we have been too conservative and that larger doses may prove more effective; certainly treatment with liver extracts and desiccated stomach preparations during the past twenty-five years has shown a wide variation in the individual needs of patients with pernicious anæmia. If doctors are unwilling to change the treatment to vitamin B_{12}, their reluctance is understandable, for the older methods, properly used, have given splendid results. Murphy,[20] of Boston, writing from his long experience, pointed out that the death-rate from pernicious anæmia in the registration area of the U.S.A. was 5·8 per 100,000 in 1925 and 1·0 per 100,000 in 1948; and it is likely that many included in the lower rate did not in fact die of pernicious anæmia. Out of 226 of his patients who died, the deaths of only 14 could be directly attributed to pernicious anæmia, and the effect of treatment can be judged from the fact that 46% of this group of 226 died at the age of seventy or over—and 26 of them were over eighty. Similar figures were produced by Wilkinson[21] from his larger series. In 1948, out of 1179 patients still alive, 1 was over a hundred, 7 were over ninety, 99 were over eighty, and no less than 396 had passed the age of seventy. Of these 1179 patients in good health, 87·5% had been treated for more than five years, 760 for over ten years, 283 for over fifteen years, and 41 for over twenty years. These impressive records must be considered when a change in the treatment of pernicious anæmia is contemplated, and we must find the ideal way to give vitamin B_{12} to achieve results as good. The value of vitamin B_{12} in other diseases cannot be regarded as definitely established.

Work for the Cardiac Patient

There are few subjects about which the average layman is foggier than heart-disease. The term worries him greatly, being associated in his mind with dropping down dead. But of course the proportion of patients with cardiac lesions who drop down dead is extremely small; many of them live to a ripe age and die conveniently in their beds. The American Heart Association, which has affiliated associations all over the United States, is greatly interested in returning such patients to work; and, in booklets and leaflets addressed to physicians, patients, and employers, it discusses the working capacity of those with lesions of different degree. In the booklet addressed to physicians[22] it offers the following practical classification:

Functional Capacity

Class I.—Patients with cardiac disease but without resulting limitation of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation, dyspnœa, or anginal pain.

Class II.—Patients with disease resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnœa, or anginal pain.

Class III.—Patients with disease resulting in much limitation of physical activity. They are comfortable at rest. Less than ordinary activity causes fatigue, palpitation, dyspnœa, or anginal pain.

Class IV.—Patients with disease resulting in inability to carry on any physical activity without discomfort. Symptoms of cardiac insufficiency or of the anginal syndrome are present even at rest. If any physical activity is undertaken discomfort is increased.

Therapeutic Classification

Class A.—Patients whose ordinary physical activity need not be restricted.

Class B.—Patients whose ordinary physical activity need not be restricted, but who should be advised against severe or competitive physical efforts.

Class C.—Patients whose ordinary physical activity should be moderately restricted, and whose more strenuous efforts should be discontinued.

Class D.—Patients whose ordinary physical activity should be much restricted.

Class E.—Patients who should be at complete rest, confined to bed or chair.

Studies made in a work-classification unit, which has been running for ten years in the cardiac clinic for adults at the Bellevue Hospital, show that a large proportion of patients with rheumatic, congenital, hypertensive, and arteriosclerotic heart-disease can, and do, work successfully; and follow-up studies of patients with a capacity down to and including IIIC, placed in appropriate jobs and given adequate medical supervision, have not produced any evidence that continued employment affects the heart condition adversely. As for performance, the U.S. Department of Labor compared the output of 1840 cardiac patients with that of 3055 workers without heart-disease doing the same types of jobs in 50 different industries: the difference in performance of the two groups was only 2%, and this was in favour of the cardiac patients. Patients graded IIIC and worse cannot usually work full-time under average industrial conditions, but this does not necessarily mean they cannot work at all.

Doctors are advised to have a short-term and a long-term plan for their patients. During or directly after an acute episode, such as a coronary occlusion, an attack of rheumatic fever, or a bout of congestive failure, the patient needs telling that restriction of his activity is only temporary, and—since the habit of work is only too easily lost—he also needs to be kept occupied with handicrafts, reading, writing, and planning for the future. "Under no circumstances," the booklet asserts, "should the patient be told that he can never again do regular work." On the contrary, the idea that a planned programme of increasing activity will be discussed later should be kept well in his mind. Once the acute condition has settled down the cardiac impairment and the functional capacity of the heart can be assessed. Various factors must be taken into account, of course—the ætiology of the lesion, pathological changes in the heart and vascular system, disturbances of rhythm and the chances of controlling them, abnormal fluctuations in blood-pressure, signs of diminished cardiac reserve, history of previous attacks, and risks of recurrence. The cardiac status can be expressed in terms of the classification already given, and, since this seems to be generally recognised by American doctors, it serves as a convenient shorthand, as well as providing comparable data for research purposes. When it comes to settling the patient in a job the doctor is urged to take special trouble. It is useless for him to say: "You could do light work now," and think no more about it; he must advise the patient, and advise him intelligently, on the work he should do. This means that he must take a detailed occupational history, including the names and addresses of employers, the types of job held, the hours worked, the pay, the patient's educational background and special skills, the aspects of his work he found a strain, the aspects he found easy, the daily travel needed and the method of transport, and the stair-climbing entailed in getting from home to job and back again. It is not unknown for a patient to take a light industrial job which on paper appears to be satisfactory in every way—until someone learns, after his death, that the factory was at the top of a steep hill. The patient can answer most of the necessary questions on a form, but if the doctor is going to find out clearly how much energy the job demands he will have to have a talk with him about it. The same sort of close inquiry is needed when the patient is a housewife, for it has been shown that "managing a household without assistance is the physical equivalent of a full-time industrial job." Nevertheless the average woman with cardiac disease can continue to run her home if she is taught to limit the time she spends on her feet and to change her methods so as to reduce her physical output. One of the association's booklets[2] tells her how to set about it.

[22] Returning Cardiacs to Work. American Heart Association, 44, East 23 Street, New York 10, N.Y., U.S.A.

The doctor's final prescription for activity is based on all the information collected. The association recommends that he should then fill in a detailed "work capacity report," which can be used as a guide by social workers and industrial employers. The amount of travelling needed is taken into account; and the doctor, besides giving an opinion on causation, lesion, functional and therapeutic classification, cardiac anxiety, emotional status, and work tolerance, also indicates, by ticks against a list, exactly what physical activities and working conditions are forbidden or limited. The booklet notes that most cardiac patients classed as IB, IIB, and IIC can work 40 hours a week in clerical and sales jobs and in most skilled and semi-skilled occupations; and that many IIIC patients can do sedentary and part-time jobs. Most patients are happier if they can return to their former jobs; but if the job must be changed the doctor ought to be able to suggest alternatives. With a good confident patient, however, reassurance and explanation are often all the help that is needed: he will then go and find an appropriate job for himself. When he is back in work the doctor should see him regularly and assess his capacity afresh.

This is an exacting programme for doctors, but from the point of view of the public as well as the patient it would be well worth achieving. As the association point out in a booklet addressed to employers,[3] the skills of workers with heart-disease can be an asset to industry; but when they are not used the worker himself becomes a liability.

Economy in Hospital Staffing

AN important memorandum from the Ministry of Health (summarised on a later page) asks boards and committees to reduce further their man-power. This reasonable request for economy is in line with national policy; but unfortunately it has been made the occasion for a serious retrograde step—namely, the imposition of central control of hospital establishments, by making it necessary for any increase in staff to be approved by regional boards in the case of staff employed by management committees and by the Ministry in the case of staff employed by regional boards. Neither the need nor the possibility of economy can be disputed. In hospitals there is still scope for the introduction of labour-saving devices and of modern methods of business efficiency. Many hospital committees, however, have already gone as far as they can with direct economies; and further saving in maintenance costs will call for expensive new equipment, the rebuilding of out-of-date laundries and kitchens, or extensive structural alterations, such as may be needed, for example, to introduce a cafeteria system.

The aim of the Ministry's approach may easily be defeated by the antagonism it will create amongst many who have worked hard in the best interests of the service; for central control is feared and detested by those who work at the periphery. If the Ministry had ruled that all staff increases must be balanced by savings under any other headings, hospital authorities would no doubt have coöperated readily; instead it has specified a group of non-medical professional staff and of technical and other staff for a 5% cut. This must cause restlessness, ill-feeling, and distrust not only among individual workers but also among the committee members who are doing their best to provide a good service with limited resources. It may easily lead to friction between management committees and boards, and between boards and the Ministry. Apparently the Ministry has not yet realised that a big peripheral hospital cannot be regarded in the same light as, for example, a post office, which year after year provides the same service and in which the staff can readily be classified. A hospital medical service is constantly remoulded by the rapid changes in knowledge; and many services are related to particular skills which happen to be available at a particular time and place. The peripheral committees should have latitude in making the best use of their resources without having to fritter away time, energy, and temper in referring details to a central authority.

This memorandum naïvely suggests that applications for increases in staff may conveniently be sent up with the annual budget, although some applications may have to be made as the year proceeds. Yet in hospitals opportunities have to be taken as they arise; and a delay of six or nine months is usually unthinkable. On the day when the staff returns are made, a matron may have only ten nurses (below the average number) in her preliminary training school, whereas twenty-five may present themselves next time. Henceforth she must seek permission to take her normal number. Who will investigate her case, and how quickly will it be done? Regional boards are having to cut their own staff and yet take on a heavy new load of responsibility which properly belongs to the management committees, whose members have been hand-picked for their sense of public duty and knowledge of local affairs.

---

[2] The Heart of the Home.
[3] These Hands are Able.

A proper spirit of economy throughout the health service must be based on mutual trust. There is no reason why a sense of trust and of service to the community should not be infused down the line from the Minister to the ward-orderly, by personal contact and transference of a sense of individual responsibility from the centre towards the periphery. The Ministry's action, by checking this trend, will cause damage at all levels.

Annotations

PREVENTION AND CURE

PREVENTIVE medicine in this country has already passed through three phases, and the form that the fourth will take is in the balance. The fire and fury of Chadwick and his followers created a new specialty—public health—from among the clinicians, and the driving force of his "sanitary idea," the quality of the men it attracted, and the prosperity of the mid-19th century combined to give us world leadership in the new science of prevention. At the beginning of the 20th century the practitioners of this science were able to extend their sway, first to a wide group of personal preventive services, and after 1929, to a hospital service which rapidly rivalled the old voluntary system. Then in 1948, in the interests of a comprehensive and integrated hospital system, public health was shorn of its hospitals—even of the fever hospitals which it had controlled for nearly a century—and of a number of its other functions, leaving many of its exponents confused and frustrated, as they were for a time in 1854 when Chadwick's Board of Health ceased to exist. Recently there have been signs of a new pattern evolving, and it is instructive to have the views of a distinguished foreigner familiar with this problem in many parts of the world.

In the course of some lectures given during a medical teaching mission to Israel,[1] Dr. Karl Evang, director-general of the public-health service in Norway, distinguished three basic systems of public health: (1) the continental European, originating in Germany and at its inception a great advance, but now too legalistic and bureaucratic; (2) the Anglo-Saxon, more flexible, pragmatic, and crusading; and (3) the Slav or Russian, which has attempted a more complete combination of curative and preventive medicine but which, alas, can seldom be studied except at second hand. The field he allots to public health is comprehensive: it should, he thinks, not only be a specialty in its own right but also be responsible for over-all planning and coördination of the whole system, including curative medicine. In his opinion neglect of curative medicine by the public-health services has been as unfortunate as the similar neglect by the clinicians of such preventive services as maternity and child welfare and tuberculosis. The central government should give centralised direction, but activity should be decentralised: the division of health functions between different government departments is largely historical, and the trend is now towards concentration.

On hospitals, Evang feels that the approach to efficient administration must not be like the approach to a mathematical problem—there are no "right answers." Nor should those who appropriate money for hospital services demand the obvious advantages of "stabilisation of budgets," which inevitably leads to stagnation. On the open versus closed hospital, he favours the closed, with safeguards covering provision of diagnostic facilities for surrounding practitioners and a system of efficient reporting on their patients; selection of staff should be obviously impartial, and there must be flexibility in the allocation of beds. Rigid allocation of beds to specialties is on the way out, as are specialised hospitals—e.g., for tuberculosis and infectious disease. "The modern trend is away from very large hospitals" and a general teaching hospital, including psychiatric, tuberculosis, and infectious-disease departments, should not exceed 700–1200 beds. An administrator with a medical degree, other things being equal, is to be preferred to a layman, and Evang quotes Goldwater as saying that "a stalwart medical superintendent can protect his hospital from the exuberance of the reckless medical enthusiast more effectively than can a non-medical superintendent," as well as guarding clinical medicine from ill-informed lay control. While this does not imply that one of the clinicians at a large hospital should take full responsibility for the administration, he pleads for more clinicians to interest themselves in administration.

> "To my mind this is a vital point: when medical activities proliferate, as they do in modern society, *medical men must take administrative responsibility*. If they do not, if they limit themselves to clinical work, others, ignorant as to all the medical factors involved, will organize the institutions in which medical men will be invited to work. This applies not only to hospital medicine, but also to all other forms of medical activity. This calls for education in health administration, a field which has been neglected in most countries."

While rejecting the complete integration of hospital and health services as being at present impossible and inadvisable in most countries, Evang emphasises the need for "bringing the student and the teaching hospital out of their present 'clinical isolation,'" quoting Newsholme's dictum that "the treatment and prevention of disease cannot administratively be separated without injuring the possibilities of success of both."

THE MASKS OF A VIRUS

THE influenza virus can assume a bewildering variety of antigenic forms; and, so far, the particular strain which causes an epidemic in any year has been recognisably different from all the strains found before. It has been suggested that this continual antigenic novelty, allied to changes in virulence, is of great importance in the annual renascence of the virus; for if it returned to us each year in the same form we would have built up too strong a barrier of immunity to allow it to trouble us again. These are, at the moment, merely speculations, but it is fortunate that the techniques for studying the influenza virus have reached so sophisticated a stage that it is possible to set about testing the truth of this and other hypotheses.

The World Influenza Centre of the World Health Organisation has, since 1947, been making a special study of the origin and spread of influenza epidemics. Although information is obtained from many parts of the world, attention is for the moment focused mainly on Europe. Here the work is grievously handicapped by the Iron Curtain, which forms an effective barrier to the exchange of news about the virus, though the virus itself brushes it aside easily enough. But despite the difficulties and the fact that relatively few people are collecting strains, a brilliant start has been made and information of the greatest interest is beginning to appear. The first report, on influenza in 1948 and 1949, was published two years ago,[1] and now comes the report on the European epidemic of 1950–51.[2] The first report suggested that the influenza epidemic of 1948–49 started in Sardinia and spread northwards through Italy. All the influenza strains isolated in Europe at that time were indistinguishable one from another, and therefore it was supposed that they had all originated from a single focus. When the epidemic of a particular year ends, the virus is lost sight of: it is true that the virus is active at all times of the year somewhere in the world, but it probably also lies dormant around the periphery of the previous epidemic area. How it exists in this dormant state we do not know, but it may be present in an avirulent form in the lungs of people living in these peripheral parts. If then a new variant emerged in one of these people, this could be the starting-point of a new epidemic.

[1] Chu, C. M., Andrewes, C. H., Gledhill, A. W. *Bull. World Hlth Org.* 1950, 3, 187.

In the new report, dealing with 1950–51, the explanation suggested is much more complicated, for the strains of A′ virus isolated were of two subtypes, called S (Scandinavian) and L (Liverpool); and moreover there were recognisable, though small, differences among the S strains. It seems therefore that there were two separate influenza-A′ epidemics at the same time throughout Europe, and that the epidemic due to the S-type virus sprang up from several distinct foci. The Scandinavian focus of S strains seemed to originate in November, 1950, from the activation of virus which had disappeared from view after causing local activity in June, 1950. The virus which went to ground in June had already lost its 1949 mask, and was of the S type. Another focus of S strains, apparently of independent origin, showed itself in Eire. From these two centres the S-type virus spread northwards through Ireland and to Great Britain and the Low Countries. The L virus caused a simultaneous epidemic with a high mortality-rate; it appeared first in Liverpool in January, 1951, and in Belfast, whence it spread to other parts of the United Kingdom. At the same time, or soon after, the L virus was found in France, Greece, Israel, Italy, Spain, and Turkey, and there is very little to suggest how it got there. Epidemics caused by this type of virus had been observed in the Southern hemisphere in June and August, 1950. It was first discovered in Australia, and then in India, South Africa, and the islands of the Indian Ocean. But at the time of its irruption into Europe it was also causing epidemics in the U.S.A. and Canada, so that it might have come eastwards across the Atlantic. At the same time as these two A′ epidemics were in progress in Europe, there was also a third one about, for which a B virus was responsible, but this is not considered in the report.

As we have said, the S strains although very similar do show slight differences among themselves. Two separate foci have been described, but it may be better to regard this epidemic as arising in a more complex way at the periphery of the previous area of epidemic spread, with the emergence of a new type of virus capable of causing a new epidemic in communities around the periphery. The L strains were all definitely homogeneous, as had been the 1948–49 virus strains, so this epidemic may reasonably be supposed to have originated from a single individual in whom this new type gained a foothold.

van der Veen and Mulder[3] have described a new type of phase variation in influenza viruses. Virus in the P phase is that recognised hitherto, but the same virus in the Q phase is very poorly reactive with its homologous antiserum in in-vitro laboratory tests. The exact meaning in physical terms of the phase variation is not at present clear; but there is an analogous phenomenon in the rickettsia of Q fever. In the laboratory it is possible to transform a virus from one phase to the other. In the epidemic of 1950–51 the majority of the S types were isolated in the Q phase and the majority of the L types in the P phase. When both types were examined in the P phase they were clearly distinguishable, but in the Q phase it was difficult to tell one from the other. This, however, does not mean that the two are just variants of a single common type; it is difficult to examine Q-phase virus with any precision because all the serological tools are blunted. The experience of these years suggests that Q-phase virus tends to be present in the first stages of an outbreak, and P-phase virus when the epidemic has gained momentum; for a virus which is neutralised only with difficulty by specific antibody will have an advantage in gaining a foothold at the periphery of the previous epidemic area. Once it has got going, it can afford to shrug its shoulders at such additional stratagems.

MOSQUITOES AND MODERN INSECTICIDES

THE females of the two chief vectors of malaria in tropical and subtropical Africa, *Anopheles gambiæ* and *A. funestus*, enter native dwellings at night looking for blood. After feeding on the occupants they rest inside the huts until their meal is digested and the ovaries have matured; the gravid mosquitoes then leave the huts in the evenings to deposit their eggs. It has long been thought that if the inside surfaces of the walls could be coated with some substance toxic to the insects, large numbers of them would be destroyed while resting. The advent of D.D.T. and the discovery of its residual properties promised to give us a means of controlling these dangerous mosquitoes; but disappointments were in store. When it was used to spray the walls, D.D.T. seemed to have some unsuspected power of repelling insects, and this counteracted to some extent the effectiveness of its undoubted high toxicity. Investigation was clearly called for.

In 1947 Kennedy[1] showed that mosquitoes are irritated by sublethal doses of D.D.T., which prompt them to fly towards the light in an attempt to escape. Then Muirhead-Thomson's experiments in Tanganyika[2] showed that D.D.T. drove many *A. gambiæ* out of the houses after they had fed. Later, Hadaway and Barlow[3] demonstrated that fine suspensions of D.D.T. were more effective than those containing larger particles. Our knowledge of the situation has now been advanced a step further by Davidson,[4] who, working in Kenya on behalf of the Colonial Insecticides Committee of the Colonial Office, has investigated various preparations containing D.D.T., B.H.C. (gammabenzene hexachloride *B.P.C.*, 'Gammexane') and dieldrin, and studied their effect on *A. gambiæ* and *A. funestus*. He tried at first to repeat Muirhead-Thomson's work, and, though he obtained rather better results with D.D.T., many mosquitoes escaped from the huts alive and were caught in the window traps. Other suspensions of D.D.T. containing smaller crystals were more effective, achieving 40–70% kills over a period of nine months, but some mosquitoes still escaped unharmed. In other huts treated with B.H.C., fewer mosquitoes escaped, and the mortality ranged from 30 to 100% over six months. Muirhead-Thomson found that B.H.C. huts were lethal to all *A. gambiæ* entering them for at least thirteen weeks after treatment. Davidson then tried a mixture of B.H.C. and D.D.T.; this combined the high initial kill of the former and the long-lasting residual effect of the latter, but again many mosquitoes were caught on their way out. The most effective substance used in these experiments was dieldrin; for besides achieving a mortality of 80–100% over nine months, it allowed the lowest proportion of mosquitoes to escape as far as the window traps.

[4] Davidson, G. *Nature, Lond.* 1952, 170, 702.

Because all three insecticides irritated the mosquitoes to some extent, and caused a proportion of them to leave the treated surfaces before they had received a lethal dose, special experiments were devised which showed that D.D.T. excited them most and that the longest contacts were made on dieldrin-treated surfaces. Finally, it was shown that the two species were affected by the insecticides even when they made no contact with the treated surfaces. Mosquitoes were suspended for different periods in cages inside the treated huts, and twenty-four hours after their removal from the huts the number of dead insects was counted. Among those from the D.D.T. huts, the mortality was variable but generally low; B.H.C. continued to give high kills for three months after treatment, presumably by a combination of fumigation and the spread of particles; and dieldrin gave consistently high kills for nine months, mainly, it was thought, by means of airborne particles.

ELECTROLYTE LOSS IN THE SPUTUM

VOMITING, diarrhœa, and sweating are the well-known causes of a loss of fluid and electrolytes which may prove serious and sometimes fatal. Few people would think that the expectoration of large amounts of sputum could prove equally serious. Nevertheless, in an astonishing case recorded by Levinsky and Kern,[1] this did actually happen. Their patient was a Jewish broker, aged 65, who was proved by needle biopsy of the lung to have pulmonary adenomatosis or benign alveolar-cell tumour. This is a very rare condition, and there are only six previous instances where the diagnosis was made in life.

The illness lasted two years, after which the patient died; necropsy was not performed. The outstanding clinical feature was a persistent cough with the expectoration of enormous amounts of watery sputum. For much of the time the amount of the sputum was not less than 400 ml. daily. In one period of four months, during which the patient was under close observation, he produced in all some 20 gallons of sputum, the total weight of which was much more than that of his own body. On many days sputum output exceeded that of urine. At the height of this remarkable phase the sputum increased to almost 2 litres a day, and the patient began to complain of severe malaise, weakness, and muscular cramps. Investigation showed serious deficiencies in the proteins and electrolytes of the body-fluids; the chloride level was particularly low. Administration of fluid, salts, and proteins, both orally and intravenously, produced a remarkable improvement in his general condition, but the copious expectoration continued. The electrolyte content of the sputum approximated to that of the blood, but its protein content was much lower. Levinsky and Kern therefore argue that the bronchorrhœa cannot have represented an inflammatory exudate, but must have been due either to secretion or to filtration from the tumour. The possibility of a fistula between the alimentary canal and the bronchial tree was excluded by careful investigation, including bronchoscopy and œsophagoscopy. In view of the histological similarity between alveolar-cell tumours of man and the pulmonary adenosis of sheep (an epidemic disease known as jagziekte), an attempt was made to infect a guineapig with the sputum, but without success.

The results of treatment in this rare condition are of some interest. Deep X-ray therapy produced a fall in the volume of the sputum to an average of 200 ml. daily, but no further improvement was obtained with a single dose of nitrogen mustard. This case is a pathological curiosity rather than a matter of clinical importance; but the report is none the less memorable for that.

TELEVISION AND THE YOUNG

AT a recent conference Dr. Cyril Garbett, the Archbishop of York, drew attention to four possible dangers of television.[1] It might, he said, occupy too much time and attention, becoming a substitute for intelligent thought and reading; it might encourage people to rely on scrappy information, headlines, and pictures rather than on the printed article; it might accustom children and young people to sensationalism, violence, and brutality; and it could be used to spread subversive political propaganda. It is unlikely that the Archbishop regarded the two last dangers as serious at present in this country; but he was rightly pointing out the uses to which this new means of communication could be put by the unscrupulous.

A report[2] compiled by Mr. Max Gordon, based on the work of a Coventry tutorial class in psychology, suggests that television may have some compensating virtues. Questionaries were sent out to 500 young people of all economic sections between the ages of fifteen and eighteen, most of them living in Coventry, and 275 forms were returned completed. At least 1 in every 4 adolescents in Coventry is believed to watch television, and Mr. Gordon calculates that replies were received from 1 in every 15 of the selected age-group. Questions, however, need to be very skilfully framed if they are to elicit accurate information, and some of the questions put to these young people could have been sent with more advantage to their parents or their teachers. Adolescents, like the rest of us, prefer to think well of themselves; and it is not much use asking them whether television has interfered with their studies, or whether it has made them more loving towards their parents, and expecting an unbiased answer. The replies to such inquiries are better ignored.

Questions on matters of fact, bearing no risk to self-esteem, are likely to be answered reliably; and it seems clear that some of these young people now often stay in to watch television where formerly they would have gone out. Boys watched television on an average of 3·5 evenings a week, and girls on an average of 3·6. One boy in every two had previously been in the habit of going out on 4 or more evenings every week. It is impossible to say off-hand whether this is a good thing or not. In this country most of us believe that family life is important and valuable to the growing child and adolescent; but it is hard to know whether a silent and absorbed group clustered round a television set are experiencing family life in any accepted sense. Again, we need to know where the adolescent used to go during his evenings out: if to a youth club or to evening classes perhaps his life is poorer; if to wander round amusement arcades with "wide boys," himself getting wider and wider, then it is surely richer. One noteworthy finding is that television has stimulated an interest in plays, including the plays of Shakespeare. But informative talks and discussions are not to the taste of these young people; variety, sport, and the news-reel hold the highest places in their esteem. They are not much disturbed by political enthusiasms, it seems, and indeed they like television almost entirely for its entertainment value. Mr. Gordon suggests that television should be made less of a tie, and should invite discriminating attention: the programmes might with advantage, he thinks, be raised to a level halfway between that of the Home Service and the Third Programme of the sound broadcast.

THE MENTAL HOSPITAL SERVICE AND ITS FUTURE NEEDS

A STATISTICAL APPRAISAL

VERA NORRIS
M.B. St. And. Ph.D. Birm.
MEDICAL STATISTICIAN, INSTITUTE OF PSYCHIATRY (UNIVERSITY OF LONDON), MAUDSLEY HOSPITAL, LONDON

THE planned development of the mental hospital service depends on successfully forecasting future trends in the incidence and prognosis of mental disorders. Predictions, however, must be based on an evaluation of the current situation. For this purpose the following statistics are available.

STATISTICAL DATA

The Hospitals

The Commissioners in Lunacy, from their appointment in 1846, until the inception of the Board of Control in 1914, published annual reports, illustrated from 1859 by statistical tables. This series is a valuable contribution to our knowledge of mental hospitals, particularly as many of those in use today are basically the same as at the time of their opening in the latter part of the 19th century. The commissioners from time to time used statistics to show the need for changes in policy. One such occasion was in 1904 when they expressed their concern at "the increasing size of County Asylums." They showed that the incidence of and death-rates from "asylum dysentery" increased with increasing hospital size and they cited the following figures for 1902:

No. of beds	*Cases per 1000 persons*	*Deaths per 1000 persons*
Less than 500	3·2	1·1
500–1000	9·8	3·3
Over 1000	14·5	4·3

The commissioners concluded:

> "Justice and economy alike demand that the means which are provided to reinstate in health of mind and body those of the industrial classes who fall by the way should be those which are best calculated to secure that result in the speediest and most effectual manner, and this we believe to be hindered by the undue growth of asylums."

The reports of the commissioners compare well with any published today, even with the valuable annual reports of the departments of mental hygiene of the State of New York, the Commonwealth of Massachusetts, and other American States. The rapid growth of mental hospital service in the 19th century is shown in table I, which also shows the corresponding figures for 1946.

Bed-space

The assessment of accommodation recognised by the Board of Control in mental hospitals is based on a standard which allows about 40 sq. ft. of dayroom space and 50 sq. ft. of dormitory space per patient (Pratt 1948). In hospitals for mental disorders there was in 1950 accommodation for 126,196 patients in recognised bed-space; but, as some of this space was still diverted to war-time uses or was awaiting restoration to its proper use, the effective accommodation was for only 120,1[illegible] patients. The number of patients actually accommodated in mental hospitals was 135,190, and thus the average overcrowding was 12·5%.

TABLE I—PROVISION OF MENTAL HOSPITALS, EXCLUDING BEDS IN WORKHOUSES

Year	County, borough, and State hospitals	Beds	Registered hospitals and licensed houses	Beds
1846	19	5560	Not given	
1851	27	7851	137	7999
1871	54	27,109	122	7078
1881	65	44,101	110	7574
1891	70	56,353	100	8199
1901	80	74,246	82	7928
1914	100	109,494	79	6038
1946	104	127,087*	52	4976

* "Out of this accommodation there remained diverted for purposes arising from the war recognised bed-space for 10,417 patients."

On Dec. 31, 1949 (*Hospitals Year Book*, 1950-51) there were 420,668 staffed beds in hospitals administered by hospital management committees, and of these 146,604 (34·8%) were in mental hospitals. During the first nine months of the National Health Service the total expenditure by H.M.C.s on hospital maintenance was £97,713,914, and of this £18,453,421 (18·9%) was used for mental hospitals. The salaries of consultants and senior hospital medical officers were paid by the regional boards and are not included in the details of expenditure given above. The average maintenance expenditure per staffed bed for different types of hospitals was:

General	£316·9	Convalescent	£153·[illegible]
Isolation	£279·5	Mental	£110·[illegible]
Maternity	£412·4	Mental deficiency ..	£119·[illegible]
Tuberculosis ..	£263·3	Other	£101·[illegible]

Staff.—Hospital statistics for 1949 (Ministry of Health 1952) show that the staff employed in mental hospitals was as follows:

	Whole-time	*Part-time*	*Whole-time equivalent* †
Consultants and S.H.M.O.s ..	252	630	..
Other medical and dental staff	474	116	..
	726	746	..
Staff nurses and S.R.N.s ..	10,905	1316	658
Student nurses	4931	—	—
Other auxiliary nursing staff	2875	4070	2035
	18,711	5386	2693
Total domestic staff	9262	1079	540

† Author's estimates.

The part-time staff figures "are the numbers of part-time appointments," so it is difficult to assess them in terms of whole-time staff. For nursing and domestic staff it has been found in the Birmingham region (private communication) that counting 2 part-time as the equivalent of 1 whole-time appointment was a useful and not too inaccurate approximation. For part-time medical staff in mental hospitals, however, the number of sessions per appointment is likely to be few. In mental hospitals most of the psychiatric staff are employed whole-time, the part-time appointments usually being for consultants in medicine, surgery, dentistry, &c., who pay periodic visits to the hospital. The approximate numbers of staff per hundred beds are then:

Consultants and S.H.M.O.s	0·180
Other medical and dental staff	0·339
Staff nurses and S.R.N.s	8·32
Student nurses	3·55
Auxiliary nursing staff	3·53
Domestic	3·01

From hospital statistics in the Birmingham region I found (Norris 1951) that the average number of nursing staff of all types per hundred available beds for all except mental and mental-deficiency hospitals was 22·8, for mental hospitals 13, and mental deficiency 14; for tuberculosis hospitals (which had lowest staff/bed rates after mental and mental-deficiency hospitals) it was 21: for large general hospitals (highest ratio) it was 60. The allocation of both money and resources to mental hospitals is thus modest.

Bed-occupancy in mental hospitals is high. In table II the percentage occupancy has been calculated on the total bed-complement, because no information to date has shown the average daily number of available beds.

---

* Except where otherwise stated figures refer only to mental hospitals and do not include hospitals for mental defectives.

BLE II—MENTAL HOSPITALS (1949) IN ENGLAND AND WALES BY SIZE AND OCCUPANCY

Beds	Mental hospitals		Average no. beds	Average beds occupied daily	% occupancy*
	(No.)	(%)			
ess than 200 ..	7	6·3	113	92	81
200–400 ..	4	3·6	307	229	75
400–600 ..	9	8·1	489	400	82
600–800 ..	13	11·7	710	703	99
800–1000 ..	11	9·9	934	907	97
000–1200 ..	15	13·5	1103	1078	98

Total ..	111	100·0	1267		

$$^{*}\,\frac{\text{Average no. of beds occupied daily}}{\text{Average no. of beds in hospital.}} \times 100.$$

(In this context "available" means open and ready for use.) The rates given in column six are thus minimum occupancy-rates.

ADMINISTRATIVE USES OF STATISTICS

The main problems facing those who wish to plan the future mental hospital service are:

(1) How many mental beds will be needed, and of what types?

(2) What provisions should be made for outpatient treatment?

(3) How many people, and with what qualifications, will be needed to staff these beds?

In this paper I have dealt with the first problem, for outpatient treatment of mental disorders is, relatively speaking, in its infancy, and until we have more information about the present-day situation we cannot judge what the future needs will be.

If mental hospitals are now short of staff and accommodation, the future position may be expected to deteriorate for the following reasons:

The population of England and Wales is steadily increasing, and will continue to do so for several decades to come under natural circumstances.

The population is ageing, and, since the incidence-rates of certain psychoses increase with age, the population of mental hospitals is likely to increase.

There is a growing awareness both in the medical profession and the lay public that mental disorders are not always incurable, and that it is not a social disgrace to be admitted to a mental hospital for treatment.

Provision of free hospital treatment is likely to encourage earlier admission.

Funds and building resources are insufficient for the proper maintenance of hospital buildings, 96% of which were first put up by 1914. During the late war maintenance was necessarily neglected, and some mental hospitals now urgently need major structural repair.

The demands for young men and women of the requisite educational level for nursing are great, and nursing has to compete for the limited supply with other occupations financially, at any rate, more rewarding.

It might be argued that treatments, such as shock therapy and leucotomy, now undertaken in mental hospitals shorten appreciably the period of hospital stay, and will thus greatly lessen the need for hospital beds. Many statistical papers (e.g., Malzberg 1939, Bond and Rivers 1944, Rees 1949) support this contention, but an important limitation of such work is the comparatively short follow-up. From the annual report of the department of mental hygiene, New York State (1950), we find that 58% of the patients resident in the State mental hospitals suffer from schizophrenia; the average period of hospital life of schizophrenic patients dying in State hospitals in 1950 was 20·3 years. To reduce greatly the need for hospital beds, the criteria of successful treatment are:

Reduction of duration of *total* hospital stay.

A low relapse-rate.

A long period of remission during which the relapsed patient can remain out of hospital.

When comparing control and treated groups the duration of stay for the latter might be significantly shorter, statistically speaking, yet the difference in time may be of little practical significance as regards the need for hospital beds. Alexander (1944, 1945) and Rees (1949) have discussed the difficulties in evaluating the efficacy of therapy. Salzman (1947) found the readmission-rates to be higher and the intervals out of hospital to be shorter among shock-treated patients than among those treated conservatively.

Penrose and Marr (1944) found that at the Ontario Mental Hospital of the patients admitted in one year 30% might be expected still to be on the hospital books four years hence. From the Commissioners in Lunacy reports (1891–1914) we find that of 16,736 patients admitted in 1891, 24·7% were under care four years, and 10·6% under care seventeen years, after admission. The proportion under care four years after admission steadily increased with the succeeding years (table III). Thus improvements in mental hospital care do not necessarily decrease the length of stay in hospital. This is probably partly due to advances in medical treatment which increase the expectation of life inside, as well as outside, mental hospitals.

Statistics are also needed to assess the effect of changes in the Acts relating to mental disorder. In 1930 voluntary admission to mental hospitals was introduced, and the start of the National Health Service in 1948 gave rise to minor modifications of the Mental Health Acts. It would be interesting to have an evaluation of the effects of these changes on mental hospital administration.

TABLE III—DURATION OF STAY

Year	Admissions	% under care at the end of the 4th year
1891	16,736	24·73
1892	16,997	26·40
1893	17,662	25·57
1894	17,440	25·95
1895	18,320	27·02
1896	18,440	26·83
1897	18,618	27·70
1898	19,056	26·99
1899	19,060	26·90
1900	19,462	27·84
1901	20,282	27·28
1902	22,534	28·12
1903	21,760	28·18
1904	21,784	27·80
1905	21,335	27·34
1906	21,565	28·69

ESTIMATION OF REQUIREMENTS

The Ministry of Health (1950) have estimated that this country needs 4 mental beds and 2 mental-deficiency beds for every thousand of the population. On this basis, the number of beds needed in 1949 for the care of patients with mental disorders alone was over 172,000. According to the population projections of the Registrar-General (1951) the number of mental beds required would be about 181,000 in 1960 and 184,000 in 1970. About 28,000 nursing staff (all grades) would be needed in 1960 to maintain the hospital establishments at the 1949 level. Over 300 whole-time psychiatrists, and 600 other medical staff, would be wanted for the mental hospitals of 1960.

This method of estimating requirements by a gross over-all bed/person ratio is unsatisfactory since it does not take into account the differential needs, both quantitative and qualitative, of diverse age-groups. The proportion of people over 65 years of age is expected to be 12·2% in 1960 and 14·2% in 1970 as against 10·8% in 1949. We may therefore expect a proportionate increase in the disorders of old age (e.g., senile dementia) and a decrease in those of the younger age-groups (e.g., schizophrenia). In 1930–34 in the State of New Jersey (Frankel 1951) 38·3% of the total first admissions were due to schizophrenia and manic-depressive psychoses, while 25·8% were due to cerebral arteriosclerotic and senile psychoses. Since then the proportion of the former has decreased and of the latter increased until in 1945–49 the proportions were 28·4% and 38·3% respectively.

The proportion of females to males over 65 will probably increase from 1·40 in 1949 to 1·53 in 1960 and 1·49 in 1970; since male and female wards are rarely interchangeable this, too, will affect the type of beds needed. The qualifications of the staff will likewise depend on these trends, because the staff requirements for acute psychotics are different from those for senile patients.

To estimate mental hospital needs we must take into account age, sex, and diagnosis. Age affects the estimates for the reasons given above, and because the younger a person is admitted with a chronic mental disorder, the longer his average expectation of hospital life is likely to be; diagnosis affects them because the number and quality of staff, and the type of accommodation needed, differ according to the type of mental disorder. Objections may be raised to the inclusion of psychiatric diagnosis on the grounds that opinions on this subject are so divergent that statistics based on them are meaningless. Many medical statisticians, among them Farr (1839), Greenwood (1949), Cohn and Lingg (1950), have pointed out that useful conclusions can be made from data which are themselves imperfect. The annual publication since 1839 by the General Register Office of detailed mortality tables has been of inestimable value in improving the health services in England and Wales, although these have been, and still are, based mainly on diagnoses made by general practitioners who are usually without the diagnostic facilities now considered essential by specialists.

Detailed information about first admissions, in contradistinction to all admissions, to mental hospitals is also necessary to assess the efficacy of modern mental hospital practice. From 1921 until 1941 the annual number of direct admissions to county and county-borough mental hospitals rose slowly from about 22,000 to 26,000, but from 1941 to 1949 the number rose rapidly until in 1949 there were 51,463 admissions to these hospitals (Ministry of Health 1952). Without an analysis of first admissions by age, sex, and diagnosis it is difficult to suggest reasons for this large increase. It may be due among other things to high relapse-rates after early discharge from hospital, to changes in policy concerning the admission and discharge of patients, or indeed to increased incidence-rates.

First admissions as a percentage of total admissions vary considerably with diverse psychoses as is shown by the admissions to mental hospitals of New York State (1950):

	First admissions shown as % of total admissions with same mental disorder
Admitted with:	
Senile psychoses	96·3
Psychoses with cerebral arteriosclerosis ..	91·6
Primary behaviour disorders	89·8
Traumatic psychoses	78·7
Schizophrenia	62·9
Psychopathic personality	64·3
Manic-depressive psychosis	34·4
All diagnoses	71·6

Thus no idea can be obtained of the relative incidence of various psychoses treated for the first time in hospital unless first admissions are given separately from readmissions.

First-admission rates will not be wholly reliable, but they will probably be the best obtainable, since patients and relatives, though they forget or suppress information about an earlier admission, are unlikely to claim one without substance. It is necessary to decide whether or not to include previous admissions for psychiatric care to hospitals other than those classified as mental hospitals. Even when accurate, first-admission rates will not measure the incidence of psychoses, but they will give an estimate of those which require hospital care. Nowadays it is common for a person suffering from depression, for example, to be admitted several times in the course of a few years. Some method of sorting out repeated admissions would be useful. With all its limitations the first-admission rate does give valuable information on this point and should be used until a central case register such as that described below is working efficiently.

THERAPEUTIC TRIALS

The success of all statistical studies aiming to assess the efficacy of treatment of mental disorders depends largely on the adequacy of long-term follow-up studies. At present, this is not only an arduous but often an unrewarding task, for the practical difficulties are formidable. But therapeutic trials are as necessary for the welfare of the mental patient as for any other type of patient; it is advantageous both to the patient and to the hospital to find out what treatment is most likely to be successful.

Since Jan. 1, 1949, a scheme has been in operation to provide statistical data about patients resident in, and admitted to, mental hospitals in England and Wales (Ministry of Health 1949). For every patient resident in the hospital at the beginning of the scheme and for each admission thereafter an index card has been completed which records essential facts about the patient. If these cards, at present collected by the General Register Office and used by them to prepare punch cards for statistical analysis, were afterwards used to provide a central case register covering the current patient population resident in mental hospitals, the burden of follow-up studies would be immensely lightened. On the discharge, or death, of a patient his card would be removed from the current register to the appropriate discharge or death file. The cards of patients later readmitted would be put back into the current register and the information brought up to date. In due course it would then be possible for clinical research-workers to assess the long-term effects of the treatments now in use in mental hospitals.

SUMMARY.

Descriptive statistics of the present mental hospital service in England and Wales are given. Their use in the prediction of future hospital needs are discussed.

It gives me pleasure to acknowledge the assistance given to me by the Board of Control, and in particular by Mr. R. Tomsett. I am grateful to the London County Council for library facilities, and to the departments of mental hygiene of several States in America, including Arkansas, California, Massachusetts, Illinois, Nebraska, New Jersey, New York, Ohio, Pennsylvania, and Virginia, for information about their statistical services.

ECONOMY IN HOSPITAL MAN-POWER

LAST year the Select Committee on Estimates[1] expressed the view that substantial economies could be made by a national review of the whole question of hospital staffing, and that regional hospital boards should be given "more extensive power of controlling the size of the staff of the Hospital Management Committees than they possess at present." The Ministry of Health[2] has now called on hospital authorities to make an immediate return of their staff numbers; to reduce staff wherever possible; and to make no increases in staff without approval of the regional board (in the case of staff employed by management committees) or of the Ministry (staff employed by regional boards).

The Ministry circular says that such economies, if operated with proper care and judgment, will contribute substantially towards economy in both money and man-power without detriment to the services provided. In recent months a number of boards and committees have reviewed their establishments, and in some instances reduction in the number of staff has proved possible. "All Boards and Committees are now asked to undertake such reviews with the aim, wherever possible, of making similar reductions, the Regional Board participating in the reviews undertaken by the Management Committees in its area."

Staff numbers should, in future, not be increased unless careful scrutiny has shown real need; and any increase in numbers must receive prior approval.

Each regional board and board of governors is to inform the Ministry, within two weeks, of the total number of staff, according to categories ([*a*] medical and dental staff down to the grade of registrar; [*b*] other medical and dental staff; [*c*] nursing and midwifery staff; and [*d*] other staff). Administrative and clerical staff are not included, in view of the action already taken to secure reductions in their numbers. The numbers shown on the return are not to be exceeded without the Ministry's approval. In the same way each management committee is to inform the regional board within two weeks of the numbers employed by it in categories (*b*)–(*d*); and again these numbers constitute a maximum, not to be exceeded without the Ministry's approval.

> "Applications for increases in these maximum numbers should not subsequently be made without the most careful consideration by the Board or Committee concerned. Before applying, they should be fully satisfied that the increase is justified by exceptional circumstances such as serious undermanning (as, for example, exists in the nursing staffs of some mental and tuberculosis institutions) or substantial increases in work, and that the need cannot be met by reorganisation or in any other way that would avoid the employment of additional staff."

With their returns completed, boards and committees should carry out a detailed review of each category to see what, if any, reduction is possible—e.g., by reorganisation of duties, use of labour-saving devices, or discontinuance of less essential work. The regional board should participate in the reviews carried out by management committees in their area in any way that may be convenient in their local circumstances. Any resulting reduction in staff should be effected as soon as possible.

> "In present circumstances the Minister feels that Boards and Committees should aim at ensuring that the reductions in staff broadly counter-balance in numbers any staff increases which may be approved. The reductions need not of course be in the same categories. Nor will it always be possible for them to be made in the same Management Committee Group, but Regional Boards are asked to do their best to see that this broad aim is achieved in their area as a whole."

Regional boards and boards of governors are asked to aim at reducing staff in category (*d*) ("all other staff") by 5% before October, 1953. A reduction of this order may not be possible in some groups, and a correspondingly greater reduction may therefore have to be sought in others.

> "It is not the intention that there should be a blind or arbitrary cut and if a Board or Committee considers that the effect of any of the reductions would be to curtail essential services, a full report of the circumstances should be made, in the case of Management Committees to the Regional Board, and in the case of Regional Boards and Boards of Governors to the Ministry. In no case should reductions be achieved by transferring domestic work to nursing staff."

Regional boards are asked to tell the Ministry the total numbers of staff in each of the categories (*b*)–(*d*) employed by management committees in their area, and also the total of the committees' administrative and clerical staff; and subsequently at the end of each quarter to make a return of such staff, by categories, showing totals, increases, and decreases. Boards are also to submit similar returns in respect of their own staff.

PREPARATION FOR NURSING AS A PROFESSION

AT the British Social Biology Council's conference on preparation for nursing as a profession, on Nov. 7, the scope of the profession, and the many openings which nursing offers, were discussed in considerable detail.

The nurses on the platform, after stating their profession's alleged inarticulateness, showed much skill in exposition.

NEW TEACHING METHODS

Miss M. B. POWELL, matron of St. George's Hospital, and Miss D. L. HOLLAND, sister-tutor at Guy's, made the medical listener feel that the best of the nursing schools are offering the student nurse many things which are creeping only gradually into the training of doctors. Some student nurses are encouraged to visit the factory, and report back to their group of students on the conditions in which a patient's accident occurred, or to go and see the home from which his social disability or infection arose. These nurses are also given the advantages of the newest educational methods.

Other speakers recognised, however, that these methods are not yet widespread, and some doubted whether they could be generally applied in training-schools throughout the country. Grammar-school headmistresses, these speakers felt, had only heard of four training-schools, all in London. Provincial training-schools often could not afford to select their nurses at all, and were faced with the problem of weeding out the unfit from a mixed bag of applicants—most of whom have left school at 16.

ASSISTANT NURSES

Miss O. M. WAIN, matron of Willesborough Hospital, gave a moving account of her conversion from training the State registered to training the enrolled assistant nurses. She pointed out that this category of nurse was preventing the dilution of the profession by unskilled labour; and in addition this grade offered the girl of inadequate education an opportunity to develop and use her skills without the intensely traumatic experience of facing the enormous academic curriculum required for the State register.

THE HEALTH VISITOR'S BACKGROUND

Miss J. M. CALDER, chief nursing officer of London County Council, raised a highly controversial issue when she said that the nurse's intimate knowledge of disease was the best background for the social work of the health visitor. Unfortunately there seemed to be no professional social workers present to argue this point from the other side. Her suggestion that the National Health Service should be called a National Sickness Service, because it was directed by pathologists (whereas it should more properly have physiologists at the helm), seemed rather to contradict this theme.

THE PRE-TRAINING GAP

The prenursing school at Southampton, under Miss A. CROWE, seems to offer the girl of secondary modern education a liberal way of bridging the gap between leaving school and beginning her training. In general, however, the feeling seemed to be that the gap could be better bridged in other ways: prenursing courses, it was felt, could produce a girl who was sick of the subject before she ever reached hospital. The prenursing candidate was too young to be employed in wards with ill people and tended to lose interest in a goal set too far away. All the matrons and sister-tutors present were enthusiastic about training for the nursery nurse's certificate as a prenursing course; it offers a year of general education in an ordinary unsegregated technical school, and valuable experience of the behaviour of normal young children. As an alternative to this, matrons preferred to take girls who had worked in ordinary occupations before entering nursing; they did not feel that this was necessarily wasteful. The best type of girl for nursing, in their opinion, was one who retained her enthusiasm during the intermediate period without added incentive.

QUALITIES IN THE NURSE

Two of the non-nurses, Miss A. CATNACH and Mrs. N. MACKENZIE, lecturer to the Royal College of Nursing, seemed anxious to stress that the profession was not closed to candidates of low intelligence quotient, though the nurses who spoke called for women of high ability who were potential leaders. Certainly the capabilities needed for nursing listed by the non-nursing speakers were not those which would specially occur to a doctor who had worked in many hospitals with many nurses. Good personal hygiene, well-brushed hair, reliability rather than brilliance, potential manual dexterity, desire to serve, and a sense of what is worth while are qualities on which a rich woman might well choose a companion; but every doctor knows of many nurses with all these qualities who are quite impossible to work with.

A FRESH VIEWPOINT

Dr. ELIZABETH TYLDEN, the last speaker, sounded the first critical note of the conference. She tackled the problem of the selection of the nurse from the point of view, not of what the interviewing matron may look for, but of what the applicant for training in nursing gets when she has been accepted. She felt that some speakers had suggested that girls of high ability were not necessarily wanted in nursing, which seemed a pity. The present training did, however, have certain disadvantages of which highly educated girls might be critical, though newer developments seem to be correcting this. From the point of view of the public, nurses in training were taught to be extremely efficient in the domestic duties of providing warmth and food, disposing of excreta, and keeping patients clean. They are not, however, taught in any formal part of the curriculum to understand the impact of disease on the patient or on the family.

The psychology syllabus seemed to be too academic and was taught by people interested in those aspects of the subject which least concerned the generally trained nurse—by psychiatrists, who were too concerned with mental illness, psychologists, who were interested in academic problems, or sister-tutors, who groaned under yet another academic burden. Moreover, it was taught in the first year, when the nurse was too concerned with her own problems of learning and doing unfamiliar things to deal with it. Dr. Tylden suggested that the help of the professional sociologists, who ran departments in many universities, and of psychiatric social workers, who had an intimate knowledge of family problems, would be more valuable. Both matrons and sister-tutors, she thought, should receive special training in the problems of adolescents and of students; and ward sisters who undertook teaching responsibilities should not merely fill in the General Nursing Council's form, but should receive due training, recognition, and perhaps even pay, as tutors. These teaching sisters should constitute a teaching staff under the guidance and jurisdiction of the sister-tutor; each member of this teaching staff could become the "tutor" of a group of nurses, follow them throughout their training, as guide, philosopher, and friend, and be consulted at the nodal points in each nurse's life, just like a university tutor.

Dr. Tylden also suggested that the nurse's uniform was donned at such an early point in the nurse's career that it could prove disadvantageous. The medical student was accustomed to working without status or prestige, and even in his final year did not carry the label which the nurse carried in the eyes of the public as soon as the uniform was put on. The danger was that the advice which a first-year nurse offered might not be discriminated by patients from that given by her senior. Both the pride and the self-assurance of the new student could thus be tested to the utmost—sometimes beyond breaking-point. The military discipline which protected the nurse of Miss Nightingale's day from charges of immorality and frivolity now seemed out of date. The Army nowadays expects initiative from its privates, rather than blind unreasoning obedience. Teachers of nursing had no need to increase their prestige by wearing special uniform or by exacting particular marks of respect such as the putting on of cuffs. The offices of sister, sister-tutor, and matron carried enormous prestige to students, and needed no such disciplinary aids.

Teaching, too, was better conducted in these days by the teacher behaving merely as an expert witness in a group, not as a mentor. Formal lectures, Dr. Tylden hinted, always improved in quality as soon as they ceased to be compulsory, and teaching was better understood by the student whose views were treated with respect. Manual dexterity could only be acquired through encouragement, and was achieved only with great difficulty in the face of criticism or sarcasm. Some of the special problems of nursing students arose from the limitations of their pre-nursing education, and from their lack of wide general experience of life; and unfortunately most teaching schools supplied only the narrower aspects of sickness within the hospital. The impact of gynæcology, and of nursing in the male wards, on the nurse could be most shattering. Sex teaching in schools was not yet universal, and hence some special instruction in sex seemed desirable for the nurse early in her training if she was not to be shocked through her ignorance. Dr. Tylden thought that some parts of the nurse's training could with advantage be pursued at ordinary technical schools, so that she would be less cut off from the rest of the student community.

In the discussion many speakers held that the uniforms and systems of hospital courtesy did not in fact exert a serious effect on the nurse in training, and that they should not be in any way modified. The seniors in the nursing profession, it was suggested, should remember to make themselves approachable in spite of the system within which they worked. Senior girls in schools should be encouraged to listen to the school broadcasts on sex, and special provision for this kind of teaching within the curriculum would then become unnecessary. The anatomy of the male was in any case included in the curriculum of the G.N.C.; and psychology—in the form of the understanding of how to handle patients—could be acquired by the nurse in training by watching how the sister behaved.

ACTION OF OVARIAN HORMONES ON UTERINE MUSCLE

In a Ciba Foundation lecture delivered in London on Dec. 4, Dr. G. W. Corner, director of the department of embryology in the Carnegie Institution of Washington, described the results of his recent work with Dr. A. Csapo. He said that the differences in biochemical composition between uterine and skeletal muscle were quantitative rather than qualitative. Csapo had demonstrated the existence in the plain muscle of the uterus of the same system that his teacher, Szent-Györgyi, had shown to operate in skeletal muscle. Contractibility in all types of muscle was due to the actin protein molecule; and the myosin with which it was associated was the enzyme that transferred energy, in the form of energy-rich phosphate, from adenosine triphosphate (A.T.P.) to the actomyosin protein complex. Actomyosin fibres had been prepared from uterine, as well as from skeletal, muscle, and these fibres would contract in vitro in a suitable fluid medium when A.T.P. was added. The concentration of both actomyosin and A.T.P. in uterine muscle was one-seventh that found in skeletal muscle, so that the ratio of the one to the other was the same in both varieties of muscle. Uterine muscle required one-quarter of a micromolecule of energy-rich phosphate per gramme of uterine muscle per contraction; and the energy requirements of skeletal muscle, as calculated from the work of Prof. A. V. Hill, were identical.

The quantity of both the contractile protein and the energy-rich phosphate compounds, which supplied the power for the contractions of the uterus, were influenced by œstrogens. In castrated animals the concentrations of actomyosin, A.T.P., and creatine phosphate fell to a low level; but they could be restored experimentally by the injection of œstrogen. The regeneration of A.T.P. that followed the injection was more rapid than that of actomyosin, for the A.T.P. might be an intermediary in supplying the energy for the synthesis of actomyosin. Progesterone had no influence on the concentrations of these components of the contractile mechanism; but it did have an effect by modifying the dynamics of the exchange of potassium between the intracellular and extracellular spaces.

When strips of rabbit uterine muscle which had been acted on by œstrogen alone were suspended in Kreb's solution, the tension developed in them gradually fell as the frequency of stimulation was decreased. A similar phenomenon in cardiac muscle was described some 75 years ago by Bowditch as the "staircase effect." The same results were obtained by Dr. Corner and his colleagues in their experiments on uterine muscle subjected to a constant rate of stimulation by increasing the concentration of potassium in the medium. When the uterine strips were taken from animals which had been previously injected with progesterone, the opposite effect was observed. The staircase went up instead of down as the frequency of stimulation was reduced. Rapid stimulation apparently led to a loss of potassium from the muscle; and progesterone, by decreasing the rate of potassium return, reversed the staircase effect—the assumption being that the potassium concentration in the cell was greater than the optimum level. On the other hand, higher temperatures permitted a more rapid diffusion and so gave a more prominent staircase effect, while the œstrogen-dominated uterus stored on ice lost the staircase effect altogether. Repeated washing of the uterine muscle strip suppressed the staircase effect and reduced the tensions developed. A decrease in the potassium-sodium ratio increased the duration of the contraction in the œstrogen-dominated rabbit uterus. In this connection, Szent-Györgyi had correlated the digitalis effect in the cardiac muscle of the frog with the drug's inhibitory action on the back-diffusion of potassium.

Potassium is needed for the conversion of glucose to glycogen and for the transformation of these forms of carbohydrate to triose phosphate before their complete oxidation to carbon dioxide and water. The energy liberated by these metabolic processes is stored as energy-rich phosphate bonds in A.T.P. and creatine phosphate, so that in this way potassium influences the activity of the myometrium. Progesterone probably exerts its effect by regulating the movement of potassium, thus controlling the availability of this ion to the metabolic system of uterine muscle. This action of progesterone might explain the reversal in response to adrenaline of the uterine muscle of the cat when it becomes pregnant. Œstrogen governs the concentration of actomyosin in uterine muscle, and regulates the quantities of A.T.P. and creatine phosphate, which are the immediate sources of energy for the contractile protein. Progesterone, by its effect on potassium movement, controls the speed of carbohydrate metabolism, thus influencing the rate at which A.T.P. and creatine phosphate are regenerated.

Parliament

QUESTION TIME

Pneumoconiosis

Mr. David Williams asked the Minister of Fuel and Power how many miners in South Wales had been certified to be suffering from pneumoconiosis since Jan. 1, 1952; how many had remained in employment at the collieries; and how many had been employed elsewhere.—Mr. Geoffrey Lloyd replied: In the first half of 1952 there were 456 new cases under the National Insurance (Industrial Injuries) Act and 53 new cases under the Workmen's Compensation Acts. I regret that the available statistics do not enable the subsequent employment history of these men to be traced.

Medical Examination of Z Reservists

Mr. J. Johnson asked the Secretary of State for War whether he was aware of the dissatisfaction found in the past about the composition of the medical boards which examined Z reservists on call-up; and whether, if former prisoners-of-war in the Far East were called up, the Minister would see that the Army medical boards included doctors who were specialists in tropical diseases, as he believed was the case in Australia and New Zealand.—Mr. Antony Head replied: I have been in touch with the Minister of Labour about this and I understand that considerable trouble is taken to see that the fact that men have been prisoners-of-war is marked on their cards, and special inquiries are made about the effect of that imprisonment on their health.

New Military Hospitals

In answer to a question, Mr. Head said that there was a programme for the construction of seven new military hospitals in the United Kingdom, but there was little possibility of building more than one during the next year or so. Everything possible was being done to carry out alterations and improvements to existing hospitals.

In England Now

A Running Commentary by Peripatetic Correspondents

St. Danckwerts' Morn—a joyous day it was!
For all the frost outside, it was not cold;
Into ten thousand bank accounts there pass
Those slips of paper, symbolising gold.
That day no doctor, whether young or old,
Forbore in speech or thought to offer praise
To him whose verdict, just as it was bold,
Brought springtime to all hearts and merry lays;
Enough! Be thankful for this day of days.

* * *

During the late hostilities an old friend of ours incurred the gratitude of an army dentist by inoculating him with a sharp needle. When our friend later developed an apical abscess in an upper incisor, the dentist dismantled the tooth with loving care and substituted an affair of wire and plastic, cunningly wrought by his own hand, and moored invisibly to the adjacent teeth. The substitute was stained with Naafi tobacco juice to match its neighbours, and the general effect was most pleasing. Later, when the moorings relaxed their grip somewhat, the tooth would vibrate agreeably in our friend's head during the purple passages in his lecture on hygiene. This tooth, which we may call the Mk. I prosthesis, had a chequered history, but was ultimately lost at the bottom of the Minch during a rough trip to Stornoway in a tank landing craft.

The Mk. II prosthesis was not obtained until after the war. This time the matter was attended to with due form and ceremony, steaming moulds and plaster casts, and our friend found himself with a large pink serrated job occluding the whole of his hard palate. At one corner of this massive contrivance, as if by accident, was attached a single tooth. Our friend viewed it with considerable distrust, the more so since it transpired that every taste bud he possessed was located in the occluded area. He was spared much anxiety, however, by the resourceful action of his wife, who trod on the prosthesis on the bathroom floor the night he brought it home and snapped off a good three-quarters of the pink part. This allowed some at least of the taste of dried egg to penetrate his dulled senses at breakfast. He was also fortunate enough to shut the prosthesis in a drawer shortly afterwards, breaking off another large portion, and thereby allowing both the prosthesis and his tongue to occupy his mouth at one and the same time. Nevertheless he remains incurably disposed to remove his tooth when anything worth tasting is to be tasted, and when sneezing he has to adopt a complicated manœuvre with his tongue lest the prosthesis should be expelled among the startled bystanders.

Our friend has now taken to academic life, and the other day he was seated in his lab. chewing on a well-earned Blue Danish sandwich when the door suddenly opened and a minor procession arrived, headed by the Vice-Chancellor, who was on a tour of inspection of scientific plumbing arrangements. Our friend rose rapidly to his feet and looked hastily for his tooth; to his dismay he found it was not in its accustomed place on the typewriter. His muttered responses to Authority lacked conviction, but they served, and it was not until he pulled out his handkerchief to mop his brow that the situation was irretrievably lost. With the handkerchief came the Mk. II prosthesis, which arched through the air and fell with a thin clattering noise full at the feet of the entire Drainage Commission.

* * *

The problem of the leisured practitioner has been solved by the Medical Sporting Association, which announces a well-rounded programme for the season 1952–53. The organisers have had in mind especially the needs of consultants, S.H.M.O.s, and registrars, but all doctors are welcome. The Lincoln's Inn Hurdlers offer plenty of sport. The Pall Mall Orientals teach fencing and judo and award fakirships for yoga and the Indian rope trick. The Harley Harriers have a paper-chase every Saturday, assembling at the Harleian. Fox-hunting has a perennial appeal: the Wigmore meets at the Old Wim Pole on Tuesdays and Thursdays at eleven, and at their New Year meet will draw the Adelphi coverts. The Tavistock Square Dancers (telegrams: Honour your partners) have a well-appointed pavilion; quieter but more expensive are the Cavendish Olde Tymers. Details of any of these facilities may be had from the secretary of the M.S.A. at St. Pancras Hospital.

* * *

I don't know whether peripatesis includes travel in a small dinghy with an outboard motor, but anyway we walked the last bit. The occasion was an up-river trip for delegates to a nutrition conference somewhere in Africa. H.E. the Governor selected three of us from the party on the government launch to accompany him, and he proved to be as good a mechanic (marine) and navigator as he is an administrator. The object of this subsidiary trip after we had left the main party exploring James Island, now the size of a tennis court and said once to have housed a garrison of 300, was to see a native village. After a hot trip up a creek bordered by mangrove swamps with interesting bird life—for the benefit of medical bird fanciers my bag was a piebald kingfisher and a large purple heron—we reached the little landing-stage where a large heap of oyster shells was the surprising equivalent of empty tins on a refuse dump at home. Perhaps it was this addition to the staple diet which was responsible for a healthy crowd of young African farmers (groundnuts) who turned out to greet us in the village 100 yards inland. The local chief, with his bodyguard of one (with a dangerous looking shotgun) did all the formalities through an interpreter. The Governor introduced us as three very distinguished doctors, but the chief could hardly have cared less. He was much more interested in discussing His Excellency's recent leave and safe return and the prospects of a good harvest. The village was remarkably clean and tidy, and the inhabitants—despite the chief's obvious no-use attitude for the medical profession—looked well fed and cheerful. The return journey on a dropping tide revealed oysters attached to the lower parts of the mangrove trees where they grow in a happy parasitic sort of life. The heat seemed less intense as we met a slight head wind. Judging by weather reports which have reached the conference by circuitous means we are much better off here than In England Now.

* * *

In a world of change, the changed attitude of patients is perhaps only to be expected. But should we not still be able to claim the unquestioning trust of our own families?

Wife: "I've had a terrible pain in my back all night. I couldn't get a wink of sleep. Do you think it's lumbago?"

Self (*reaching for the marmalade, reading the film critic in the morning paper, and keeping an eye on the clock*): "Oh yes dear, I'm sure it is."

Wife: "What do you think I should do? Do you think I ought to stay in bed?"

Self (*with visions of the chaos that would ensue*): "Oh no, definitely not. You'll get fixed and your back will be much worse. You must keep moving about."

A week later, after the pain has gone, my wife is entertaining some friends to tea.

Wife: "I had a terrible attack of lumbago last week. As usual my husband didn't do a thing about it. That's the worst of being married to a doctor."

Friend: "They talked about lumbago on the wireless the other day. There was a doctor in Woman's Hour."

Wife: "What did he say?"

Friend: "He said you should go to bed straight away and stay there till the pain is better."

Wife: "My husband said I had to keep up and moving."

Friend: "Ah! but the radio doctor was a specialist."

How is this situation to be met? We are betrayed from within the Citadel. What are the B.B.C., the G.M.C., and the B.M.A. doing about this threat to medical family life? How can you play the oracle to your family or your patients if a rival specialist oracle on the radio contradicts you?

Letters to the Editor

AGRANULOCYTOSIS DURING ISONIAZID THERAPY

SIR,—In your issue of Nov. 15 Dr. McConnell and Dr. Cheetham report the development of pellagra in a man after three weeks' treatment with isoniazid in doses of 8 mg. per kg. body-weight per day. I describe here the case of a child who developed agranulocytosis after 3 months' treatment with isoniazid by the same scheme of dosage.

The patient, aged $4^1/_2$ years, was admitted to the Derby City Hospital in a state of semi-coma, and tuberculous meningitis was diagnosed. Treatment was begun with systemic and intrathecal streptomycin, with *p*-aminosalicylic acid, and with isoniazid in daily doses of 4 mg. per kg. body-weight. On the 18th day it was decided to continue treatment with isoniazid alone; the daily dose was increased to 8 mg. per kg. body-weight.

In the 10th week of treatment, and again in the 12th week, the child developed localised staphylococcal infections of the skin without associated constitutional disturbance. Penicillin was administered systemically on the first occasion; but with the recurrence of the infection 2 weeks later no drug was used and the infection subsided spontaneously. Blood-counts were done weekly, and were normal apart from a moderate neutrophil response during the intercurrent infections. In the 14th week there was a further recurrence of the staphylococcal skin lesion. On this occasion it was extensive and the individual lesions were less well localised. An obvious deterioration of the patient's general condition occurred, with listlessness and a rise of temperature to 100°F. Examination of the cerebrospinal fluid excluded relapse of the tuberculous meningitis. A white blood-cell count showed a total of 4900 per c.mm., of which only 1% (49 per c.mm.) were neutrophils. The values for red cells, hæmoglobin, and platelets were all normal. There was no evidence of throat or mouth lesions.

Isoniazid was promptly withdrawn, and aureomycin and penicillin were administered to control the infection. The patient's condition improved clinically within 24 hours. 2 days after withdrawal of the drug the bone-marrow showed active granulopoiesis with 17% myeloblasts, 17% myelocytes, 15% metamyelocytes, and 28% neutrophil polymorphs of the myeloid series. The peripheral blood now showed 363 neutrophils and 2299 immature granulocytes per c.mm. 3 days later, the neutrophils had increased to 6698 per c.mm.; and thereafter progress was satisfactory.

There can be little doubt that isoniazid was responsible for the agranulocytosis, for the blood changes were quickly reversed after the drug was withdrawn. This toxic manifestation is probably related to long-continued administration of large doses of isoniazid. The Medical Research Council report[1] says that only a few toxic effects were observed when the drug was given for 3 months in daily doses of 3 mg. per kg. body-weight up to a maximum of 200 mg. daily. It is doubtful whether this relative freedom from toxicity prevails when the drug is given in large doses over long periods.

I am grateful to Dr. D. V. Hubble for permission to publish this case.

Derbyshire Hospital for Sick Children, Derby.

MORE INDUSTRIALISATION OR MORE AGRICULTURE?

SIR,—Five years ago you published articles by me on the economic crisis then facing this country.[2] I queried the wisdom of the extreme emphasis placed on exports, and urged that the proper response to the changed situation was a shift of capital and labour into agriculture. I argued that the cost of foodstuffs would continue to rise both here and abroad, and that only by allowing farmers a much larger share of the national income would it be possible to regain stability.

At that time those who chiefly influenced official policy contested that the high price of food in the world markets was exceptional, that sooner or later it would fall, and that to encourage agriculture at home to achieve a higher level of production by offering higher prices for the produce would prove a shortsighted policy which would leave us stranded when it became possible to buy again in the world market. The counter-argument, that if the earnings from our export trade no more than broadly sufficed to pay for raw materials we should not in any case have the wherewithal to buy food abroad, was then ignored, as in many quarters it still is today. I went further, and urged that, once free trade among individuals was abandoned in favour of national controls over imports and exports, the questions at issue became social questions, and that the further industrialisation of England in the drive for exports was socially a mistaken policy, as well as economically faulty. It was in fact likely to inhibit the natural reaction to the alteration of our economic environment—namely, a doubling or trebling of the man-power and services devoted to agriculture at home.

The course of events since that time has gone far to justify the views thus expressed. The ever-increasing difficulties attendant on an export policy in a world which is more and more hostile to imports are now becoming a commonplace. But the progress towards a revaluation of the part that food must play in our economy is slow and uncertain, and there is even today no adequate appreciation of the need to draw resources into agriculture at home by allowing the scale of rewards to the farmer to go on swinging up and up so long as they bring increased production. If there is one point in our economic machinery more critical for our welfare (and perhaps survival) than any other, it is to be found in the mechanism for reviewing the prices of agricultural produce. It is natural enough for those who represent the consumer to claim that the farmer must not be paid more than a "fair" price, and that his receipts must be related to the cost of production. But this is the wrong basis on which to approach the matter, and the bringing of the complication of a fair profit into what is essentially a matter of supply and demand is a source of endless confusion. The question which must be asked is—assuming we need greatly to step up agricultural production by such and such an amount, how much must the community be prepared to pay the farmers to make this a profitable proposition? If the answer be that to enrol the necessary labour and create the necessary facilities will use, let us say, about twice the proportion of our national income that is thus employed today, the sooner we recognise the fact the better. Only about one-eighteenth of our population is at present engaged on the land—maybe we do indeed need greatly to increase the proportion. As I argued five years ago, such a prospect is by no means altogether dismal: for every step towards that goal means so much the less pressure for machine-made exports, and brings in sight the possibility of manufactures and services for the home market at price levels dictated by abundance rather than by scarcity.

Those who carry some responsibility for forming public opinion on these matters should do their best to prepare the country for still greater emphasis on home-produced food, though it cost twice as much as it does today: and they should at the same time adjust their outlook to a world in which forced exports play a less and less prominent part, and all the thousand things we can make in this country become available to us at prices which will help to comfort us for having to buy food we have grown for ourselves.

YOUR 1947 CORRESPONDENT.

ESTIMATION OF BLOOD-DEXTROSE

SIR,—In your issue of Nov. 22 I read with great interest the preliminary communication by Dr. Vere on the estimation of blood-dextrose with the ophthalmoscope.

Surely Dr. Vere has adapted his instrument as a saccharimeter? This instrument, which is widely used commercially to measure the concentration of sugar in solutions, depends on the fact that when plane polarised monochromatic light is passed through a solution containing sugar (or other optically active substances), the plane of polarisation of the light is rotated by an amount depending on the wavelength of the light, the thickness of the solution, and the concentration of the optically active substance in the solution.

That Dr. Vere is measuring this rotation is indicated by the fact that a variable analyser rotation is required to produce extinction of the reflex. If the plane of polarisation of the light were not being rotated during its passage through the eye, extinction of the reflex would always occur with the analyser in the same position, whatever the intensity of the light emerging from the pupil.

A "HARLEQUIN" COLOUR CHANGE IN THE NEWBORN

SIR,—Two cases of the condition appositely termed by Dr. Neligan and Dr. Strang (Nov. 22) the "harlequin syndrome" have been observed in a premature-baby unit here during the past month. The signs were exactly as described by them; the pupils were not observed.

The first baby, delivered normally, weighed 4 lb. at birth and was admitted 3 hours later. She was then extremely cyanosed and distressed and was resuscitated with difficulty. The first attack was observed on the 4th day of life, and four further attacks were noted during the next 4 days while the baby was lying naked in an incubator.

The second baby weighed 5 lb. 3 oz. at birth, and had signs of atelectasis for 2 days, during which time she was kept in an oxygen box. Feeding was begun on the 3rd day, but she vomited each feed; during a feed on the 5th day an attack was noticed. The vomiting subsided on the 6th day, and did not recur; no further long-continued examination of the baby when naked was therefore made, and no further attacks were observed.

This syndrome has been sought in mature babies, but in these it has not been detected.

DWARFISM AND AORTIC MALDEVELOPMENT

SIR,—Your annotation of Nov. 29, in which you draw attention to the association of congenital cardiac defects with ovarian agenesis, is timely.

Goldman et al.[1] reported that, in their series of 14 cases of coarctation of the aorta, 4 out of 5 females showed shortness of stature and abnormal digits; and the 3 of these who were adults had clinical evidence of ovarian hypofunction; the other was a girl, aged 8 years.

On the other hand, patients seen at endocrine clinics with growth stunting, neck webbing, and primary amenorrhœa (Turner's syndrome) should be examined carefully for congenital cardiac defects. Of 4 such patients at present attending the endocrine clinic at Stobhill General Hospital, Glasgow, 2 have congenital aortic stenosis.

I think that you are wrong to imply that the association of ovarian agenesis with coarctation of the aorta constitutes Turner's syndrome. The syndrome frequently occurs without demonstrable cardiac defect, and in none of the 7 cases originally described by Turner[2] was coarctation noted. Further, the opinion that ovarian insufficiency accounts for retardation of growth in this syndrome is wrongly imputed to Albright et al.[3] These workers discuss "5 possible causes for the diminished rate of growth in this syndrome . . . and believe it results from decreased adrenal cortical function."

ORAL ANTIBIOTICS AND SPONTANEOUS HÆMORRHAGE

SIR,—At a time when oral administration of antibiotic drugs is becoming more frequent, I wish to draw attention to a possible danger in their use. During experiments on rats I have found that chloramphenicol, given by mouth for some days, greatly enhances the animals' susceptibility to a single dose of oral anticoagulant ('Tromexan'). The average prothrombin-time 24 hours after our standard experimental dose of anticoagulant was 22·7 seconds (rat normal is 13·5 seconds); but in animals to which chloramphenicol had been administered for 4 days before the anticoagulant, the prothrombin-time rose to an average of 33·0 seconds.

A likely explanation of this finding is that, by modifying the flora of the gut, the antibiotic indirectly reduces the amount of vitamin K produced. The balance between the absorption of vitamin K and of the anticoagulant is thus disturbed, and the effect of the latter is consequently enhanced. This would be consistent with the results observed in other conditions where vitamin K is deficient.

It seems desirable to bear this experimental finding in mind when oral antibiotics and dicoumarol-like anticoagulants are to be administered concurrently.

THE OTHER 60,000

SIR,—It seems to be generally accepted that general practitioners form the largest section of registered medical men and women in the country and *that the* majority of medical graduates enter general practice. *It* is rather startling, therefore, to learn from Mr. H. A. Marquand's speech in the House of Commons[4] *that* in 1951 there were fewer than 20,000 doctors engaged in general practice in this country—18,195 principals and 1724 assistants—whereas there were in the *same* year well over 80,000 persons on the Medical Register.[5]

Where, I wonder, are the missing *60,000*? Surely specialist services do not employ more medical manpower than general practice?

Manchester.

EFFECTS OF HEXAMETHONIUM

SIR,—In answer to queries by Dr. Whiteside and by Dr. Coigley (Nov. 22), the evidence that hexamethonium is a pulmonary vasodilator might account for some of the benefits produced in bronchitis. The drug, however, may have other actions, such as relaxation of bronchial muscle; and it would be premature to ascribe clinical improvement to a possible vascular effect.

In answer to Dr. Cookson's query, the centre of gravity of the body as a whole lies somewhere about the pelvis. As the lungs are above this level with the body in the upright position, some drainage from the thorax in this position might be expected. The point we made, however, was that the cardio-pulmonary *blood volume* seems to decrease in the upright position only when normal innervation is present, and this decrease in blood content does not occur under hexamethonium. It is better to look at the results of the cardio-pulmonary blood volume as a group rather than stress individual answers, as these are as yet open to some experimental error. Our data on vital capacity are not adequate to answer his other query. A complete study of total lung volume would be required before drawing any further conclusions.

ANÆSTHESIA FOR TONSILLECTOMY IN CHILDREN

SIR,—I was most interested in Dr. Bullough's paper (Nov. 22) and wholeheartedly agree that children exposed to psychic trauma have long memories of it.

I am, however, against the use of intravenous thiopentone for children in whom the tonsils are to be dissected with the aid of the Boyle-Davis gag. Laryngospasm is a serious complication which most commonly arises from mechanical stimulus to the larynx itself—for instance, from the insertion of the Boyle-Davis gag, the packing of the tonsillar bed, or the trickling down of blood into the laryngeal area. If the spasm does occur, it is most difficult to prevent the child from becoming cyanotic. I do not use intravenous thiopentone for tonsil dissections unless I am prepared to intubate, which in my opinion is the only safeguard against laryngospasm.

I believe that a certain number of children readily accept the "needle," but in my experience the majority dread it. I knew an anæsthetist who, before inserting the needle, sprayed ethyl chloride on to the cubital fossa.

Whenever possible I visit the children on the day before the operation. While listening to their chest I encourage them to "puff away like a little engine." Boys invariably enjoy that idea, and little girls do not like to fall short. Premedication consists of sodium quinalbarbitone ('Sodium Seconal'), in dosage according to body-weight, which is given per rectum $1\frac{1}{2}$ hours before operation, and atropine gr. $\frac{1}{100}$ half an hour preoperatively.

If the child arrives in the anæsthetic room asleep, ethyl chloride is dropped on the mask, which is held about 3 in. from the face. The mask is gently lowered while the child loses consciousness, and anæsthesia then proceeds in the normal way.

If the child arrives in the anæsthetic room awake, I remind him of the game we played the day before; he or she usually puffs away quite happily, and occasionally even comments on the scent in flattering terms, until unconsciousness supervenes.

I am convinced that the majority of children leave for home with two outstanding memories: (1) the ice-cream they received for tea on the day of admission; and (2) the funny man who came to the ward to play the "engine game" with them.

West Herts Hospital,
Hemel Hempstead.

ERIC GOLDSMITH.

SIR,—I was very interested in Dr. Bullough's article. During twenty years' combined general practice and anæsthetics I had ample opportunity of seeing the great value of adequate pre-anæsthetic sedation of children. The average child who is induced with ethyl chloride when conscious is seriously affected by the experience for six months to a year. When visiting the child at his home, anything that the doctor does or says which reminds the child of hospital produces signs of fear varying from a mild protest to hysterical screaming; and the permanent result is dread of an anæsthetic.

At this hospital we have for many years given bromethol ('Avertin') to children who are having their tonsils and adenoids dissected—a total of over 6000 cases. The results have been highly satisfactory. A generation of children has grown up with no dread, in fact with no memory, of having an anæsthetic. Often a child, when asked by his parents if he has had his operation, replies cheerfully and unconcernedly, "No, Mummy, but I have got a sore throat."

We have absolutely no difficulty with depression of the respiratory centre. Though the child breathes shallowly after bromethol, full oxygenation is maintained and the lightest stimulant—e.g., induction with nitrous oxide—produces deep breathing. The cough reflex is very active, and both it and the respiratory centre are, in our experience, much less depressed than they are by morphine, quinalbarbitone ('Seconal'), or thiopentone. There is no increased tendency to laryngeal spasm.

Anæsthesia is induced either by an ethyl-chloride/ether sequence, or by nitrous oxide, oxygen, and trichlorethylene; either way is smooth and rapid, and maintenance by a Boyle's type of machine with a Boyle-Davis gag requires much less ether than with other types of premedication. Swallowing and coughing return quickly after the anæsthetic, and the child is returned to the ward in the same lateral position as he arrived.

Children, with their high metabolic-rate, are very tolerant of bromethol, and we have had no anxiety of children being "too depressed." Occasionally children are restless during recovery and they are given 'Nepenthe' in the usual dosage. We feel that it is unjustifiable to have the child wide awake, uncomfortable, and possibly crying. If the child can have several hours of light sleep after his operation, with cough and swallowing reflexes active, while all oozing from the tonsillar beds is ceasing, we are delighted. The fear that unless children are quickly awake postoperatively they are liable to inhale blood-clot is, we believe, unfounded; this is more likely to occur as the result of careless dissection and faulty hæmostasis. The inhalation of droplets of whatever is in the mouth does, of course, occur, but much more so if the child is wide awake and crying.

The only disadvantage of this technique which need be seriously considered is the suggestion that basal narcosis makes more work for the nursing staff. This is mainly a matter of organisation. The grouping of the operation cases under the supervision of one nurse until recovery is complete is the best way to solve this problem. The little extra work required—and it is only a little—is well repaid by the peace in the ward, the reduction of vomiting, and the unconcerned children that awaken a little surprised to find they have sore throats.

The ideal place for a child to fall asleep is in bed, and the least disturbing way of achieving this is by a drug administered per rectum.

Warneford General Hospital,
Leamington Spa.

JAMES A. KNOTT.

EXAMINATION OF RIB BONE-MARROW FOR TUBERCLE BACILLI

SIR,—Dr. March and Mr. Barton (Nov. 29) suggest that "ribs removed at thoracoplasty or at resection could be used in orthopædic units for grafting in tuberculous disease of bone without risk of implanting tubercle bacilli into the tissue of the recipient."

I must deny this most emphatically, for in my own experience two patients who received thoracoplasty ribs for spinal fusion for scoliosis developed tuberculosis at the site of implantation. These ribs were from donors who had had pulmonary tuberculosis, but the ribs were resected with care and chosen for the bone bank as being free from adhesions or neighbouring disease. They were placed in streptomycin-penicillin solution as soon as they were taken from the donor and stored at −20°C until used. The washings of the bone were sterile.

The patients developed sinuses at the site of the bone graft, and *Mycobacterium tuberculosis* was recovered from them.

In my experience it is wrong to exclude the presence of *Myco. tuberculosis* in bone by the examination of smears and Löwenstein cultures. If Dr. Marsh and Mr. Barton had implanted the marrow in a muscle pouch in guineapigs their results might have been different; but, be that as it may, two patients who have received apparently healthy ribs have become infected thereby.

London. C. H. LACK.

THERAPEUTIC APPLICATION OF PLASMA CHOLINESTERASE

SIR,—Workers at St. Bartholomew's Hospital[1] report that by intravenous injection of human plasma cholinesterase they have abolished, in a patient, the effect of succinylcholine. The anticholinergic effect became evident when the patient's plasma cholinesterase level had risen by about 50%, at which time the whole-blood cholinesterase had not risen significantly. Dr. Evans and his colleagues, in pointing out that the cholinesterases of plasma and of erythrocytes have different saponifying potentialities, refer to plasma cholinesterase (which is less specific for acetylcholine) as a "pseudocholinesterase."

Perhaps it is mostly emotional bias that makes me dislike this last term. Ten years ago, being convinced that cholinesterase was the major analeptic factor in plasma transfusion for shock, I agitated for the salvage of the discarded cholinesterase-containing beta-globulins from the war-time plasma-fractionation programme, and was overruled on the ground that it was "only a pseudocholinesterase." But is this name reasonable? We know that hæmoglobin, besides performing its physiological function of combining reversibly with oxygen, has an incidental propensity for combining with carbon monoxide, nitric oxide, isonitriles, and divalent silicon compounds; but we do not therefore call it a "pseudohæmoglobin." And the differences in reactivity spectrums between a "specific" cholinesterase, like that of brain or erythrocyte, and a "non-specific" cholinesterase, like that of intestinal mucosa or plasma, is chiefly one of degree. This degree, in turn, is contingent on the enzyme's function. Intracellular cholinesterases (and they are rather ubiquitous) are components of a cholinacetylase-acetylcholine equilibrium, regulating the cell's permeability, particularly for cations. They naturally encounter little except acetylcholine, and they may therefore enjoy a leisurely "specificity." They do so, however, at the expense of a later phylogenetic development, the "extracellular" or transport cholinesterases, whose function is to protect the body against the many exogenous and endogenous cholinergics with which it is periodically called upon to cope. We therefore find them where they will operate: in the saliva of an animal which may mistakenly eat a deadly calabar bean; as a permeability barrier in the wall of the vertebrate intestine, which commonly contains an otherwise overwhelming cholinergic dose of proteolysis products; in the plasma of a human with emotionally engendered acetylcholine flooding from the basal ganglia—or the recipient of a dose of succinylcholine. A cholinesterase with so broad a function must be capable of neutralising a variety of cholinergics besides acetylcholine, and fortunately plasma cholinesterase does this.

From these considerations it was evident that plasma cholinesterase—the *fraction* which I wanted to see stockpiled as an analeptic—might be a therapeutically applicable and versatile anticholinergic. On that basis, Dr. Walter Ward, Dr. Fred Johnson, and Dr. Edwin McLean, of Cutter Laboratories in Berkeley, California, agreed to pursue the plasma enzyme rather than the pharmaceutically more expedient one contained in erythrocytes. While Proewig, in Germany, has reported on the therapeutic activity of the latter,[2] my own experience with plasma cholinesterase, now extended to over 150 infusions in 80 patients, allows me to assure Dr. Evans and his colleagues that it is as innocuous and useful as their observations suggest. I have usually given it in conjunction with packed-erythrocyte transfusion,[3] but it has also been used in other ways and in diverse conditions. In my experience no untoward effect has come of doubling or trebling the plasma cholinesterase level; but in three patients in whom it was quadrupled there was extreme flushing and mental confusion lasting throughout the rise (usually 24-72 hours). In myelosuppressive blood dyscrasias this rise in transport cholinesterase is apt to be followed by a sharp sustained rise in erythrocyte cholinesterase, along with normopoiesis, confirming previous observations with massive plasma and with infusions of cruder cholinesterase preparations.[4 5] Infusion of plasma cholinesterase has not been particularly beneficial in hæmorrhagic shock but it has proved of such value in surgical shock, and in shock accompanying coronary occlusion, that in two local hospitals it has become an emergency-room item. From this standpoint, Schacter's results in experimental shock in dogs[6] seem applicable to humans.

I have had no opportunity of trying cholinesterase in radiation sickness, but it is worth mentioning that mice have been completely protected against 750r (the LD_{100}) of X-irradiation by giving them, three days previously, the amount of cholinesterase contained in 5 ml. of human plasma. This may be due to the known radiation resistance of mice sensitised by any foreign protein, but the matter needs exploration. Burn et al.[7] found a decrease in transport cholinesterase (called by them "pseudocholinesterase") of the intestinal wall of irradiated rats, and I regard this decrease as responsible for enhanced permeability of the intestinal wall and thus for the lethal proteosæmia which supervenes in these animals. It had previously been shown that in man the blood cholinesterase falls sharply after ordinary therapeutic irradiation.[8] From this it seems likely that in radiation sickness cholinesterase infusion will have the same effect as administration of terramycin or 'Chloresium,' which protect the animal by limiting absorption of cholinergic proteoses formed by coliform flora in the intestinal tract. Cholinesterase would also directly neutralise proteoses ("peptones") in the blood-stream. (Experimentally, it has been found that infusion of human plasma cholinesterase will cut short peptone shock in dogs or cats.)

When it was observed that, in cases where they induced remission in the myelosuppressive blood dyscrasias, terramycin, chloresium, or cortisone all raised the initially low blood cholinesterases characteristic of these conditions, a general concept evolved: it appeared that cholinesterase therapy would be useful only where (as in macrocytic anæmia, pemphigus, and surgical shock) the blood cholinesterase is depleted. But the observations at St. Bartholomew's Hospital on succinylcholine intoxication, as well as my own clinical experience, indicate a wider application. Some of the observed therapeutic effects, seen as they are in patients whose blood cholinesterase is normal or even raised, remain inexplicable. For example, a patient with generalised sarcoidosis, and another with ulcerative colitis, both in extremis following failure of adrenocorticotherapy, suddenly started to recover after a single intravenous injection of 2·5 ml. of a plasma cholinesterase concentrate (400 times the concentration of normal plasma

given only as a last resort and on no rational basis whatever. Furthermore, in 7 cases of severe, protracted, antihistamine-resistant penicillin urticaria the improvement following cholinesterase therapy was truly amazing. Likewise, single infusions of plasma cholinesterase have seemed instrumental in reversing cachectic trends in some patients with inoperable neoplastic disease.

Preliminary investigations, herein merely hinted at, have raised more questions than they have answered about the applicability of cholinesterase in treatment. It is indeed fortunate that a pharmacodynamically active preparation has finally been made available, so that investigators of the calibre of the St. Bartholomew's Hospital group may continue to elicit the answers needed.

ANTIDIURETIC SUBSTANCE IN HUMAN SERUM

SIR,—The careful experiments of Dr. Hawker (Dec. 6) show that serum from normal and pregnant women is antidiuretic when injected intraperitoneally into rats. It is most improbable, however, that this property of serum is related in any way to the water exchange of the subject, for the following reasons:

(1) Ames and van Dyke[1] have shown that the antidiuretic action of sera may be much greater when given intraperitoneally than when given intravenously.

(2) Dicker and Ginsburg[2] have shown that the antidiuretic substance in rat serum is absent from rat plasma.

(3) Brun et al.[3] withdrew large volumes of blood from donors after fainting—one of the most powerful stimuli to the release of antidiuretic hormone (A.D.H.)—and transfused them into normal recipients. They made no statement about the titre of A.D.H. in the blood, but inspection of their figures shows that it must have been equivalent to about 0·01 milli-units (mU) of 'Pitressin' per ml.

(4) In normal subjects, an intravenous injection of 1 or 2 mU of pitressin at the height of water diuresis will reduce the urine flow. I have withdrawn blood from dehydrated normal male subjects, hydrated them, and injected each intravenously with his own serum an hour later, when the urine flow was rising. No antidiuretic effect was observed: the titre of A.D.H. in each serum was equivalent to less than 0·1 mU of pitressin per ml. Simultaneous assay by the intraperitoneal technique in rats, however, gave figures for the antidiuretic activity similar to those found by Dr. Hawker and by Lloyd and Lobotsky[4]—namely, about 2·0 mU of pitressin per ml. (These results not yet published.) There is no reason why this method should not be extended, withdrawing a pint of blood and injecting the serum into the donor or into a normal recipient.

Middlesex Hospital,
London, W.1. A. A. G. LEWIS.

DEATH AFTER ANÆSTHETIC WITH HYPOTENSION

SIR,—Dr. Bodman (Nov. 29) reports the death, following hypotensive anæsthesia, of a man who was found post mortem to have extensive carotid atheroma. In conclusion he observes that carotid disease, like coronary disease, may be "another hazard sent . . . to plague the anæsthetist." Accepting this sentiment, one may at least say that the patient imposes the hazard on the anæsthetist unwittingly, but can the reverse be maintained?

Consider what happened to this "fit man of 76."

For an operation calling for no muscular relaxation, and involving no immediate surgical risk, he was given in succession and over a short space of time 'Omnopon' and scopolamine, thiopentone, pethidine, tubocurarine, a 10% cocaine spray, gas and oxygen, and pentamethonium bromide; and four of these were given intravenously. After this his respiratory mechanism was paralysed and his blood-pressure was between 50 and 60 mm. Hg.

Clearly, many patients have circulatory disease which is undetectable, or undetected, before operation. And merely to give the surgeon a bloodless field, it seems unjustifiable to treat patients in this way.

Windsor, Berkshire. DOUGLAS BELFRAGE.

DIAGNOSIS OF BREECH PRESENTATION

SIR,—The clinical diagnosis of breech presentation is occasionally made difficult by the patient's obesity, or by her tendency to "guard" against the merest attempt to palpate her abdomen. In such circumstances, I have for some years used a simple procedure which I have found of considerable value and which I have not read of in any medical publication.

If, after making the usual examination, I am still uncertain whether a breech or a vertex occupies the upper pole of the uterus, I place my left hand against the right side of the patient's abdomen, just below the level of the fundus of the uterus, the palmar surface of the hand and fingers facing medially. I then ask the patient to turn on to her right side, still keeping my left hand in the position described. As she does so, gravity causes the vertex (or breech) to fall towards the examining hand. A flick of the fingers of the left hand will now ellicit ballottement if the vertex occupies the upper pole, and the round shape and hard consistence of the head will be easily appreciated. On the other hand, ballottement will not be possible if a breech occupies the upper pole, and the softer and less easily defined outline of the breech will be felt by the fingers.

I first made this observation some years ago when I was a house-surgeon, and I have found that little practice is necessary, even in otherwise difficult cases, to differentiate in this way between breech and vertex with reasonable certainty.

Apart from the fact that this simple test may reduce the number of requests for X-ray examination, it has the added virtue that it is reliable and depends upon nothing but the hands and the sensitivity of the fingers.

Dunfermline. R. G. WHITELAW.

TERRAMYCIN

SIR,—I refer to your annotation on this subject (Nov. 29). The paper by Dr. Finland and his colleagues is quoted as saying that doses of 0·25 g. six-hourly "give significant, continuous blood plasma concentrations." I have not been able to find this passage in the paper. Further, this dosage is totally inadequate for patients over 3 years of age.

Bliss et al.[1] have shown that terramycin is bacteriostatic in concentrations of 4 µg. per ml. for most susceptible organisms, and this is regarded by most workers as the minimal inhibitory concentration. Welch[2] found with a dosage of 0·25 g. six-hourly that the blood-serum assay levels in adults never exceeded 2 µg. per ml.

A series of 50 infants and children, under the care of Mr. A. B. Wallace in the burns unit in the Royal Hospital for Sick Children, Edinburgh, had 0·25 g. or more six-hourly, and the assay levels fell below 4 µg. per ml. in 24% of cases.[3]

As toxic effects you mention diarrhœa and stomatitis; but these do not occur in children even when the drug is given without the protection of a gelatin capsule.

We cannot support your statement that such toxic effects as occur are "minimised by milk," but we agree with Parsons and Wellman[4] that sodium bicarbonate gr. 10–20, twenty minutes before each dose, is the most effective "buffer."

You state that "remarkable alterations in the intestinal flora" occur during terramycin therapy. You do not mention *Streptococcus fæcalis*, *Bacterium coli*, proteus, *Pseudomonas pyocyanea*, or other normal fæcal

bacteria as sensitive organisms, so may I ask against which organisms you conceive of the drug being active in producing this alteration?

The drug is said to have "no action at all on proteus and *Ps. aeruginosa* or in typhoid and salmonella infections." Hobby et al.[5] noted an action on *Salmonella typhi* and *Ps. pyocyanea*. Also Bliss et al.[1] found it effective against proteus, *Ps. aeruginosa*, and *S. typhi*, and against some strains of the latter two organisms it is active in very small concentrations.

There is considerable evidence that terramycin, for all its shortcomings, is at the moment the doyen of the large-bowel sterilising agents.[6] It is an important drug in the treatment of the infections of childhood, and is much less toxic for children than adults. Most authors have encountered reactions in 50% or more of adults treated; but in children they occur in less than half this proportion. In Finland's series of 87 adults the drug had to be withdrawn in 13%. We found this necessary in only 4% of our younger patients.

I do not believe that the drug should be dismissed as a poor relation of aureomycin or as a stand-by for penicillin, particularly in general practice (where the oral route is ideal) or in the children's hospital.

Liverpool School of Tropical Medicine. H. D. RITCHIE.

SIR,—You state that terramycin has no action at all on proteus and *Ps. aeruginosa*, or in typhoid and salmonella infections, mumps, measles, chickenpox, smallpox, malaria, and trichinosis. However, the inclusion of *Ps. aeruginosa* and typhoid and salmonella infections in this list is incorrect; for terramycin has been found to be effective against many strains of pseudomonas, particularly in urinary tract infections[7] because of its ability to attain high concentrations in the urine.

Favourable clinical results have also been obtained in typhoid and salmonella infections.[8–12] However, further investigations must be made before any final conclusion can be drawn regarding the rôle of terramycin in the treatment of these infections.

Pfizer Ltd., London, W.1. R. K. PHILLIPS
Director of medical services.

*** We tended, like Keefer,[13] to dismiss (perhaps too hastily) terramycin in the treatment of pseudomonas and salmonella infections, for favourable results have undoubtedly been achieved in some instances. But opinions are by no means unanimous and, as Dr. Phillips reasonably suggests, final judgment must await further investigations.

We regret that the reference to the statement about "*significant, continuous blood plasma concentrations*" was incorrect; the words were those of Welch,[2] to whose work Mr. Ritchie refers. The plasma levels attained (1–2 µg. per ml.) are none the less "significant and continuous"; for it does not necessarily follow that concentrations of a drug demonstrated to be bacteriostatic *in vitro* must invariably be achieved in the plasma before the drug can work. For example, Lyons[14] said of chloramphenicol that "the clinical response to treatment with this drug is often superior to that suggested by sensitivities as determined in vitro." Moreover, the data recorded by Bliss et al.[1] give no conclusive evidence for accepting the figure of 4 µg. per ml. "regarded by most workers as the minimal inhibitory concentration." For gram-positive cocci they cited 0·04–1·2 µg. per ml.; for gram-positive bacilli 0·01–0·5 µg. per ml.; and for gram-negative bacilli (about which we were reserved) 0·6–5·0 µg. per ml. for *S. typhi* and *Hæmophilus influenzæ*, and 3·1–100 µg. per ml. for pseudomonas and proteus.

Mr. Ritchie has been unfortunate in his experiences with milk as a means of reducing toxic effects. Herrell et al.[15] (and many clinicians and ward-sisters in this country) have had more encouraging results, while Parsons and Wellman,[4] whom Mr. Ritchie mentions as advocates of sodium bicarbonate, observed that "the use of milk, which allows maximum absorption, is simple and effective."

In the matter of the reactions of the common bowel organisms to terramycin, Baker and Pulaski[16] have demonstrated that terramycin will eliminate coliform bacteria from the fæces. Gram-positive cocci may be completely suppressed or may survive unchanged; *proteus, meanwhile, becomes dominant*.—ED. L.

Public Health

Tuberculin Matriculation or Mass Radiography?

WHICH is the more effective—continuous tuberculin testing of the whole population by the system described by Gedde-Dahl as "tuberculin matriculation,"[17] or mass radiography? Johansen and Hjort[18] have compared the two systems in the district of Gloppen on the West Coast of Norway, where tuberculin matriculation has been in operation since the autumn of 1943 and mass radiography since the autumn of 1950. The tuberculin (Pirquet) test was repeated every year among tuberculin-negative persons and those who had been vaccinated with B.C.G. Tuberculin matriculation was applied to a total of 5891 persons; mass radiography was applied to 3870—all over the age of 14. Only 3·9% of those eligible for tuberculin matriculation, and 19·6% of those eligible for mass radiography, did not undergo these tests. Neither method is foolproof, and each tended to show up the shortcomings of the other. Tuberculin matriculation proved useful in discovering and keeping under control convertors before they had developed radiologically demonstrable changes. Johansen and Hjort conclude that in their district both methods are necessary, and that their investigation has failed to show which is the more effective.

Obituary

GERALD TYLER BURKE

C.I.E., M.D. Lond., F.R.C.P.

Lieut.-Colonel Burke, a former secretary of the Medical Council of India, died at Bexhill-on-Sea on Nov. 13 at the age of 70.

He was born in 1882, the son of an officer of the Army Pay Department. He studied medicine at St. Bartholomew's Hospital, taking the Conjoint diploma and the M.B. Lond. with honours in 1907. Two years later he entered the Indian Medical Service by competitive examination. During the first world war he served in East Africa and, after the Armistice, in Constantinople where he was in charge of the medical wards in large military hospitals. He was three times mentioned in despatches.

During a period of study leave in 1922 he obtained the M.D. and M.R.C.P., and he returned to India with the intention of specialising in medicine and medical education. On securing his transfer to the civil side of the I.M.S. he was posted to the United Provinces for duty. The wide experience he gained as a district medical officer in that vast and densely populated province made him proficient in general surgery, operative ophthalmology, and gynæcology, and broadened his clinical outlook, but it did not shake his determination to specialise in medicine, and in 1929 he was appointed to the chair of medicine at Lucknow University. He was elected F.R.C.P. in 1933. His painstaking methods, devotion to the interests of his patients, and kindly firmness with his students made him an ideal professor, and he was greatly beloved by both Europeans and Indians in Upper India.

In 1935 he was persuaded to accept appointment as secretary of the recently created All-India Medical Council, though he gave up his clinical post with reluctance. Despite the medico-political tension of that time Burke, as a transparently honest and fairminded man, was persona grata with official and non-official members alike. On his retirement in 1938, he was appointed C.I.E.

On his return to this country he was appointed to the standing medical board of the India Office, which, in 1947, became the Board of the Commonwealth Relations Office.

"During his nine years in that office," a colleague writes, "recruits to the civil and military services in India passed through his hands. The multitude of sick and disabled officers of the Indian Army who came before him at regular intervals after being invalided from the East also greatly appreciated his fatherly wisdom and gentle dealing."

Burke's first wife died in 1937, leaving a grown-up daughter. His second wife survives him with two small sons.

IAN EARLE McCRACKEN

M.D. Edin., B.Hy. Durh., D.P.H.

Dr. Ian McCracken, senior lecturer in public health at the London School of Hygiene and Tropical Medicine, died on Nov. 30 after a short illness.

He was a North-country man by birth and affection. Coming from the Scottish borders he knew and loved the lands around Melrose, Kelso, and Tweed. It was against this background that much of his research into country practice and the growth of the dispensary system was conducted.

Dr. McCracken's father was a well-known general practitioner in Newcastle, and he himself practised there independently for many years. Graduating in Edinburgh in 1924, he took his public-health qualification in the University of Durham at a much later date, when he had already acquired a wide reputation as a fine clinician and a wise family doctor. In 1937 his health, which had never been robust, broke down under the strain of a profession to which he gave himself heart and soul, and he was obliged to curtail his activities. He took up laboratory work in the public-health service, and in 1940 offered his services to the medical officer of health (Sir John Charles) for civil-defence duties. In this way he became more and more closely associated with the public-health department in Newcastle and, when Sir John Charles was appointed to the Ministry of Health, in 1944, Dr. McCracken succeeded him on a temporary basis.

At the end of the war his health again gave cause for anxiety, but after a period of rest and treatment he was able to join the staff of the London School of Hygiene as a part-time research-worker in the history of public medicine. In the course of time he assumed full-time duties, and he devoted himself without stint to the welfare of the school. Happily he was able to give his energies in full measure to his two abiding interests—the personal guidance of students in their work, and the study of medical history. Through his early death at the age of 52 Dr. McCracken leaves a wide circle of friends who mourn his loss; and many groups of students of the post-war years will remember him as a wise and kindly adviser, a scholar, and a friend.

J. M. M.

JOHN JAMES DUNCAN KING

D.Sc. Lond., Ph.D. Sheff., F.D.S. R.C.S.

Dr. King, whose death, at the age of 45, we have already announced, was the first director of the Medical Research Council's dental research unit.

He qualified L.D.S. R.C.S. from King's College Hospital, London in 1929, having received a certificate of honour in operative dental surgery in 1928. After holding a house-appointment at King's he spent two years as an assistant in private dental practice.

The trend of his future career was already evident when he took the diploma in public dentistry at the University College of Dundee in 1932. Soon afterwards he asked Lady Mellanby for an opportunity to study research methods under her guidance. With a M.R.C. grant he was appointed to the staff of the Sheffield University field laboratories where researches on nutrition and dental caries were then being carried out. His interest in the dental aspect of Sir Edward Mellanby's work on vitamin-A deficiency led him to study the gingival tissues; and he always retained his interest in paradontal diseases. Among other species he made use of ferrets, which was the first time these animals had been used for nutritional studies. He was awarded the degree of PH.D. of Sheffield University on the results of these and other investigations.

In 1938 he made a long and arduous series of observations on the incidence of dental caries in the Isle of Lewis, not only doing hundreds of mouth examinations but collecting useful information about the diets of the island children. His findings were briefly reported in our columns and later incorporated in a M.R.C. special report.

At the outbreak of the late war, while holding a Beit fellowship, Dr. King joined the Army Dental Corps and continued to investigate gingival diseases, particularly trench mouth. Full of ideas on this subject he returned to do experimental work in London. He studied the gingival tissues of ferrets, using a capillary microscope of his own design; and, as always, he constantly returned to the human subject to assess the possible practical importance of his findings.

In 1946 when the M.R.C. set up a dental research unit at King's College Hospital Medical School, King was the natural and almost inevitable choice as director. In 1948 he visited Trinidad and British Guiana to make a characteristic, careful survey of caries and paradontal diseases in the natives. He was elected a fellow of dental surgery of the Royal College of Surgeons in 1949. He was an active member of the M.R.C.'s dental research committee, and at the time of his death he was helping to prepare a report on a sugar and caries investigation sponsored by the committee.

H. N. G. writes: "King would not commit himself to any theories which had not been completely substantiated. No-one, as yet, has succeeded in completely solving any of the outstanding dental problems but it is certain that the pioneer work of Lady Mellanby, from which King's investigations stemmed into original fields, have paved the way to their ultimate solution. King's work throughout demonstrated the interaction of nutritional, mechanical, and infective factors in dental disease. In particular he was able to show how paradontal disease in animals could be induced by injury from salivary calculi and how bone-gnawing with retention of muscle attachments could, by friction, prevent tartar formation and the associated gingivitis. Recently he had made extensive studies of the reaction of the gingival tissues to 'Epanutin.'

"King's life was devoted to his work. He was a friendly, most likeable man, often outspoken and devoid of guile. He never had an easy time because it was difficult to arouse the interest of his colleagues and thus obtain all the coöperation he felt he needed. For years he had difficulty in attracting workers to dental research, but by his sincerity and doggedness he succeeded in building a most efficient unit."

ALBERT EDWARD WALKER

M.B.E., M.D. Edin.

Dr. Edward Walker was the last of the stalwarts of the medical profession in Huddersfield who flourished in the early years of this century—men like John Irving, Peter McGregor, Marshall, Porritt, and Robinson—and he has outlived all his contemporaries by many years. He died on Oct. 21 in his 90th year.

He was born at Golcar, a village on the outskirts of Huddersfield, built on the steep slopes of a spur of the Pennines. He went to school at Pannal College near Harrogate, and he studied medicine at Edinburgh University where he qualified in 1884, proceeding to his M.D. in 1892. He practised all his working life in Huddersfield, and from 1905 to 1922 he was physician to Huddersfield Royal Infirmary.

He also took an active part in the affairs of Huddersfield. Keenly interested in education, he was a member of the old school board and later of the education committee. He served on the public library and art gallery committees, and he was at one time a member of the board of governors of Almondbury Grammar School, and a governor of the Huddersfield Technical School. During the first world war he was secretary of the Huddersfield division of the British Medical Association, and in recognition of his work he was appointed M.B.E.

C. D. P.-S. writes: "Edward Walker's deafness cut him off from many interests in his later years, but his hobbies of walking and reading—history was his special subject—and the wireless kept him from mental rustiness, and he retained a remarkable youthfulness of spirit. His appearance seemed to change little with his advancing years; and he was mentally alert to the end of his life. Only two or three weeks before his death he was out and about, accompanied by his dog, a constant companion."

In 1893 Dr. Walker married Miss Ethel Learoyd, who died several years ago. He leaves a daughter and three sons, two of whom are doctors. Mr. Arnold Walker, F.R.C.O.G., is chairman of the Central Midwives' Board, and Dr. Geoffrey Walker is carrying on his father's practice in Huddersfield.

DUNSTAN BREWER

M.R.C.S., D.P.H.

Dr. Brewer, who was for twenty years medical officer of health for Swindon, died on Nov. 30 at the age of 77.

He was born in Kensington, the son of Henry William Brewer, and he was educated at St. Charles College, Notting Hill, University College, and St. Mary's Hospital, where he qualified in 1897. After holding an appointment as assistant medical officer at the Kensington Infirmary he joined the staff of the Metropolitan Asylums Board in 1902. Two years later he took the D.P.H., and in 1908 he was appointed medical inspector of schools to the West Riding county council.

In 1920 he became M.O.H. for Swindon and superintendent of the Victoria Hospital there. During the next twenty years, under his guidance, the public-health services of the town were greatly developed. On his retirement in 1940 the council thanked him for his long and outstanding service to the town, and the local education committee also met to record their appreciation of his work for the children of the borough. His colleagues presented him with a silver rose bowl.

R. P. C. writes: "Dunstan Brewer was known to all in the profession in Swindon, not only as M.O.H. but as one to whom we could go at any time with problems. He was always helpful to young men starting in general practice, and his dealings and speech were open and straight. As superintendent and chairman of the medical committee of the Victoria Hospital he encouraged a friendly spirit while getting business through without delay. At our clinical meetings he discussed technical subjects lucidly, and as a speaker he was clear-headed with a keen sense of humour. As M.O.H. for a neighbouring rural district, I found him a kindly and helpful colleague when epidemics affected both our areas. We all regretted losing him on his retirement."

Diary of the Week

DEC. 14 TO 20

Monday, 15th

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, S.E.1
5 P.M. Dr. T. H. Whittington: Myopia, and Care and Treatment of Myopic Patient.

INSTITUTE OF CHILD HEALTH, The Hospital for Sick Children, Great Ormond Street, W.C.1
5.30 P.M. Prof. E. C. Amoroso: Comparative Physiology.

Tuesday, 16th

BRITISH POSTGRADUATE MEDICAL FEDERATION
5.30 P.M. (London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1.) Prof. J. D. Boyd: Development of Heart in Relation to Congenital Heart-disease.

INSTITUTE OF DERMATOLOGY, St. John's Hospital, Lisle Street, W.C.2
5.30 P.M. Dr. G. B. Dowling: Tuberculosis of the Skin.

WEST END HOSPITAL FOR NERVOUS DISEASES, 40, Marylebone Lane, W.1
5.30 P.M. Dr. Douglas Gordon: When the Electro-encephalogram Helps.

EUGENICS SOCIETY
5.30 P.M. (Burlington House, Piccadilly, W.1.) Prof. Roger Russell, PH.D.: Experimental Studies of Hereditary Influences on Animal Behaviour.

CHELSEA CLINICAL SOCIETY
8.30 P.M. (South Kensington Hotel, 41, Queensgate Terrace, S.W.7.) Mr. Basil Henriques, J.P., Dr. William Moodie: Juvenile Delinquency.

Wednesday, 17th

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5 P.M. *Section of Comparative Medicine.* Dr. R. Lovell, Dr. S. De Navasquez, Dr. J. B. Enticknap, Dr. Cuthbert Dukes: [illegible]
8.15 P.M. [illegible] tice. Dr. A. B. Davies, Dr. F. E. [illegible]: Fitness to Drive a Vehicle.

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. C. D. Calnan: Treatment of Fungous Infections.

Thursday, 18th

BRITISH POSTGRADUATE MEDICAL FEDERATION
5.30 P.M. (London School of Hygiene and Tropical Medicine.) Prof. A. Hemingway: Dynamics of the Heart Beat.

ROYAL SOCIETY OF MEDICINE
5 P.M. *Section of Dermatology.* Dr. R. L. Waterfield: Observations on the Development of the L.E. Cell.

LONDON JEWISH HOSPITAL MEDICAL SOCIETY
8.30 P.M. (11, Chandos Street, W.1.) Radiography of the Vertebræ. Carcinoma of the Rectum. *Pyloric Stenosis.* (Film meeting.)

Friday, 19th

ROYAL SOCIETY OF MEDICINE
4.30 P.M. *Section of Epidemiology and Preventive Medicine.* Dr. F. E. Camps, Dr. D. Thomson: Acute Epiglottitis. Dr. W. C. Cockburn: Treatment of Whooping-cough with Antibiotics.

ROYAL EYE HOSPITAL
5.30 P.M. Mr. Howard Reed: Slit-lamp Appearances and their Diagnostic Value.

INSTITUTE OF DERMATOLOGY
5.30 P.M. Dr. G. B. Dowling: Tuberculosis of the Skin.

BIOCHEMICAL SOCIETY
2 P.M. (St. Bartholomew's Hospital Medical College, Charterhouse Square, E.C.1.) Scientific papers.

Saturday, 20th

CAMBRIDGE UNIVERSITY
10.15 A.M. (Addenbrooke's Hospital.) Postgraduate symposium on surgical diagnosis and minor surgery.

NUTRITION SOCIETY
10.15 A.M. (University Department of Biochemistry, Sheffield, 1.) Conference on the Rôle of Vitamins in Metabolic Processes.

Notes and News

CENTRAL MIDWIVES BOARD

In 1902 the Midwives Act first brought the registration of midwives under official control. Last week, on Dec. 3, the Central Midwives Board marked the fiftieth anniversary of this event by a dinner, held in the Apothecaries' Hall, London. Mr. Iain Macleod, in a brief speech before he returned to the House of Commons, paid tribute to Miss Elizabeth Greaves, who for twenty-seven years up till 1952 was the Ministry's representative on the board. He remarked also on the happy relations between the Ministry and the board, and wished that the Ministry's dealings with other professions were so constantly amicable. The National Health Service, he pointed out, had revealed a need for still more midwives. Sir John Charles, chief medical officer to the Ministry of Health, recalled that in 1878 William Farr had spoken of "the deep dark continuous stream of maternal mortality." Up till then the needs of the woman in labour had not been wholly ignored: from 1518 the Royal College of Physicians of London included midwifery in its curriculum (though "this must have been a Collegiate figment of the imagination"); and from 1829 the Society of Apothecaries ran two courses in midwifery. In 1878 a private member's Bill to regulate the practice of midwifery was introduced, but it failed. In 1902, however, Parliament acted. For nearly thirty years Sir Francis Champneys presided over the board, until his death in 1930. Sir John Charles noted with pleasure the steady growth in the representation of midwives on the board: whereas in 1902 no midwife was included, it now had 6. Sir John Charles was proposing The Board; and, in replying, Mr. Arnold Walker, its chairman, first spoke of the honour of holding the dinner in the Apothecaries' Hall, where the first steps towards statutory control of midwifery had been taken. He went on to express the hope that some day the maternity service would be controlled by a single hand. The municipal midwifery service introduced in 1936 had been, he said, very efficient and very happy; this was a remarkable tribute to local authorities throughout the land. Many, he suggested, might regret that municipal responsibility for the service had been ended by the National Health Service Act. Thanks to the system of "split" training, the midwifery service had never failed in the war years. The board was now experimenting with a system of training which linked the district more closely with the hospital. In conclusion, Mr. Walker presented an illuminated address to Miss Greaves. Prof. A. A. Moncrieff, vice-chairman of the board, welcomed the guests in cordial terms. Sir Wilson Jameson, who, as master of the Society of Apothecaries, was both guest and host, responded. It was 150 years, he said, since the society began its fight for midwifery. The Midwifery Profession was proposed by Sir Allen Daley; and in her reply, Miss N. B. Deane, president of the Royal College of Midwives, suggested that British midwives could make a still greater contribution to planning health services both nationally and internationally.

ROSE SIMMONDS MEMORIAL FUND

A fund has been opened in memory of the late Miss Rose Simmonds, one of the first dietitians in this country, to provide prizes or scholarships in dietetics. Prof. Dorothy S. Russell, F.R.C.P., Dr. W. G. Wimbush, and Mr. W. R. S. Ritchie, C.A., together with the chairman and treasurer of the British Dietetic Association, have agreed to act as trustees. Donations may be sent to the treasurer of the association, 251, Brompton Road, London, S.W.3.

WORLD-WIDE PLANS FOR BIRTH-CONTROL

A new international organisation for the study of methods of birth-control and the spread of information about them was formed in Bombay on Nov. 29 at the closing session of the third international conference of planned parenthood.[1] The organisation is to be known as the International Planned Parenthood Federation, and it will take the place of the present international committee on planned parenthood. Regional offices will be established in New York, London, and Bombay, and later in other parts of the world. For the time being, at any rate, the headquarters will be in London. The conference, which was attended by 400 delegates representing fourteen countries, elected as honorary presidents of the federation Mrs. Margaret Sanger, head of the Planned Parenthood Federation of the United States, and Lady Rama Rau, president of the Family Planning Association of India. One of the objects of the federation will be to press for the inclusion of family planning institutes in the national health programmes of all countries; and the conference recommended that every country should aim at making advice about birth-control available to 80% of its women in the next ten years.

THE ADDICTION AND THE MAN

Harold Maine has written an autobiographical account of his alcoholism and mental illness.[1] He is an American, a moderately successful professional writer who became alcoholic in his 'teens; and he describes, with considerable insight and literary ability, his unsettled early life and his failure to come to terms with a harsh situation. He became a chronic alcoholic, the black sheep of his family and the despair of his first and second wives. Both his marriages ended in divorce, and he sank to the depths of alcoholic degradation. In the attempt to get cured he sought hospital treatment in a variety of institutions, in most of which he found that the doctors were remote and indifferent and the attendants ignorant and systematically brutal. Despite all this he found a sense of kinship with his fellow-patients, and when his craving for drink had subsided he eventually became an attendant himself. Of the institutions in which he subsequently worked, a Veterans' hospital was the most appalling, and this at a time when the public was being led to believe that everything was being done for the mentally ill ex-Serviceman. Mr. Maine's story is the more convincing because he is evidently a man of wide sympathy and great tolerance, and he views even callous attendants and caste-conscious doctors as victims of a vicious system too vast for them to oppose. Like the public, whose dirty work they are doing, they have a deep need to persuade themselves that the mentally ill are getting the best possible treatment. When they fail in this they take refuge in the cynical saying "Once a nut, always a nut!": thus placing the patient in a subhuman category, and relieving their sense of guilt about their treatment of him. Despite the horrors, this book is rewarding because of the unconscious self-revelation of a man of great humanity and courage, endowed with pity for every human being except himself.

AN UNUSUAL VIEW OF SIERRA LEONE

Mr. Pearce Gervis was stationed in Sierra Leone during part of the war, and shortly after his arrival at Freetown he took the opportunity of pushing up-river and into the interior. By what was almost an accident he was adopted by a native village, and the villagers built him a fine hut. From there he went further inland. Mr. Gervis has a discerning eye and a pleasant style. In addition he is a photographer of quite unusual skill. The result is, for the general reader, a wholly satisfying travel book,[2] which is adorned by over sixty magnificent photographic studies.

This work is of considerable importance to the student of primitive medicine. References to the "Poro school"—the initiation school for young men—are frequent in works on this subject; but the rites are secret, and few authors attempt to give particulars. Certainly no white man has previously ever lived in the Poro. Mr. Gervis was fortunate in having been able to resuscitate from drowning a youth belonging to the village which had adopted him, and this led to his reluctant admission to a Poro school in the neighbourhood. He was in effect admitted as an assistant master in order to demonstrate the method—and was presented as a test with a youth who had been immersed almost, but fortunately not quite, beyond the point of resuscitation. This particular Poro school must have ranked high among similar institutions—almost like a public-school in England. The youths spent a considerable time in it—three years in the case of a chief's son—and they learned many things which would be useful in adult life. Mr. Gervis witnessed the operation of circumcision, which was performed in the early morning after a night spent in wild dancing, during which the subject danced till he became unconscious from exhaustion. He was then laid face downwards over a stream of very cold water, so that the sex organs were immersed in it until the morning. The anæsthetic effect seems to have been satisfactory. The actual operation was performed with a piece of broken poison-bottle, encrusted with the blood of many previous victims. The author was able to introduce some cleanliness and an antiseptic, and it is to be hoped that the deaths from sepsis which previously took

place have been much reduced in number. At another Poro school of a less ambitious nature the operation was carried out with a safety-razor blade.

In the course of his wanderings Mr. Gervis met "Dr. Ruth," a middle-aged British gynæcologist who had spent much of her life as an independent benefactor of the natives. Doctor Ruth eventually gained admission to a Susu Bundu initiation school for girls, and her account of the operation which is there performed is included in the book. This well-produced work is of unusual interest to the historian and the anthropologist.

University of Cambridge

On Nov. 29 the following degrees were conferred:

M.D.—P. H. Buxton, P. D. B. Davies, J. Perrin, D. G. Vulliamy, Lionel Wolman.

M.B., B.Chir.—*Nancy I. Cardno, J. H. Newton, Petrie M. Newton.

M.B.—* Svarna L. Bhatia.

* By proxy.

University of Dublin

On Dec. 4 at the school of physic, Trinity College, the following degrees were conferred:

M.D.—D. W. Montgomery.

M.B., B.Ch., B.A.O.—M. M. Berber, R. M. Bowman, H. W. Bridge, H. M. O. Brown, Margaret E. Charleton, D. D. Chesney, Leila L. Dyer, W. B. C. Fagan, J. C. H. Haythornthwaite, Ruth A. Helsby, Marie T. Hyde, Rupert Indar, G. M. Irvine, Sheila King, J. J. G. Kneafsey, M. C. Latham, Anna M. K. Little, K. W. H. B. McAlpine, O. R. McCarthy, M. A. McVicker, B. A. Montgomery, J. R. Polson, Mavis Sayers, Sarah B. Schwartzberg, C. A. H. Trench, Betty E. Wallace, R. G. B. Williamson.

Royal College of Physicians of London

Dr. D. A. K. Black will deliver the Goulstonian lectures on Tuesday and Thursday, Jan. 13 and 15, at the college, Pall Mall East, S.W.1. He will speak on Body-fluid Depletion. The Milroy lectures will be given by Dr. W. R. S. Doll on Tuesday and Thursday, Feb. 10 and 12, on Bronchial Carcinoma—Incidence and Ætiology. All four lectures are at 5 P.M.

Royal Faculty of Physicians and Surgeons of Glasgow

At a meeting of the faculty on Dec. 1, with Dr. Andrew Allison, the president, in the chair, the following were admitted fellows of faculty:

W. M. Dennison, J. C. Dick, Bernard Isaacs, Leo Schamroth, Marjory B. Snodgrass, D. G. C. Whyte.

Radioactive Substances Advisory Committee

Sir Charles Darwin, F.R.S., has been appointed chairman of this committee in succession to Sir Henry Dale, O.M., who has retired. Prof. G. R. Cameron, F.R.S., has been appointed a member of the committee.

First World Congress on Fertility and Sterility

This congress will be held from May 25 to 31 in New York. It is sponsored by the International Fertility Association with the coöperation of the American Society for the Study of Sterility. Further particulars may be had from the chairman of the local arrangements committee, 1160 Fifth Avenue, New York, 29, New York.

Symposium on Anticholinesterases

On March 27 and 28 at the Wellcome Research Institution, Euston Road, London, N.W.1, the British Pharmacological Society and the fine chemicals group of the Society of Chemical Industry are holding a symposium on this subject which will include discussions on chemical features which confer inhibition; mode of action in vitro; acute effects of the mode of action in vivo; chronic effects of the mode of action in vivo, including effects on man. Further particulars may be had from Mr. George Brownlee, D.SC., physiology department, King's College, London, W.C.2.

Presentation to Dr. R. J. Allison

On Nov. 27, the members of the past and present staff of the Milford Chest Hospital presented Dr. Allison, to mark his retirement, with a triple-speed record-player, a cheque, and an album containing the signatures of the contributors. He has been superintendent of the hospital since it was opened, nearly 25 years ago, as the Surrey County Sanatorium. Tributes were paid to him by Sir Geoffrey Todd, F.R.C.P. (on behalf of the South-West Metropolitan Regional Hospital Board), Dr. K. A. Soutar (Surrey County Council), Mr. J. T. Pyne (chairman of the hospital management committee), and Dr. A. S. Herington (deputy physician-superintendent of the hospital).

First International Congress of Physiotherapy

The first congress of the World Confederation for Physical Therapy is to be held in London from Sept. 7 to 12. Further particulars may be had from the press officer of the Chartered Society of Physiotherapy, Tavistock House (South), Tavistock Square, W.C.1.

Burns on Television

In the television series *Matters of Medicine* on Monday Dec. 15, at 9.30 P.M., there will be a programme on the Treatment of Burns.

CORRIGENDA: *Bovine Tuberculosis and Human Tuberculosis.*—In the two tables accompanying the letter by Mr. L. Pitcher, M.R.C.V.S. (Dec. 6) the words *per annum* were wrongly placed at the head of columns 3 and 6 in each table. The figures in these columns actually represent the *total* number of notifications of pulmonary tuberculosis in the years given in columns 2 and 5. The words *per annum* should have appeared above columns 4 and 7, which give the notifications per 100,000 population *per annum*.

Epidemic Hæmorrhagic Fever.—In the paper by Captain A. J. Rowe, in our issue of Nov. 15 (p. 980), the date of the first appearance of this disease among United Nations forces in Korea was given incorrectly. It should have been given as June, 1951.

Appointments

ANDREWS, G. S., M.D. Brist.: consultant pathologist, hospitals in the Newport, East Monmouthshire, and North Monmouthshire areas.

BEARD, A. J. W., M.D. Lond., D.A.: anæsthetist (consultant), National Heart Hospital, London.

JACOBS, H. B., F.R.C.S., D.O.M.S.: asst., ophthalmic outpatient department, Middlesex Hospital, London.

Leeds Regional Hospital Board:

DAVIDSON, WILLIAM, M.B. Glasg., D.P.H.: asst. chest physician (S.H.M.O.), York and Scarborough area.

HILL, R. L. T., M.B., B.SC. Glasg., D.M.R.D.: consultant in radiology, Bradford "A," Bingley, Keighley, Skipton, and Settle groups.

MCDOUGLE, H. A., M.B. Edin.: asst. anæsthetist (S.H.M.O.), Hull "A" and East Riding groups.

NAKIELNY, E. A., M.B. Polish School of Medicine, Edin.: asst. chest physician (S.H.M.O.), Hull area.

Welsh Regional Hospital Board:

EVANS, C. J., M.B. Lond., B.SC. Wales, F.R.C.S.: consultant thoracic surgeon, Glantawe, Mid-Glamorgan and West Wales H.M.C.S.

LLOYD, D. O., M.B. Lond., D.P.M.: asst. psychiatrist (S.H.M.O.), North Wales Hospital for Nervous and Mental Disorders, Denbigh.

LLOYD, G. H. T., M.D. Lond., M.R.C.P.: consultant physician, Clwyd and Deeside H.M.C. group.

PORCHER, H. I. H., M.D. Lond., D.P.H.: asst. psychiatrist (S.H.M.O.), Morgannwg Hospital, Bridgend.

WILLIAMS, O. G., M.D., B.SC. Lond., M.R.C.P.: consultant pathologist, hospitals in the Swansea and Llanelly areas.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

Births, Marriages, and Deaths

BIRTHS

BULLOUGH.—On Dec. 1, at Hope Hospital, Salford, to Anna (née Cicognani), wife of Mr. A. S. Bullough, F.R.C.S.—a daughter (Irma).

DICKSON.—On Nov. 30, at Walton-on-Thames, to Evangeline (née Sladen), wife of Mr. John W. Dickson, F.R.C.S.—a daughter.

POULTON.—On Nov. 28, at Forest Gate Hospital, London, to Hel (née Iremonger), wife of Dr. E. Maclean Poulton—a son.

RUSSELL.—On Dec. 5, at Hartlepools Hospital, to Isabel, wife of Dr. Frank Russell—a son.

STEVENS.—On Dec. 2, at Oldchurch Hospital, Romford, to Ann, wife of Dr. J. D. Stevens—a son.

MARRIAGES

GIBB—FEETHAM.—On Nov. 8, at Oxford, William Eric Gibb, F.R. to Mary Edith Gertrude Feetham, M.B.

DEATHS

BREWER.—On Nov. 30, at Rockingham Rectory, Market Harborough, Dunstan Brewer, M.R.C.S., D.P.H.

MCCRACKEN.—On Nov. 30, Ian Earle McCracken, M.D. Edin., D.P.H., of Ladbroke Grove, London.

SQUIRE.—On Nov. 27, in Exmouth, Walter Perfect Squire, M.R.C. major, R.A.M.C. retd, aged 92.

THE AFFERENT-LOOP SYNDROME

BILIOUS REGURGITATION AFTER SUBTOTAL GASTRECTOMY AND ITS RELIEF

CHARLES A. WELLS
M.B. Lpool, F.R.C.S.
PROFESSOR OF SURGERY IN THE UNIVERSITY OF LIVERPOOL

I. W. MACPHEE
M.D. Glasg., F.R.C.S., F.R.C.S.E.
RESEARCH ASSISTANT, DEPARTMENT OF SURGERY, UNIVERSITY OF LIVERPOOL

AMONG the unpleasant symptoms following subtotal gastrectomy bilious regurgitation is one of the most common, most troublesome to the patient, least clearly differentiated, and easiest to cure. It is surprising that more attention has not been paid to this symptom as a distinct entity in the post-gastrectomy syndromes. Nausea, distension, sweating, and deficient absorption are manifestations of altered function, and, as all those who have tried to correct them are aware, present an exceedingly difficult problem in treatment; but bilious regurgitation has, in our experience, proved to be easily remedied, especially when severe.

In the many reports published on post-gastrectomy problems the frequency of bilious vomiting can be recognised, but it has rarely been differentiated from the other post-gastrectomy symptoms. Steinberg (1950) clearly recognised the syndrome of afferent-loop stasis, and Wells and Welbourn (1951), in a study of the mechanism of the various post-gastrectomy syndromes, first clearly defined the cause of this bilious vomiting, and devised a remedy which was subsequently found to differ but little from Steinberg's treatment.

Afferent Loop Stasis

MECHANISM

This is a problem in simple mechanics, a kink developing in the afferent loop of any of the gastrojejunal anastomoses. The condition does not therefore follow the Billroth-I type of gastrectomy. It is seen especially in the Finsterer-Lake type of antecolic *right-to-left* anastomosis associated with a Hofmeister valve. When the afferent loop is too long, the tendency to kinking is all the more pronounced (fig. 1*a*). The weight of a loaded colon, it has also been suggested, drags the afferent loop down and kinks it at its point of suspension from the lesser curvature of the stomach. More rarely a very short afferent loop is also liable to kink at its junction with the stomach (fig. 1*b*). This phenomenon is sometimes observed in the retrocolic Polya type of anastomosis; it rarely follows gastro-enterostomy and the older limited partial gastrectomy with Polya type of anastomosis. In these operations the afferent right-to-left loop is not carried so high and consequently does not kink when the upright posture is assumed. For this reason afferent-loop stasis is most commonly seen with the most radical gastric resections, and the modern type of operation is particularly liable to this complication. Conversely, afferent-loop stasis is much more infrequent after total gastric resections because the Roux-en-Y type of anastomosis does not lead to kinking of the afferent loop. The anastomosis of œsophagus to jejunum with entero-anastomosis is clearly immune from afferent-loop stasis.

Occasionally some other factor may contribute to this kinking (fig. 1); we observed it in 1 case when the afferent loop has become bound down by adhesions to the anterior parietal wall; in 1 case of gastrojejunocolic fistula (fig. 1*d*), and in 1 case after torsion of the afferent loop. This last condition has also been noted by Gaillard (1951) occurring twelve years after the original gastrectomy.

No matter what type of anastomosis may have been done, and no matter how extensive the gastric resection may have been, any cause whereby the afferent loop becomes kinked at its junction with the stomach leads to the typical symptoms of afferent-loop stasis. They must be clearly differentiated from symptoms arising from the efferent limb of the anastomosis.

CLINICAL FEATURES

Within an hour, and usually much less, after a meal the patient complains of a bitter taste in the mouth and the regurgitation of yellow, green, or brown bile *quite unmixed* with food. This, by itself, is almost pathognomonic of afferent-loop stasis. If the bilious vomiting be severe, food may finally be ejected, as the upset in motility spreads further down the gastro-intestinal canal. The vomiting of food, however, is always preceded by bilious regurgitation. This condition is so common in the first few weeks after gastrectomy that its occurrence should occasion no surprise. By the end of three months after operation, however, it should have subsided; and, if it has not, the true afferent-loop syndrome has probably become permanently established. Rarely the onset of bilious regurgitation is delayed for years after the gastrectomy.

The bilious regurgitation following a meal is often related to the ingestion of fatty foods. The passage of fat into the efferent limb of the jejunal loop is associated with an increased liberation of bile, which tends to accumulate in the almost closed afferent loop. The pressure and distension associated with increased motility to overcome the obstruction increase and are often associated with a feeling of fullness sometimes amounting to pain. This is very similar to efferent-loop spasm, but the patient with afferent-loop stasis is sometimes aware of the discomfort to the *right* of the midline. When the pressure in the afferent loop rises sufficiently high, the duodenal contents are suddenly liberated into the stomach and efferent jejunal limb, and some of the bile-stained fluid is regurgitated unmixed with food. The sudden relief of tension relieves the patient of his pain or discomfort, he suddenly becomes hungry again, and he may have another meal within fifteen minutes of the first.

Often, however, the pancreatic and biliary secretions may remain dammed up for a day or days. The patient then complains of continuous epigastric pain or dis-

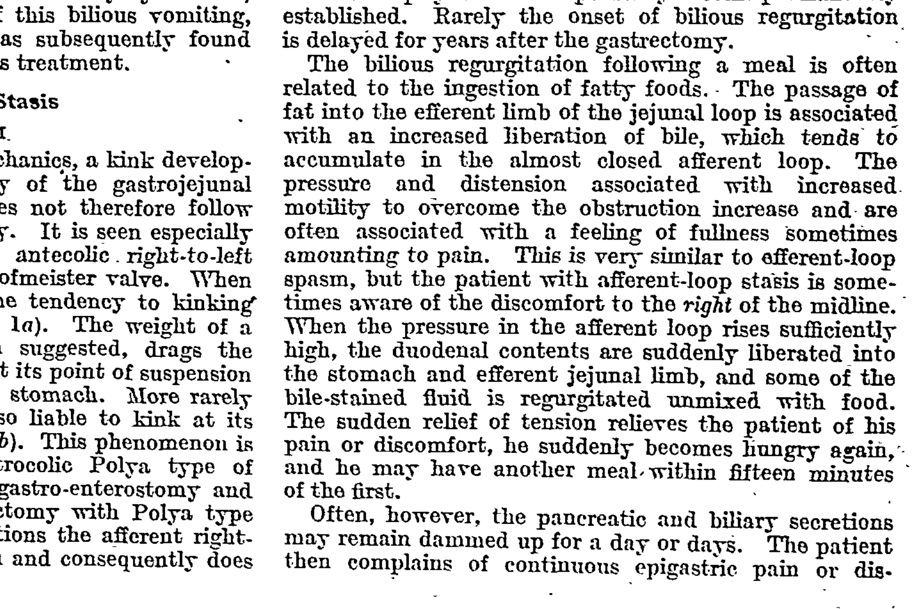

Fig. 1—Causes of obstruction of afferent loop: *a*, too long loop; *b*, short loop; *c*, kinking of retrocolic anastomosis; *d*, gastrojejunocolic fistula.

comfort, a permanent feeling of fullness, nausea, and anorexia, all made more severe by a meal. The stools are then bulky, pale, and offensive, and contain a high proportion of split fat. A slight icteric tinge of the conjunctiva may be detected. Such patients often volunteer the statement that they have a feeling of nervous depression during this stage. Quite suddenly, and not necessarily in direct relation to a meal, there may be a massive bilious vomit of 1 or 2 pints, associated with immediate relief of all the symptoms and then with a desire for food. Such patients with symptoms of splanchnic stimulation (nausea, feeling of fullness, and anorexia) are therefore very liable to eat too little food and, as the years pass, they become undernourished. Signs of hypovitaminosis, anæmia, and weight-loss may rapidly develop and increase the patient's misery. In the present series the incidence of malnutrition was much higher among patients with afferent-loop syndrome than in those without it.

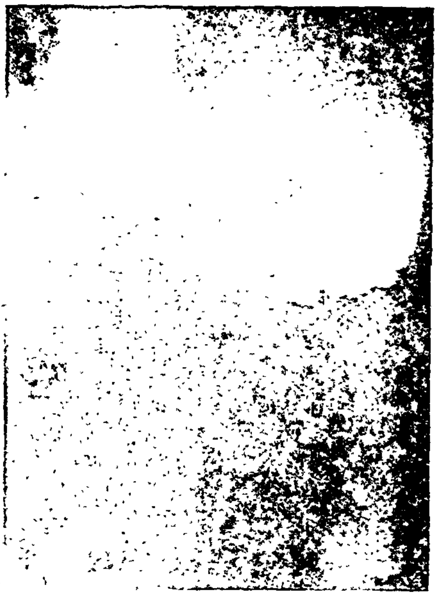

Fig. 2—Typical barium radiograph in afferent-loop stasis. Note absence of barium from afferent loop.

The retention of secretions within the afferent loop gives rise to some symptoms very similar to the efferent-loop syndrome. The excessive fullness after even a small meal, the nausea, and the anorexia are not due to the "small stomach" but to increased intestinal activity. In the efferent loop this seems to be due to hypermotility following the distending and stimulating effect of food (Wells and Welbourn 1951); in the afferent loop it is due to increased motor activity in a partly closed loop distended with secretions. Great care should be taken, however, to distinguish between the two syndromes. The efferent-limb syndromes are not amenable to the same surgical treatment as afferent-loop stasis with its semi-obstruction.

X-RAY APPEARANCES

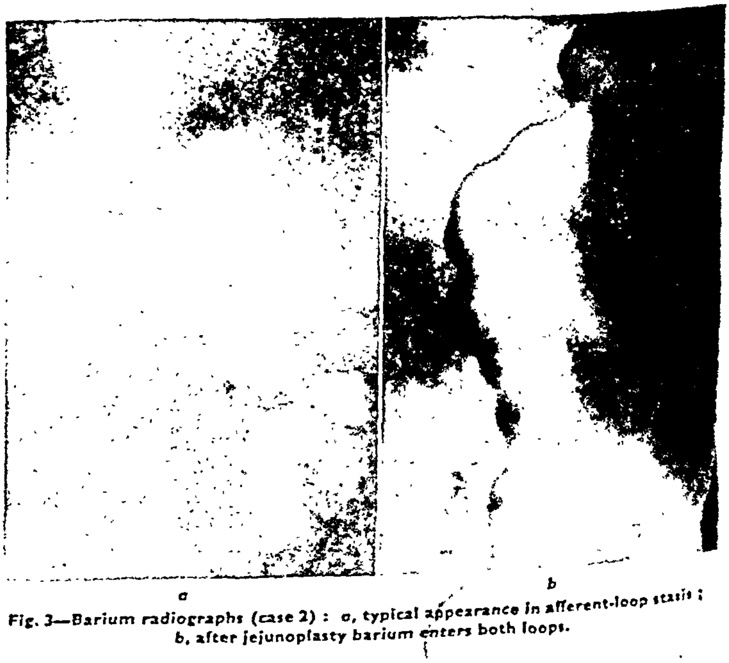
It is typical of the afferent-loop syndrome that the stomach remnant appears normal, and that barium passes rapidly and freely down the efferent limb. It is also typical that barium *does not enter the afferent loop* (fig. 2). The radiologist rarely comments on this, but in our experience it is an almost constant finding in afferent-loop stasis. On the other hand, the fact that barium *does not enter the afferent loop* does not necessarily mean that the condition is afferent-loop stasis.

After surgical reconstruction of the stoma to relieve the syndrome barium is often seen to enter the afferent loop. This is not associated with symptoms. Fig. 3 shows the appearance in case 2 before and after operation.

RELATION TO TYPE OF OPERATION

Goligher and Riley (1952), in a study of the post-gastrectomy syndromes, have pointed out that the type of anastomosis has little bearing on the occurrence of postprandial symptoms. As regards rapid emptying, efferent-limb symptoms, and malnutrition this has also been our experience. Radiography after a barium meal shows that a stomach without a pyloric sphincter empties rapidly, no matter what anastomosis may have been done. However, it is apparent that bilious regurgitation does not follow the Billroth-I type of gastrectomy, there being no afferent loop. Goligher and Riley also indicate that they have no recent experience of gastro-enterostomy or the related incidence of postprandial symptoms. We have had the good fortune recently to study the late results of vagal section and gastro-enterostomy in more than 40 patients. Owing to the courtesy of Mr. M. J. Bennett-Jones, we have had access to his case-records and operation notes on these patients. It is clear from this series that the immediate postprandial symptoms are not nearly so common after gastro-enterostomy as after gastrectomy, owing probably to the fact that afferent-loop stasis does not develop. The afferent loop in the ordinary posterior gastro-enterostomy is not suspended so high and is therefore less liable to acute angulation at the stoma. Provided the loop is in no way kinked as it passes upwards towards the mesocolon, the features of afferent-loop stasis should therefore not be encountered.

Capper (1952) has discussed the "early" symptoms which developed in 79 of 660 patients subjected to gastrectomy; 41 of them had bilious regurgitation after food, either with or without visceral symptoms, and were relieved when they lay down after a meal. In our view these patients undoubtedly had afferent-loop syndrome. As Butler (1951) has indicated in the same series, the early symptoms did not occur in the 102 patients who had undergone the Billroth-I type of gastrectomy. Further, if the patients with the syndrome lay down before a meal, bile-stained fluid could be aspirated from the stomach, allowing the patient thereafter to consume a larger meal. Again, the passage



a b

Fig. 3—Barium radiographs (case 2): *a*, typical appearance in afferent-loop stasis; *b*, after jejunoplasty barium enters both loops.

of a mercury-loaded bag into the stomach induced the symptoms; but, after aspiration of bile from the stomach, introduction of the bag did not induce the symptoms with the same weight of mercury. Butler and Capper next did 128 gastrectomies in which the stomach attachments along the lesser curvature were reconstituted (Capper 1951), whereupon the syndrome occurred in only 1% compared with 13% in 113 controls. They conclude that the non-occurrence of "dumping" in their second series was attributable to better suspension of the stomach. Conversely, they attribute the occurrence of "dumping" symptoms in general to an autonomic nervous disturbance set up by traction on the stomach. It appears to us that an afferent-loop element is evident in a high proportion of their first series, and that relative freedom from post-gastrectomy symptoms in the second series may well be attributed to the avoidance of afferent-loop stasis. Suspension of the stomach and afferent jejunal loop in the way they describe would have just this effect.

Pulvertaft (1952), in a careful follow-up study of 632 Polya-type gastrectomies done by the late A. H. Visick, reported 59·4% free from postprandial symptoms, 22·1% with regurgitation of bile, and 32·7% with "dumping" (visceral) symptoms. Of these two groups with postprandial symptoms 14·3% had both bilious regurgitation and visceral symptoms. As in Capper's (1951) series, therefore, about half of all the patients with early postprandial symptoms complained of bilious regurgitation, and of these about half had also the associated visceral symptoms commonly called "dumping" symptoms.

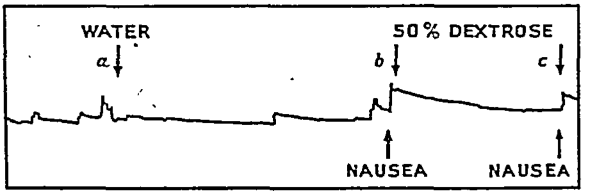


Fig. 4—Tracing from balloon in efferent loop, showing that intestinal spasm may be caused by hypertonic irritant.

Significance of Syndrome

Most observers consider that the symptoms of "dumping" are due to distension of the small gut as the food passes rapidly and in an undigested state from the stomach remnant. Muir (1949), Machella (1949, 1950), and Goligher and Riley (1952) have all reproduced the symptoms of epigastric fullness and nausea, sometimes associated with the other visceral and vasomotor symptoms of the whole "dumping syndrome," by distending the small bowel. This requires closer examination. The introduction of a balloon into the efferent limb is not necessarily associated with symptoms. If the distending force is applied slowly enough, the bowel may dilate slowly before the force, no contraction or spasm is produced, and therefore no symptoms are experienced. Fig. 4 shows the results of distending the small bowel *slowly* with water at *a* immediately after a peristaltic contraction: the pressure within the lumen of the bowel remains unchanged, the gut distending before the increased pressure. When, however, at *b* and *c* 50% dextrose is introduced in the same *very slow* manner, spasm follows, associated with all the visceral and vasomotor symptoms of the condition. As Welbourn (1951) has indicated, the specific cause of the symptoms under discussion is the hyperperistalsis which follows a rapidly induced distending force in the jejunum. Distension without hyperperistalsis is not effective.

INCIDENCE OF BILIOUS REGURGITATION

No. of patients	Free from symptoms	Symptoms		
		Mild	Moderate	Severe
293	240 (*81·9%*)	17 (*5·8%*)	5 (*1·7%*)	31 (*10·5%*)

When the symptoms occur only from activity in the efferent jejunal limb, Wells and Welbourn (1951) describe the condition as the "efferent-loop syndrome." This was formerly thought to be common. When, however, such symptoms are associated with bilious regurgitation, the distending force is clearly within the afferent loop, and it is at this site that the hypermotility arises. As already stated, such a condition appears in at least 50% of all cases of jejunal symptoms following the Polya types of gastrectomy. In fact the condition is probably very much commoner than this, but where bilious regurgitation is not in evidence the diagnosis is not so simple. The tracing in fig. 4 is from such a patient with postprandial epigastric fullness, nausea, weakness, and sweating, associated with considerable loss of weight after a Polya gastrectomy. There had never been any vomiting of bile or of food. The tracing indicates that his efferent jejunal limb was not unduly sensitive to hypertonic irritants, his response being little different from that of a normal person. Glazebrook (1952), in a study of the patterns of intestinal motility in cases of true "efferent-loop syndrome," demonstrates all the abnormal patterns usually encountered. Since this patient, therefore, had no abnormal sensitivity of the efferent jejunal limb, it was presumed that his symptoms were referable to a semi-closed afferent loop in spite of the absence of bilious regurgitation.

In our opinion this type of case is probably much commoner than heretofore believed. For this reason, when a patient has typical jejunal symptoms but does not show the patterns of efferent-loop hypermotility as described by Glazebrook, the afferent-loop syndrome in a forme fruste should be suspected. If the condition is severe, jejunoplasty is strongly recommended. After more complete analysis along the lines suggested here the incidence of true efferent-loop syndrome may prove to be much lower than was previously believed.

In our study of this problem we have excluded all operations done during and after November, 1951, and all gastrectomies done for conditions other than peptic ulcer. We have also excluded all patients who have not been followed up at short intervals each year. This leaves a residuum of 293 patients who form the basis of the current investigation. All patients who have had bilious regurgitation for more than six months after operation are included. The accompanying table shows that 53 patients fall into this category. Of these, 17 have been classified as having mild symptoms (less than one attack a month), 5 as having moderate symptoms (less than one attack a week), and 31 as having severe symptoms (more than one attack a week). Of the 31 patients with severe symptoms 16 have already been subjected to operation for relief of symptoms, and all are now totally relieved.

The present series contains some problem patients who have had their initial gastrectomy done elsewhere. An incidence of 18% in the whole series, however, indicates that the afferent-loop syndrome is distressingly common, and our experience has caused us to revise our concepts of the frequency of post-gastrectomy symptoms.

Treatment

Though a little bilious regurgitation is usual in the early weeks after gastrectomy, the condition usually subsides, and no treatment is required. Where bilious regurgitation persists, the need for operative treatment depends on the severity of the condition. Where it occurs on only a few occasions each month, and does not interfere with the patient's occupation or social activities, operation is not required. The avoidance of fatty foods will decrease the number of attacks, but then careful watch should be kept on nutrition. The "ulcer diet" after gastrectomy undoubtedly increases the frequency and severity of the attacks.

Jejunoplasty

This operation, first suggested by Steinberg in 1934 (Steinberg 1952), described by Hoag and Saunders (1941), and modified by Steinberg (1949), was suggested by Wells and Welbourn (1951) as a satisfactory method of relieving the obstruction to the afferent loop. The operation for this purpose has been described in detail by Steinberg (1949). As he originally described it, the operation was part of the initial subtotal gastrectomy and planned to enlarge the gastric reservoir. Steinberg (1952) has now done the operation on 255 patients with what he considers to be gratifying results. Included in this series are 25 cases where the jejunoplasty was done for a post-gastrectomy state. In all but two instances these patients have obtained complete relief from their symptoms. Steinberg believes that these two patients may never have had peptic ulcer at the outset. Fourteen post-gastrectomy cases have now been treated by us in this way, with immediate and satisfactory results. Illingworth (Muir 1949) has diverted the afferent-loop secretions away from the stoma by making an entero-anastomosis between the afferent and efferent limbs. This operation serves the same purpose but endangers the region of the stoma by subjecting it to gastric secretion unmixed with duodenal contents.

A brief description of some of the cases treated by jejunoplasty is appended here. Unless expressly stated, the gastrectomy was of the high subtotal type described by Wells and Brewer (1948) with an antecolic anastomosis of the Finsterer-Lake type and with a Hofmeister valve.

Case 1.—A man, aged 53, with a duodenal ulcer underwent subtotal gastrectomy in 1945. This was followed by severe bilious vomiting after meals and by abdominal pain. Jejunoplasty was done on Aug. 2, 1950. On Nov. 15, 1951, he had complete relief from bilious vomiting and pain and had gained 12 lb. in weight.

Case 2.—A woman, aged 46, who had had a duodenal ulcer for twenty years, underwent subtotal gastrectomy on March 8, 1950. This was followed by severe bilious regurgitation. When in good health she weighed 9 st. 4 lb., before operation she weighed 7 st. 12 lb., and after operation she weighed 7 st. 5 lb. Jejunoplasty was done on Feb. 27, 1951. On June 16, 1951, she had no bilious regurgitation, and had gained 1 st. 2 lb. in weight.

Rotation of Afferent Loop

In one instance, where the afferent loop was too short, a rotation of the afferent loop had taken place and the bowel was constricted by the tight mesentery of the efferent limb.

Case 3.—A man, aged 33, had undergone elsewhere on Feb. 7, 1950, gastro-enterostomy and vagotomy for duodenal ulcer. This was followed by frequent vomiting of food but not of bile. On Sept. 21, 1951, he underwent subtotal gastrectomy. Vomiting of food now ceased, but its place was taken by repeated postprandial bilious regurgitation. On Dec. 18 barium was noted to enter both limbs of the jejunum but remained in the afferent loop for three hours. On Jan. 4, 1952, the twist in the afferent loop was undone and jejunoplasty done. In June the patient reported complete relief from bilious regurgitation. He was then working hard at a heavy job and was still gaining weight.

Barium was seen to enter the afferent loop but not leave it. This evidence, though not appreciated at the time, indicated that the obstruction to the afferent loop was not due to the usual kinking at the junction with the lesser curvature of the stomach.

Retrocolic Anastomosis—Billroth-I Operation

This was the only case in the series of bilious regurgitation after retrocolic anastomosis (fig. 1c). The number of cases in which this operation was done, however, was very small. Because of the short afferent loop jejunoplasty was impossible. The anastomosis was converted into the Billroth-I type.

Case 4.—A man had a retrocolic Polya gastrectomy done for ulcer in 1948. This was followed by severe bilious vomiting three or four times a day. His weight fell from 10 st. 10 lb. to 7 st. He came again for operation on July 27, 1951. Because of the short afferent loop it was impossible to do a jejunoplasty. The anastomosis was converted to the Billroth-I type, and vagotomy was done. On Oct. 4, 1951, the patient still had bilious vomiting, along with food, but only about once every ten days. He was much improved, and now ate most foods. He weighed 8 st. 9 lb. His stools, formerly light in colour, were now dark. By Dec. 13, 1951, bilious vomiting and vomiting of food had ceased.

Colonic Implant

Moroney (1951) has described an operation in which a segment of transverse colon, 4–6 in. long, is implanted between the gastric remnant and the cut edge of the duodenum. Such an operation, if it allows a reservoir for food, holds considerable possibilities in the treatment of some of the post-gastrectomy syndromes. It has been so used in the present series to prevent efferent-loop symptoms, as in case 5, where both afferent-loop and efferent-loop symptoms were experienced by the patient. The anastomosis, being of the Billroth-I type, excludes the possibility of further afferent-loop symptoms.

Case 5.—A woman, who had had symptoms of duodenal ulcer for several years, underwent subtotal gastrectomy on Feb. 1, 1949. In August, 1949, she had lost over 1 st. in weight and now weighed 6 st. 6 lb. She had severe diarrhœa. A barium meal showed no abnormality of the stoma. On April 20, 1950, investigation showed fæcal fat 86% split, 14% unsplit. Blood-sugar curves showed hypoglycæmia at the end of 1 hour after a meal. The patient complained of bilious regurgitation, colicky abdominal pain, loss of weight, diarrhœa, and lack of energy, associated with almost continuous nausea after a meal. On Nov. 30, 1950, she weighed 7 st. $2\frac{1}{2}$ lb., and in May, 1952, 6 st. 7 lb. On June 18, 1952, a 4-in. colon implant was inserted between stomach and duodenum, after the previous partial gastrectomy had been undone. The postoperative course was very satisfactory, the patient remaining completely free from vomiting. On leaving hospital she weighed 6 st. On Aug. 1, 1952,

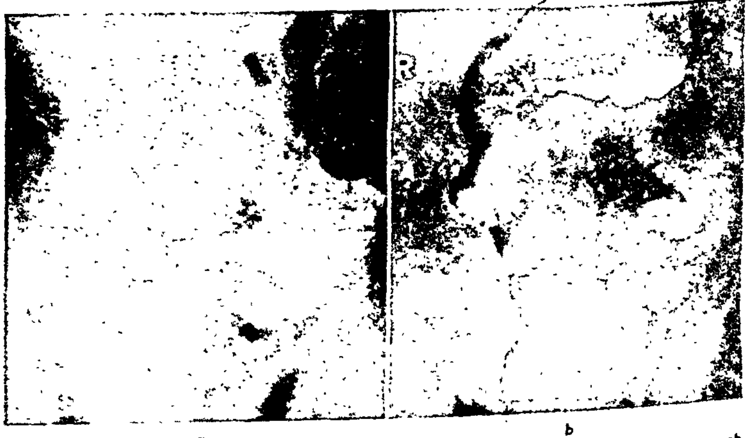

Fig. 5—Subtotal gastrectomy (case 6) : *a*, radiograph 3 hr. after barium meal (stomach is empty) ; *b*, after colonic implant, radiograph 3 hr. after barium meal (stomach not yet empty).

she was eating larger meals than ever before. She did not eat pastry and fried fish, because they induced nausea, but otherwise her diet was normal. She had no bilious vomiting and no diarrhœa, and her stools were of normal colour. She still had a feeling of faintness on exertion. Her hæmoglobin was 86% and weight 6 st. 11 lb.

This operation described by Moroney has also been utilised by us where a second gastrectomy has had to be done at a higher level in a patient who already has had symptoms of afferent-loop stasis.

Case 6.—A man, aged 64, had had epigastric pain and vomiting of food since 1942. In health he weighed 9 st. 3 lb. In April, 1951, partial gastrectomy was done elsewhere for gastric ulcer. After the operation he had bilious regurgitation and lost weight. A barium meal showed a large gastric remnant, and there was occult blood in his fæces. At operation on Feb. 12, 1952, it was found that only a third of his stomach had been removed at the previous operation. An adequate subtotal gastrectomy was now done and a 4-in. colon implant inserted between the cut end of the stomach and the duodenum. On June 27, 1952, he reported that he had no pain or vomiting and was eating all foods and taking moderately large meals, with no postprandial symptoms. He was gaining weight.

Fig. 5 shows barium radiographs of this patient at the end of three hours both before and after the colon-implant operation. A comparison indicates the considerable delay in complete gastric emptying after the Moroney type of operation.

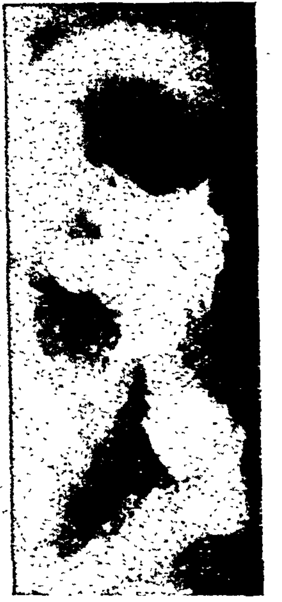

Fig. 6—Barium radiograph of only patient in present series who had symptoms due to afferent-loop reflux.

Afferent-loop Reflux

The study of barium-meal radiographs after gastrectomy shows that barium often passes backwards into the afferent loop. Owing to the nature of the operation it is seen most often in the left-to-right type of anastomosis—e.g., the Moynihan type (Ogilvie 1947). One of the reasons for advocating the Hofmeister type of valved anastomosis was specifically to avoid this reflux of food into the afferent loop. The tacit assumption, however, that the reflux of barium, and therefore of food, into the afferent loop is associated with symptoms has not been proved. This reflux occurs very commonly after gastro-enterostomy without causing symptoms. In the present cases of afferent-loop stasis the appearances after jejunoplasty indicate that barium now passes into the afferent loop, and yet no symptoms have been observed. Further, reflux is often observed after subtotal gastrectomy in symptomless cases. Forcheri (1951) has observed in a study of 50 cases that the reflux of food into the afferent loop does not cause symptoms. Goligher and Riley (1952) have also shown that the reflux of food and barium into the afferent loop is rarely associated with symptoms. The suggestions of Ogilvie (1935), Maingot (1948), and Mimpriss and Birt (1948) that reflux is a cause of symptoms cannot therefore be substantiated. Whatever merit the Hofmeister type of valve with right-to-left type of anastomosis may have, it cannot be supported *per se* as a prevention of "dumping" symptoms.

As Wells and Welbourn (1951) have indicated, the symptoms of afferent-loop reflux, when they do occur, are vomiting of *food mixed with bile*, associated with visceral symptoms. The syndrome is quite uncommon after the Finsterer-Lake type of gastrectomy with a Hofmeister valve. Indeed, only one true case of the condition has been observed in the present series (fig. 6). The vomiting of food and bile after the Billroth-I type of anastomosis is, of course, due to a different mechanism.

We are indebted to Mr. M. J. Bennett-Jones, F.R.C.S., of St. Helens Hospital, for the details of his cases of gastro-enterostomy and vagotomy; and to Miss Barbara Duckworth for the line drawing.

HEALING POLYARTERITIS NODOSA

OBSERVATIONS ON THREE CASES AFTER A.C.T.H. AND ON ONE CASE AFTER SYMPATHECTOMY

W. St. C. Symmers
M.D. Belf., M.R.C.P.
PATHOLOGIST, GENERAL HOSPITAL, BIRMINGHAM; SENIOR LECTURER IN PATHOLOGY, UNIVERSITY OF BIRMINGHAM

J. A. Litchfield
M.B. Birm., M.R.C.P.
SENIOR MEDICAL REGISTRAR, GENERAL HOSPITAL, BIRMINGHAM

A HUNDRED years have passed since Rokitansky (1852) described a case in which he had found multiple small aneurysms on the visceral arteries at necropsy; Eppinger (1887) showed histologically that Rokitansky's case was an example of polyarteritis nodosa. Since then several hundred cases have been reported, and many cases now go unpublished. Recent reviews include those by Harris et al. (1939), Miller and Daley (1946), and Rose et al. (1950). It is our purpose to refer here only to some aspects of the disease which are relevant to its course and prognosis and particularly to the healing of its lesions.

It is salutary to recall that Kussmaul and Maier (1866) indicated the possibility of clinical diagnosis, the possible value of biopsy, and the possibility of recovery or intermission in polyarteritis nodosa. The diagnosis was made at the bedside in the second of their 2 cases, and muscle biopsy was performed; the patient himself drew attention to the similarity of his illness to that of the patient who had died of "periarteritis nodosa." When the paper was written he had shown no sign of active disease for several months.

Grant (1940) pointed out that one of the commonest misconceptions about polyarteritis nodosa is that it is invariably fatal, usually in a few months. He calculated that the average duration of the illness in most of the published cases was from four to six months, but that the average duration of 70 cases with adequately recorded histories was just over two years if account was taken of previous illnesses which could reasonably have been manifestations of polyarteritis. The duration of the disease may indeed sometimes be measured in years; remissions and even long intermissions may occur, and perhaps permanent recovery—although the occurrence of spontaneous intermissions makes it essential that reports of clinical recovery should be considered with reserve. "Recovery" had lasted more than one year in only 11 of the 20 cases of supposed recovery discussed by Klein (1949), and it is doubtful if the diagnosis of polyarteritis nodosa was justified in some of these cases; Klein's own second case was probably an example of the localised appendiceal arteritis which Plaut described in 1951. It is important to recognise also that healing of the vascular lesions does not necessarily imply recovery from the effects of the disease, for the patient whose arteritis has healed with fibrosis may yet die from interference with the blood-supply to vital structures.

Apparent recovery has taken place in polyarteritis nodosa after treatment with antisyphilitic drugs (Schmorl 1904, Spiro 1919), sulphonamides (Goldman et al. 1942), penicillin (White 1947), and penicillin and anti-histamine drugs (Sutherland 1948, Tomenius 1949); it is interesting that almost all these drugs have been suggested as a cause of the disease in other cases (Miller and Daley 1946). Before the recent introduction of cortisone and adrenocorticotropic hormone (A.C.T.H.) to therapeutic practice no treatment could be relied on to influence the course of the disease favourably. The ameliorating effect of adequate dosage with these hormones has been described in all the published cases thus treated (see Selye 1950, 1951a), except one (Brodthagen et al. 1951) in which the diagnosis is open to doubt. Although these drugs have been in use for too short a time for their value to be assessed properly, the regularity with which serial biopsies during treatment have shown healing of arteritic lesions, and with which relapses following withdrawal of the drugs have responded to their readministration, suggests that the improvement may be attributed to the treatment.

The remarkable healing of the lesions which may be seen after treatment with A.C.T.H. was demonstrated in 3 of the following cases of polyarteritis nodosa. Comparable healing was seen in the 4th case after sympathectomy for malignant hypertension.

Healing after Treatment with A.C.T.H.

THE FIRST CASE

Case 1.—Mrs. A, a housewife, born in 1903, had good health until January, 1950, when for two weeks she suffered from colic and severe bloody diarrhœa. In April, 1950, she had an attack of dizziness, followed by vomiting. High blood-pressure was diagnosed, and rest in bed was ordered. During the next two weeks neuritis developed in both arms. By July, 1950, the neuritis had subsided and she began to get about again; she felt exhausted and was troubled by vague retrosternal pain and by dyspnœa on exertion. Her condition deteriorated steadily, and she was admitted to the General Hospital on Nov. 9, 1950.

Condition on Admission

She was wasted and anxious. Her heart was enlarged; the apex-beat was in the fifth intercostal space, 2·5 cm. outside the midclavicular line, and the second sound was accentuated in the aortic area. Pulse regular (88 per min.); blood-pressure 240/130 mm. Hg. Retinal arteries thickened and tortuous; no papillœdema. Other systems normal. No fever.

Investigations

Urine: protein ++; occasional erythrocytes and hyaline and granular casts; sterile. Urea concentration 2·46 g. per 100 ml. of urine; blood-urea 28 mg. per 100 ml.; standard urea clearance 114%. Peripheral blood: erythrocytes 4,290,000 per c.mm.; Hb 10·2 g. per 100 ml.; leucocytes 13,500 per c.mm. (neutrophils 76%, eosinophils 1·5%, lymphocytes 9%, monocytes 13·5%); erythrocyte-sedimentation rate 38 mm. in one hour (Wintrobe). Basal metabolic rate +4%.

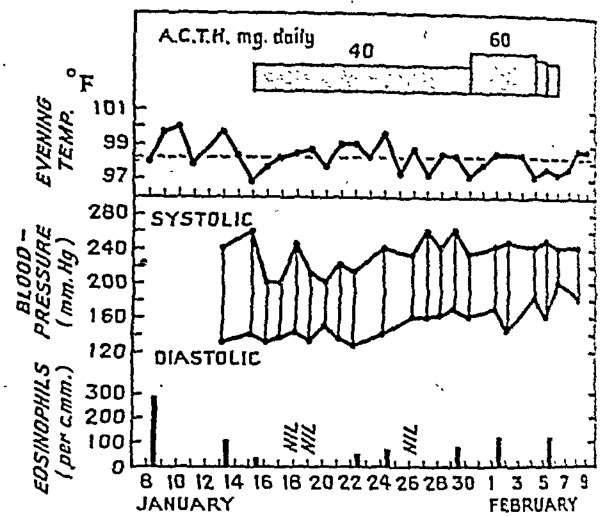

Fig. 1 (case 1)—Dosage of A.C.T.H., temperature, blood-pressure, and eosinophil-counts.

Progress

Two weeks after admission a remittent pyrexia began which never exceeded 101°F (38·3°C); the heart-rate corresponded to the temperature. The patient became listless and apathetic and sweated heavily at night. Aching precordial pain was present for hours at a time and was not affected by nitroglycerin. Repeated electrocardiograms showed only left ventricular preponderance. The blood-pressure did not vary significantly. Radiographs of the chest showed only cardiac enlargement. Serum-agglutination reactions for salmonella, brucella, and dysentery organisms were negative. The Paul-Bunnell test was negative. The urine remained sterile. No occult blood was found in the stools.

Dec. 5.—A course of hexamethonium bromide was started; the initial dose of 0·25 g. twice daily by mouth was gradually increased to 0·5 g. five times a day by *Dec. 12*. This drug had little effect on the blood-pressure and was withdrawn on *Dec. 15* because it caused severe nausea.

Jan. 1, 1951.—A painless expansile pulsatile swelling, 1 cm. in diameter, was noticed in the left cheek. The development of this aneurysm in association with the other clinical findings led to the diagnosis of polyarteritis nodosa, although biopsy of a pectoral muscle on *Jan. 3* showed no abnormality. On *Jan. 7* severe throbbing pain suddenly developed in the left forearm, the musculature of which immediately became swollen, hard, and pulsatile; a loud systolic bruit was heard, and it was considered that an aneurysm had burst. The arm returned to normal during the next two weeks.

The patient's general condition continued to worsen. On *Jan. 15* a course of A.C.T.H. (Armour) was started (fig. 1). Considerable subjective improvement followed, although pyrexia persisted and her weight fell from 49 to 45 kg. On *Jan. 22* an expansile pulsatile swelling with a loud systolic bruit was noted above the right clavicle; its size increased rapidly for two days until it measured 5 cm. in diameter. By *Jan. 30* it had become hard and non-pulsatile; the facial aneurysm had by now also hardened and ceased to pulsate.

Feb. 4.—Shortage of A.C.T.H. necessitated reduction of dosage, and treatment was stopped on *Feb. 6*; 995 mg. had been given intramuscularly in twenty-two days. The patient's condition did not alter appreciably after withdrawal of A.C.T.H. until *Feb. 23*, when she complained of generalised aching abdominal pain. This persisted until *Feb. 28*, when she suddenly collapsed with signs of internal hæmorrhage and died in a few minutes.

Necropsy Findings

Several hundred saccular aneurysms were found on visceral and parietal arteries; their diameter ranged from 0·1 to 5·5 cm. The largest included those which had been detected during life: one arising from the right inferior thyroid artery (5·5 cm.), one in the left cheek (2·5 cm.), and one in the muscles of the left forearm (2·5 cm.). The last-mentioned was surrounded by a large organising hæmatoma; an identical lesion in the right calf had not been observed before death. All the aneurysms were filled with adherent thrombus.

The peritoneal cavity contained more than 1300 ml. of blood which had tracked through the liver from one of several aneurysms surrounded by fibrous tissue in the vicinity of the porta hepatis. A second freshly ruptured aneurysm in the liver had given rise to a large subcapsular hæmatoma. The heart (340 g.) showed left ventricular hypertrophy, and the kidneys (combined weight 270 g.) had the appearances of hypertensive nephrosclerosis.

Histology

Lesions of polyarteritis nodosa were numerous in most organs and tissues. All the lesions showed advanced or complete healing by fibrosis; fibrinoid material had disappeared from all but a few vessels (fig. 2); lymphocytes and large mononuclears predominated in the rather scanty cellular exudate, and neutrophil polymorphs and eosinophils were rare or absent. Many of the affected vessels were occluded by organising thrombus, and some were recanalised. All the aneurysms examined had undergone thrombosis; a few fibroblasts had invaded the peripheral hyaline zone of the thrombus, but there was no effective organisation; in some instances the vascular lumen was separated from the peri-aneurysmal tissues only by a thin layer of unorganised thrombus and poorly consolidated fibrous tissue. Small hæmorrhages were common in the wall of the sacs, and there was often much blood pigment in the vicinity. Some of those peripheral nerves which were involved in the fibrosis round adjacent aneurysms showed minor degenerative changes in the myelin sheaths and axons; no arteritic lesions were found within the nerves. In addition to polyarteritic lesions, hypertensive arteriolosclerosis was present, particularly in the kidneys.

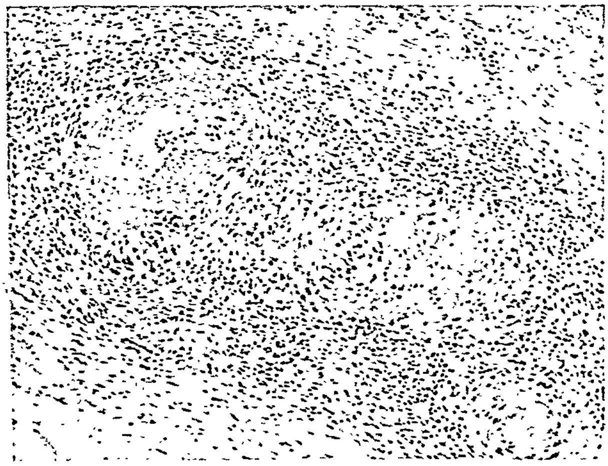

Fig. 2. (case 1)—Healing polyarteritic lesions, showing fibrosis and predominance of large mononuclears and fibroblasts in cellular reaction: remnants of fibrinoid are present in this lesion, which shows much less advanced healing than most of the lesions in this case. (Hæmatoxylin and eosin. × 96.)

THE SECOND CASE

Case 2.—Mr. B, a general labourer, born in 1929, had excellent health until the beginning of December, 1951, when his ankles were painful and swollen for three days. A few days later his calves became painful to touch, although they were not spontaneously sore. He began to feel ill and feverish. Thirst, polyuria, and nocturia developed. Within three weeks he was too ill to leave bed, and on Jan. 3, 1952, he was admitted to the General Hospital.

Condition on Admission

His temperature was 99·6°F (37·6°C). His calf muscles and right biceps brachii were very tender; the joints were normal, and some loss of power in the legs and right arm appeared to be due to muscular pain. There were no abnormal neurological findings, and the other systems were also normal. Blood-pressure 135/80 mm. Hg.

Investigations

Cerebrospinal fluid: normal pressure; two cells in 3 c.mm.; reducing substance 106 mg. per 100 ml.; protein 20 mg.; chloride (as NaCl) 690 mg.; Lange curve 1100000000; Wassermann reaction negative (0·5 ml. of C.S.F.). Urine: protein ++; sp. gr. 1·012–1·024; numerous erythrocytes; occasional epithelial and granular casts; sterile. Blood: packed-cell volume 47%; erythrocytes 5,060,000; Hb 14·1 g.; leucocytes 16,500 per c.mm. (neutrophils 86%, lymphocytes 9·5%, monocytes 4·5%); erythrocyte-sedimentation rate 14 mm. in one hour (Wintrobe). Serum Wassermann and Kahn reactions negative. Agglutination reactions for salmonella, brucella, dysentery, and leptospira organisms negative. Chest radiographs and electrocardiogram normal.

Progress

There was slight pyrexia throughout the illness. During January the patient's condition changed little. Two blood-cultures proved sterile. The blood picture altered gradually: the hæmoglobin fell to 10·4 g. per 100 ml. and the leucocytes to 9800 per c.mm. (neutrophils 76%, eosinophils 16%). Transient paræsthesiæ and weakness in the limbs were associated with local impairment of touch and pain sensation. He complained occasionally of pain in various large joints, which appeared normal on examination. Polyarteritis nodosa was suspected, and a muscle biopsy at the end of February showed typical lesions.

March 2.—He complained of "stinging" in the lower part of the abdomen; his temperature was 102°F (38·9°C) and there was tenderness in the hypogastrium and iliac fossæ. On *March 11* he coughed up a little blood-streaked mucopurulent sputum, which yielded a heavy growth of *Streptococcus viridans* and coagulase-positive *Staph. aureus;* cultures for tubercle bacilli were sterile. Chest radiographs remained normal, the cough was never severe, and hæmoptysis was not repeated.

March 14.—A course of A.C.T.H. (Armour) was started with a daily dose of 20 mg. given intravenously in 500 ml. of physiological saline solution over eight hours (fig. 3). On *March 18* severe melæna occurred, and the Hb decreased rapidly to 4·7 g. per 100 ml.; transfusion of 4 litres of blood restored it to 10·4 g. On *March 19* the dose of A.C.T.H. was changed to 30 mg. intramuscularly every six hours. On *March 26* a course of 300,000 units of penicillin intramuscularly twice a day was started. On *March 29* he developed sudden pain in the left arm, and a tender swelling was found occupying the bicipital groove; the pulses were normal, and no œdema developed.

Although there was no dramatic response to A.C.T.H., the patient felt better, and his general condition steadily improved. His blood-pressure remained normal. He had slight abdominal pain occasionally; there was no further melæna, and the blood-picture remained substantially unaltered. The course of A.C.T.H. ended on *April 1;* the total amount given was 1780 mg. in nineteen days. On *April 2*, while still receiving penicillin, he was wakened by severe pleuritic pain in the left side, and coughed up a little dark sputum. Pleural effusion developed rapidly on the left side, causing gross displacement of the mediastinum and severe respiratory distress in spite of repeated thoracenteses. The fluid was turbid and yellow, and contained 3·25 g. of protein per 100 ml.; cultures yielded a heavy pure growth of *Bacterium coli.* A course of streptomycin was started. On *April 3* aspiration of the effusion produced only 40 ml. of thick purple fluid:

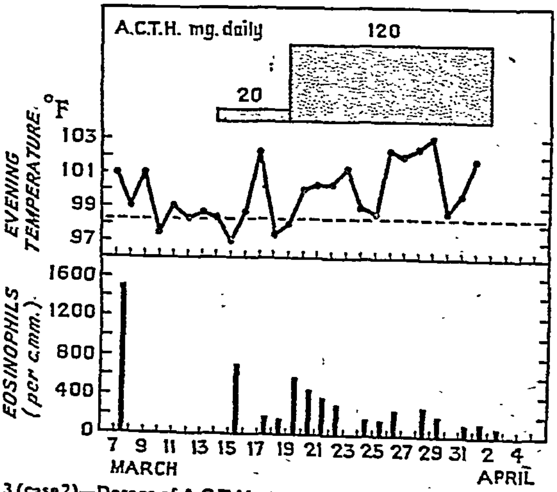

Fig. 3 (case 2)—Dosage of A.C.T.H., temperature, and eosinophil-counts.

The patient's condition deteriorated rapidly, and he died on April 3, forty hours after the onset of pain in the chest.

Necropsy Findings

The left pleural sac contained 1900 ml. of thin fibrinopurulent exudate, and the left lung was completely collapsed. The spleen (300 g.) was necrotic and sealed off from the general peritoneal cavity by fibrinous adhesions; its capsule had partly disintegrated, and a collection of thick purple pus was present between it and the diaphragm; a thoracentesis needle-track led into the abscess. The splenic artery and vein, left brachial artery, right axillary vein, prostatic plexus, and veins in the calf muscles were occluded by organising thrombus; there were no apparent prethrombotic changes in their walls. A few thrombosed aneurysms up to 1·0 cm. in diameter were present on visceral arteries. The kidneys (combined weight 440 g.) were large and congested. A few small infarcts of different ages were present in the kidneys and testes, and there were several small ulcers in the lower ileum. *Bact. coli* was isolated in pure culture from the spleen and pleural exudate.

Histology

Arteritic lesions were less numerous than in case 1; all showed advanced healing or were healed. Arterioles in the synovia of large joints and in many peripheral nerves were involved; demyelination and interstitial fibrosis were seen in the affected nerves. The thrombus in the splenic and brachial arteries and in the veins was organising; there was no underlying arteritis or phlebitis. The spleen was infarcted, and suppuration had developed at the margin of the infarcted tissue, where coliform bacilli were present. The ileal ulcers were healing: they appeared to have originated by confluence of focal areas of ischæmic necrosis. Many glomeruli showed epithelial crescents, capsular adhesions, and fibrinoid change; all the affected glomeruli were undergoing organisation, and healing was usually far advanced.

THE THIRD CASE

Case 3.—Miss C, housekeeper, born in 1891, had had nasal catarrh for many years and winter bronchitis since 1945. In October, 1949, asthmatic bronchospasm complicated bronchitis for the first time; penicillin relieved this attack of bronchitis but was not effective in a recurrence in April, 1950, which responded to streptomycin administered after a heavy growth of Friedländer's bacillus had been obtained from the sputum; lobelia and grindelia kept the spasm under control. A blood-count at that time showed red cells 5,270,000 per c.mm., Hb 14·7 g. per 100 ml., and leucocytes 8100 per c.mm. (neutrophils 68·3%, eosinophils 7%, lymphocytes 19·7%, monocytes 5%). A trace of protein and occasional hyaline casts were found in the urine, and the patient gave a history of polyuria and nocturia for many years. Asthmatic bronchitis recurred in August, 1951, and responded to penicillin, but neither penicillin nor streptomycin was effective in a severe attack in December, 1951. She was admitted to the General Hospital on Jan. 6, 1952.

Condition on Admission

The only abnormal clinical findings were the signs of chronic bronchitis with bronchospasm. Blood-pressure 130/80.

Investigations

Radiography showed evidence of chronic pansinusitis, although antral washings were clear on each side. A heavy growth of *Strep. viridans*, Friedländer's bacillus, and *Neisseria catarrhalis* was obtained from the washings and from sputum. Chest radiography showed emphysema and a little basal fibrosis. Vital capacity 2400 ml. Electrocardiogram normal. Serum Wassermann and Kahn reactions negative. Blood: erythrocytes 4,780,000; Hb 13·3 g. per 100 ml.; leucocytes 9400 (neutrophils 41·5%, eosinophils 39·5%, basophils 0·5%, lymphocytes 18%, monocytes 0·5%); erythrocyte-sedimentation rate 16 mm. in one hour (Wintrobe). Plasma-albumin 3·5 g. per 100 ml., plasma-globulin 3·2 g. Urine: no protein; occasional erythrocytes and hyaline and granular casts; sterile.

Progress

A week after admission the patient complained that she had had numbness and pins-and-needles in the hands and feet since *Jan. 1.* There were no objective neurological signs until *Jan. 26,* when loss of ankle-reflexes and weakness of dorsiflexion of the feet were observed. On *Jan. 28* a white-cell count showed leucocytes 17,500 per c.mm. (neutrophils 41·5%, eosinophils 42·5%). Polyarteritis nodosa was suspected, and a muscle biopsy on *Feb. 8* showed typical acute lesions with very numerous eosinophils. *Feb. 11*: weakness and sensory disturbances of neuritic type in hands and feet and wasting of the thenar muscles were present.

Feb. 12.—A course of A.C.T.H. (Armour) intramuscularly was started. There was slight subjective improvement in the neurological condition during the course but no alteration in the objective findings. Bronchospasm had begun to improve before A.C.T.H. was given and continued to do so. *Feb. 18*: plasma-albumin 4·2 g. per 100 ml., plasma-globulin 2·8 g.; the plasma-proteins subsequently varied little. On *March 7* A.C.T.H. was withdrawn; the total dose was 1695 mg. in twenty-five days. On *March 10* a muscle biopsy showed healing of polyarteritic lesions, with fibrosis and a cellular infiltration consisting predominantly of plasma cells, although eosinophils were still to be found. The biopsy wound healed rapidly. On *March 14* a blood-count showed red cells 4,400,000 per c.mm.; Hb 12·5 g. per 100 ml., and leucocytes 15,600 per c.mm. (neutrophils 85%, eosinophils 0·5%, lymphocytes 13%, monocytes 1·5%). On *March 16* the patient was discharged home. She had been afebrile throughout her stay in hospital; her blood-pressure had varied little and was 120/80 on discharge.

Subsequent Course

Her condition remained stationary for a few weeks. She felt well, although inconvenienced by pain and weakness in the limbs. Early in May she became increasingly dyspnœic on exertion and her ankles were swollen. On *June 7* she was readmitted to hospital in severe congestive heart-failure. Her heart was enlarged; the apex-beat was in the fifth interspace, 2·5 cm. outside the midclavicular line. Blood-pressure 130/110. Pulse regular and feeble, rate 110 per min. There was wasting of the small muscles of the hands and gross impairment of common sensation and kinæsthesia in hands and feet, with loss of the patellar and ankle reflexes. Blood-urea 190 mg. per 100 ml. Urine: protein +++; sp. gr. 1·008–1·015; numerous erythrocytes; occasional hyaline and granular casts. Blood: erythrocytes 3,710,000; Hb 11·3 g.; leucocytes 4900 (neutrophils 68%, eosinophils 0·5%, basophils 0·5%, lymphocytes 28·5%, monocytes 2·5%).

The patient's condition deteriorated in spite of treatment with digitalis and morphine, and she died suddenly on *June 29.* She had severe pain in the hands and feet during the last few weeks of her illness; the distribution and quality of pain never suggested myocardial ischæmia.

Necropsy Findings

The heart (400 g.) was enlarged; the left ventricle was hypertrophied, and both ventricles were dilated. There were small foci of myocardial fibrosis; no infarcts were seen, although the apical part of each ventricle contained organising thrombus. The superficial coronary arteries were patent and almost free from atheroma. The viscera showed chronic venous congestion, and there were serosal effusions and dependent œdema.

Histology

Lesions of polyarteritis nodosa were widespread; none was found in the lungs. All the lesions were apparently completely healed by fibrosis, and there was little or no cellular accumulation round them. No aneurysms were found. Many peripheral nerves showed patchy demyelination and interstitial fibrosis round obliterated arterioles. Healing glomerulitis identical with that in case 2 was present. There was considerable myocardial fibrosis, associated with arteritic lesions, and there were multiple small areas of fresh or organising infarction, particularly underlying the mural thrombus.

DISCUSSION

Reparative fibrosis of the vascular lesions is not uncommon in untreated polyarteritis nodosa. The remarkable feature of the three cases described above was that all the affected vessels which were seen showed advanced or complete healing, whereas in untreated cases healing lesions are outnumbered by those which show active destructive inflammation. As more than 120 blocks of tissue were examined histologically in each of the present cases, we believe that the absence of any lesions which were not healing may be considered to be representative of the state of the vasculature as a whole. Complete spontaneous healing of polyarteritis nodosa has seldom been reported; Pickert-Menke (1920), Manges and Baehr (1921), Arkin (1930, case 5), and Davson et al. (1948, case 13) described the only acceptable cases which we have been able to find. That the number of spontaneously healed cases has represented such a small proportion (considerably less than 1%) of the published cases of the disease seems to be evidence that healing in the present cases may be attributed to treatment with A.C.T.H. We have found no detailed accounts of pathological findings in other cases of polyarteritis nodosa treated with A.C.T.H., but post-mortem histological findings similar to ours have been described briefly in cases treated with cortisone (Engleman et al. 1950, Baggenstoss et al. 1951, Drury et al. 1951). Comparable healing of arteritic lesions in successive muscle biopsies during treatment with cortisone or with A.C.T.H. has been recorded by Carey et al. (1950), Selye (1950), and others.

Aneurysms, which were present only in cases 1 and 2, showed less organisation than non-aneurysmal lesions. Inadequate fibrosis of their walls and lack of effective organisation of the enclosed thrombus apparently predisposed to small hæmorrhages and consequent increase in size of the lesions by accretion to the thrombotic mass; in some instances massive hæmorrhage occurred, one of those in the liver in case 1 proving fatal because its situation precluded spontaneous arrest of bleeding. Aneurysms of identical structure and with the same liability to rupture are found in untreated polyarteritis nodosa, and it is unjustifiable to attribute their defective fibrosis in our cases to A.C.T.H., particularly since there was no apparent deficiency in the development of fibrosis of the non-aneurysmal lesions. Published observations on the effect of A.C.T.H. and cortisone on the formation of scar tissue are conflicting. Several workers have commented on the apparently normal healing of biopsy and other wounds in patients receiving large doses of these hormones (Carey et al. 1950, Slick et al. 1951), although Baxter, et al. (1951a) observed retardation of reparative fibrosis during treatment with A.C.T.H., and Baxter, et al. (1951b) described an inhibitory effect of cortisone on wound-healing in animals.

Ischæmic lesions were remarkably few in relation to the extent of the vascular involvement in our cases. The myocardial fibrosis and infarction in case 3 were clearly related to occlusive healing of arteritic lesions of the interstitial branches of the coronary arteries, and the patient's death from rapidly progressive myocardial failure was undoubtedly due to this consequence of polyarteritis nodosa. Visceral infarcts have been conspicuously numerous in spontaneously healed polyarteritis nodosa (Arkin 1930) and in some cortisone-treated cases (Baggenstoss et al. 1951). Meacham et al. (1951) suggested that vigorous hormone therapy might effect too rapid healing, with fibrous obliteration of the vessels, and so cause widespread infarction. Though this possibility deserves consideration, the findings in our cases indicate that this complication is not inevitable with the dosage used; however, as in case 3, even infarction of restricted extent may by its situation lead to death. Occlusive healing of the arteritic lesions may have been responsible for the gradual rise of the diastolic blood-pressure in case 1 (fig. 1) and for the development of arterial hypertension in case 3: when the latter patient left hospital after the course of A.C.T.H her blood-pressure was normal and her heart was not enlarged; twelve weeks later, when she was readmitted in heart-failure, the diastolic pressure was 110 mm. Hg, and left ventricular hypertrophy as well as dilatation contributed to the cardiac enlargement then present.

The widespread but by no means generalised glomerulitis in cases 2 and 3 was similar to that described by Davson et al. (1948) in non-hypertensive patients with polyarteritis nodosa and renal failure. Neither renal failure nor hypertension was observed in case 2, and renal failure was manifested in case 3 only by the high blood-urea level during the terminal phase of cardiac failure, to which it probably was essentially secondary. The total duration of illness in case 2 was four months, and urinary symptoms developed during the first month. It is difficult to estimate the duration of polyarteritis nodosa in case 3, in which death took place six months after the onset of neuritic symptoms; there was no good evidence that the asthmatic bronchitis and accompanying eosinophilia which began almost three years before her death were related to polyarteritis; the presence of some chronic renal disorder was indicated by the history of polyuria and the finding of proteinuria and casts two years before death, although histological examination did not show any lesion other than glomerulitis of the type commonly associated with polyarteritis nodosa. Healing of the glomerular lesions in these cases may also be attributable to A.C.T.H., for the glomerulitis of this disease is probably a manifestation of the same pathogenetic mechanism as that which underlies the development of the arteritis itself.

No beneficial effects of A.C.T.H. on the peripheral neuropathy were observed in these cases. In cases 1 and 2 the neuritic symptoms subsided before treatment began, and in case 3 the treatment brought no appreciable relief. In all 3 cases histological examination indicated that the nervous damage was secondary to vascular lesions.

None of the recognised side-effects of A.C.T.H. therapy was observed in cases 1 and 3. No serious disturbance of electrolyte balance was shown in any of the cases by frequently repeated chemical and electrocardiographic investigations. Case 2, however, requires further discussion in relation to possible complications of the treatment. The immediate cause of death in this case was respiratory embarrassment and toxæmia associated with subphrenic and pleural infection. In accordance with recorded experiences during treatment with A.C.T.H. or with cortisone (Derbes and Weiss 1951) the presence of serious sepsis was clinically latent before the fulminant development of the pleural effusion. Both the pleurisy and the subphrenic abscess had obviously lasted too long for either to have developed as a result of inadvertent misplacement of the thoracentesis needle. Probably the pleurisy developed by transphrenic spread of infection from the abscess complicating the suppurative splenitis, which had clearly developed as a complication of infarction due to thrombosis of the splenic artery, although the source of infection was obscure. Infection possibly took place during a bacteriæmia which, as the organism concerned was *Bact. coli*, may have originated in the intestinal ulceration. No angiitis underlay the thrombosis of the splenic and other large vessels; though thrombosis was possibly merely symptomatic of the patient's general condition, it may have developed as a direct complication of treatment with A.C.T.H. The effects of A.C.T.H. and cortisone on coagulation have been inconstant (Smith et al. 1950). Cosgriff et al. (1950) observed thrombosis or embolism in 11 of 175 patients treated with A.C.T.H.; their observations included thrombosis of the radial artery, venous thromboses, pulmonary embolism, and myocardial infarction; they suggested giving anticoagulants to patients under prolonged treatment with A.C.T.H. or with cortisone, particularly careful dosage being necessary because the hormones can induce unusual sensitivity to anticoagulants.

Healing after Sympathectomy

Case 4.—Mr. D, a market-gardener, born in 1898, had good health until January, 1950, when he developed bronchopneumonia, which responded slowly to penicillin. Convalescence was protracted, supposedly because of incipient heart-failure associated with swelling of the hands and feet, and he was away from work for seventeen weeks. Polyuria developed during this illness and became steadily severer during the rest of his life.

In February, 1951, he began to suffer from headache which within a few days became so severe and unremitting that he had to give up work. His blood-pressure, which was 150/80 mm. Hg when the headache began, rose rapidly. Early in May his sight became blurred; his vision soon amounted only to perception of light. He was admitted to the Queen Elizabeth Hospital, Birmingham, on June 16, 1951.

Condition on Admission

His heart was large, the apex-beat was in the fifth intercostal space in the anterior axillary line, a faint systolic murmur was heard at the apex, and the second sound was accentuated in the aortic area. Pulse regular (72 per min.). Blood-pressure 205/130. There was severe papillœdema, with retinal hæmorrhages and exudates. The other systems were normal.

Investigations

Urine: protein 2–3 g. per litre (Esbach); occasional erythrocytes and hyaline casts. Blood-urea 48 mg. per 100 ml.; urea clearance 103% of normal. Peripheral blood: erythrocytes 4,940,000 per c.mm.; Hb 13·8 g.; leucocytes 10,200. Electrocardiogram: left axis deviation. Blood-pressure ranged from 195/120 to 230/135.

Surgical Treatment (Mr. V. S. Brookes)

The clinical diagnosis was malignant essential hypertension. Although the patient was considered to be a poor subject for surgery, it was decided to carry out sympathectomy in view of the incapacitating headache and deteriorating vision. On *June 22* the left sympathetic chain (from the second thoracic to the second lumbar ganglion inclusive) and splanchnic nerves were removed. Headache was completely relieved, and the blood-pressure fell to 120/80; vision did not improve. As was expected, after the first-stage operation the blood-pressure gradually rose from 125/80 on *July 7* to 205/130 on *July 16*. On *July 17* the right sympathetic chain (from the second thoracic to the first lumbar ganglion inclusive), the splanchnic nerves, and part of the cœliac ganglion were resected. The operation and the first few hours afterwards were uneventful; the blood-pressure was 100/60. Twelve hours after the operation the patient collapsed; his respirations fell to 8 per min., his pulse was weak (80 per min.), and his blood-pressure rapidly became undeterminable; he died within a few minutes.

Necropsy Findings

The heart (500 g.) was much enlarged by left ventricular hypertrophy; the valves were normal. There was slight atheroma of the aorta and coronary arteries. The kidneys (combined weight 400 g.) contained a few cortical scars and small recent infarcts; their architecture was otherwise normal. A small firm dark-red nodule was present in one testis.

Histology

Polyarteritic lesions were numerous in various organs (fig. 4); healing was as advanced as in case 3, and no acute lesions were found. The nodule in the testis was a typical thrombosed polyarteritic aneurysm. Hypertensive arteriolo-sclerosis was also present, and there was fibrinoid necrosis of some afferent glomerular arterioles and glomeruli; the necrotic lesions were under [illegible]. Many other glomeruli showed healing; [illegible] with that in cases 2 and 3. Sclerosing granulomatous folliculitis was present in the spleen.

Operation specimen.—The finding of polyarteritic lesions in the necropsy material led to examination of serial sections of a ganglion obtained at the first operation. A small artery in the periganglionic tissue showed the typical appearances of acute polyarteritis nodosa with no evidence of healing.

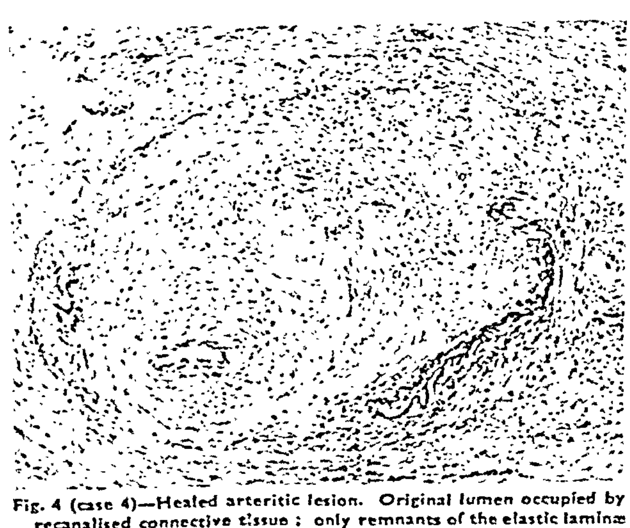

Fig. 4 (case 4)—Healed arteritic lesion. Original lumen occupied by recanalised connective tissue; only remnants of the elastic laminæ survive. (Weigert's elastic stain and carmalum. × 94.)

DISCUSSION

As only 17 pieces of tissue were examined microscopically in case 4, there were less adequate grounds than in the 3 cases treated with A.C.T.H. for assuming that the histological findings were representative of the vasculature as a whole. Nevertheless every one of the numerous lesions found showed advanced or complete healing, in contrast to the typical acute lesions in the surgical specimen obtained twenty-five days before death. Comparable healing of the glomerulitis and granulomatous splenic folliculitis (Ball and Davson 1949) of polyarteritis nodosa was also observed.

The history suggests that polyarteritis nodosa may have dated from the pneumonia, eighteen months before death, although the presenting manifestation of malignant hypertension developed only six months before death. Although Smith and Zeek (1947) suggested that arterial hypertension is the cause of polyarteritis nodosa, and although hypertension of the lesser circulation may cause lesions in the pulmonary arterial tree which are histologically indistinguishable from those of polyarteritis nodosa (Symmers 1952), there is no convincing evidence that hypertension causes this disease-entity. In the case under discussion malignant hypertension probably developed as a consequence of the arteritis. Nevertheless it is difficult to dissociate the healing of the arteritic lesions from the fall in blood-pressure maintained for two weeks after the first-stage sympathectomy, and it is relevant that the necrotic arteriolar lesions of malignant hypertension also showed evidence of repair. The mechanical strain imposed on a diseased vessel by severe hypertension could well prevent healing of established arteritis; a sustained fall in blood-pressure might break a vicious circle and allow other factors to operate in the establishment of healing. It may be significant in respect of this that one of us (W. St. C. S.) has observed that healing and healed lesions are relatively more numerous in those cases of polyarteritis nodosa in which arterial hypertension was absent or late in development, and that aneurysms are commonly more numerous and larger in cases in which hypertension was severe.

We know of only 1 published case in which surgical treatment for hypertension was undertaken in the presence of polyarteritis nodosa. Horne et al. (1950) reported the case of a man, aged 36, with malignant hypertension; splanchnicectomy was performed, and active polyarteritic lesions were said to be present in the resected tissue; six years later the patient was free from symptoms and his blood-pressure was normal.

Conclusions

Some tentative conclusions concerning the treatment of *polyarteritis nodosa* may be drawn from the 4 cases described here. Although 2 of the 3 patients treated with A.C.T.H. unquestionably died of polyarteritis nodosa, these 3 cases are important because an extended histological study post mortem revealed objective evidence of the remarkable extent to which the lesions of polyarteritis nodosa may heal by fibrosis under the influence of A.C.T.H. The paradoxical association of healing of the lesions and death is not remarkable in a disease which threatens every organ with the consequences of vascular occlusion.

It is this paradox which makes the therapeutic problem of polyarteritis nodosa particularly difficult; in many cases the lesions must already be widely disseminated by the time the diagnosis is made, and often the vasculature of vital organs will already have suffered such damage that no treatment will save the patient from disablement or death.

Our findings justify further trial of A.C.T.H. or cortisone therapy in polyarteritis nodosa. The possibly disastrous effects of obliterative healing of affected vessels in organs such as the heart and kidneys do not seem to us to be a contra-indication to treatment; the same effects might as readily develop if the patient survived long enough for healing to take place naturally. The risks are outweighed by the chance that even a small proportion of patients who would otherwise die of the disease may be cured by treatment instituted before potentially lethal damage has been done to the vasculature of vital organs. Accurate diagnosis at the earliest possible stage in the course of the illness is therefore of fundamental importance in relation to successful treatment. At the time of writing we have under observation cases of histologically confirmed polyarteritis nodosa which remain free from all evidence of disease a year or more after treatment with A.C.T.H. Such cases, however uncertain their ultimate outcome, are a further encouragement to persevere with this treatment.

The similar healing after sympathectomy in the fourth case was of particular interest. If lowering the blood-pressure in hypertensive patients with polyarteritis nodosa can cause healing of the arteritic lesions, better therapeutic results may possibly be obtained with A.C.T.H. or with cortisone if the hormone therapy is supplemented in such cases by antihypertensive treatment with drugs or by surgery. The case for such combined treatment is strengthened somewhat by the evidence that the lesions of polyarteritis nodosa may be most numerous in those cases in which arterial hypertension is present, and that hypertension appears to predispose not only to the formation of aneurysms but also, as in case 1, to their rupture. It must be remembered, however, that A.C.T.H. and cortisone may possibly cause or aggravate arterial hypertension, although the evidence is conflicting (Selye 1951b); whether in cases of polyarteritis nodosa this is a result of occlusive vascular healing or an effect of the hormone unrelated to its therapeutic activity, the risk is one which may well be thought worth taking in view of the prognosis of the untreated disease.

Summary

Four cases of polyarteritis nodosa are reported in which all the arteritic lesions showed advanced or complete healing.

Of the 3 patients treated with A.C.T.H., 2 died of complications of the disease, unavoidable in one case, and possibly due to arterial hypertension in the other; the treatment may have caused the death of the third patient.

In the fourth case the lesions healed after sympathectomy for malignant hypertension.

Antihypertensive measures may have a place as an adjuvant to hormone therapy in the treatment of hypertensive patients with polyarteritis nodosa.

We wish to thank Dr. J. M. Malins, Prof. A. P. Thomson, Dr. Clifford G. Parsons, and Mr. A. L. d'Abreu for allowing us to publish the clinical histories of cases 1, 2, 3, and 4 respectively; Dr. M. G. FitzGerald for his assistance at the necropsy in case 1; Dr. G. W. Thorpe and Dr. D. B. Brewer, who performed the necropsies in cases 3 and 4 respectively, for their coöperation; Dr. P. M. Moody for the diagrams: and Mr. Allan Ayres for the meticulous preparation of more than a thousand histological sections.

FATAL APPENDICITIS

THE DECLINE IN MORTALITY

W. SKYRME REES
M.B. Birm., F.R.C.S.
SURGEON, CAERNARVON AND ANGLESEY HOSPITAL, BANGOR, WALES; LATE SURGEON, DUDLEY ROAD HOSPITAL, BIRMINGHAM

ON returning to civil practice after the war, I gained a clear impression that the prognosis of all types of emergency surgery within the abdomen had improved. Particularly in appendicitis did it appear that patients who might have died before 1939 were now getting well, and getting well quickly. The Registrar-General's (1950) figures show that in 1948 the number of deaths from appendicitis in England and Wales was less than half that in 1934. Whereas 3193 peoople died of appendicitis in 1934, only 1257 did so in 1948, and the decline in the mortality figures in the intervening years, though not evenly distributed, is progressive (fig. 1).

It does not necessarily follow from these figures that the prognosis has improved: they may only indicate that fewer people are falling sick with appendicitis, and, in spite of the decrease in the absolute numbers of deaths, the mortality-rate may be unchanged. Thus from the Registrar-General's figures alone it is not possible to say that the prognosis in appendicitis has altered at all since 1934. The figures do, however, show that appendicitis does not kill half as many people each year now as it did in 1934.

A second glance at fig. 1 leaves no room for complacency even in this fact when, in this day and age, in England and Wales, more than 100 persons die every month from appendicitis. This eminently treatable condition still deals death on too large a scale, particularly in this country where the surgical services are

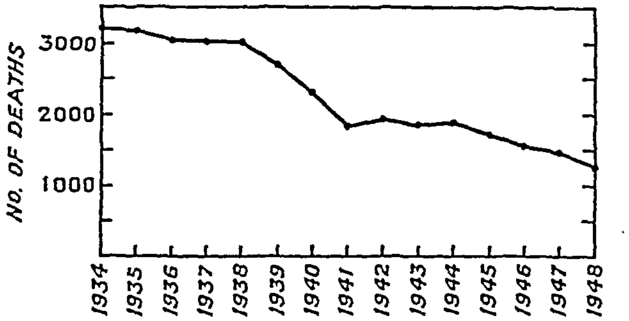

Fig. 1—Registrar-General's figures 1934–48 showing decline in numbers dying annually in England and Wales of appendicitis.

minutely and expensively organised. More than half the people who die are under 45 years of age, bread-winners, mothers of families, children, adolescents, and young adults. The treatment is too effective, the operation is too safe, and the outcome should be too certain, for these figures to be satisfactory.

INVESTIGATION

In 1946, on my appointment to a hospital where a large proportion of the emergency surgical work of a great city had been done by a skilled staff for the preceding eighteen years, it became my special interest over the next four years to observe the types of cases in which appendicitis was still fatal. From the well-kept hospital records generously provided for me by my surgical colleagues, and the industry of the office staff, all the cases of appendicitis over three different four-year periods were reviewed.

The organisation of the hospital lent itself to such an investigation. The long tradition of emergency surgical work had produced finely balanced units, each of 100 beds, each looked after by two surgeons, a registrar, and a house-surgeon. The pathological and X-ray departments were coöperative. The nurses, both in the operating-theatre and in the wards, accepted emergency surgery as one of their chief duties. The presence of almost the same surgeons for the greater part of the time under review made for the easy grouping of the cases of appendicitis into a classification based on the severity of the inflammation, since there was uniformity of description of the organ at operation. Most of the operations were done personally by the consultant staff; those done by junior officers were under close supervision.

There was also uniformity of treatment throughout the years, and the basic attack on the acutely inflamed appendix altered little. Details changed, but the surgical principle that an acutely inflamed appendix should be removed at the earliest possible moment after diagnosis, unless there was some overriding reason why this should not be done, was strictly observed.

The periods selected were 1934–37, 1940–43, and 1947–50. In 1934–37 most of the modern advances in general surgical technique were in use. The significance of fluid and salt balance, and the importance of giving parenteral saline solution when the intake by mouth was inadequate, had been generally accepted in the hospital. The importance also of early diagnosis and treatment, and of the time when operation might not be advisable and observation of a palpable lump might be the best course, were equally in the minds of the experienced surgeons responsible for the care of these patients.

In 1940–43 the new factor was the advent of chemotherapy, the new drugs being used in the treatment of the worst cases of appendicitis.

In 1947–50 there were two new factors: (1) antibiotics, and (2) the use of stomach suction, or decompression of the small bowel, in the treatment of peritonitis.

In all the periods the first and most important factor in treatment was the skilled and practised use of proven surgical principles. The other advances—chemotherapy, antibiotics, and bowel decompression—were adjuncts, albeit useful, to good surgery. Never is it suggested that they can purchase indulgences for ill-conceived or badly performed operations.

OPERATIVE TECHNIQUE

Technique remained remarkably constant not only through the years but also among the different surgeons. The standard approach to the appendix was through a muscle-splitting incision in the right iliac fossa. The appendix was removed, except when it was not easily available in an abscess. Most abscesses were treated by drainage only, but even here the appendix was removed if it presented. Whenever the appendix was removed, it was routine practice to crush and tie the base. The stump of the removed appendix was embedded in the cæcal wall. If for any reason it could not be embedded, a drainage tube was placed down to it. Gentleness in handling all the tissues, particularly the intestines, was practised assiduously to prevent postoperative ileus. Drainage tubes were often used in 1934–37; there was a general tendency to drain only the very worst cases in 1940–43; while 1947–50 occupies a middle position in this respect. In all the periods there was a greater tendency to drain children's abdomens.

In 1940–43 chemotherapy, though begun, was not general; nor was it standardised. Many different chemotherapeutic drugs were given by mouth, parenterally, and intraperitoneally, and the same surgeon did not always use the same method.

In 1947–50 the use of antibiotics, either alone or with chemotherapy, was general in cases complicated by any type of peritonitis or abscess.

CLASSIFICATION OF CASES

A simple classification according to the surgeons' findings at operation was used. Appendicitis being progressive, some easily recognisable milestones along the march of the inflamed appendix from simple acute inflammation affecting only the appendix to perforation with general peritonitis were taken to divide the cases into categories.

Group I includes all those cases where, at operation, the surgeon found that the inflammation was confined

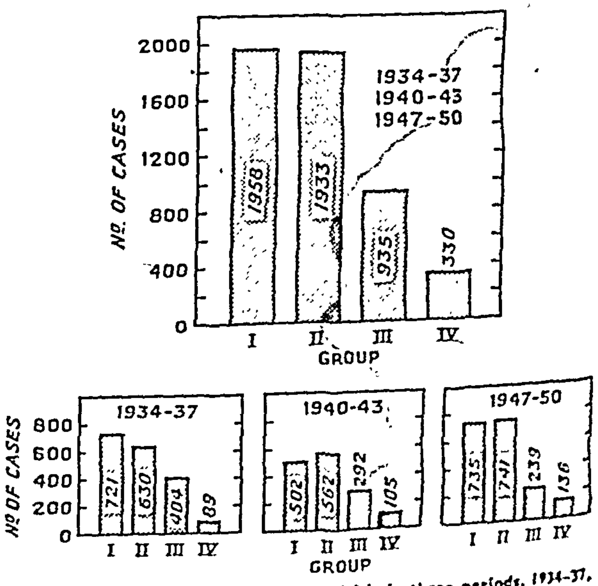

Fig. 2—Analysis of 5156 cases of appendicitis in three periods, 1934–37, 1940–43, and 1947–50, as a whole and separately. Numerals on histograms show numbers of cases.

to the appendix wall and there was no visible spread to the peritoneum of the right iliac fossa.

Group II includes the cases where the inflammation had spread from the appendix to the right iliac fossa, and the beginnings of a spreading peritonitis were present.

Group III includes the cases where an abscess had formed in relation to the acutely inflamed appendix. These cases are among those which are not operated on, and consequently the diagnosis was made on the history and the presence of a firm and tender lump in the right iliac fossa or palpable on rectal examination. In a few cases at operation an unsuspected abscess was found in what had been diagnosed as a group-I or a group-II case. The term appendix abscess in all cases refers to primary appendix abscess and not to residual abscess developing after removal of the appendix.

Group IV includes those cases where there was acute appendicitis with general peritonitis. This was the smallest group numerically, but at all times this group carried the highest mortality-rate.

The numbers of cases in each group are indicated in fig. 2 and the accompanying table.

Only undoubted cases of acute inflammation were dealt with. If there was any doubt on this point, the case was excluded from the series. In the examination of the case-notes the nomenclature was usually found to be simple and self-explanatory. The group of cases labelled miscellaneously "subacute appendicitis," "obstructive appendicitis," "recurrent appendicitis," "interim appendicectomy," &c., were closely examined, and most could firmly be excluded on the surgeons' notes, as not being of acute inflammatory origin.

It was recognised at the outset that the whole purpose of the inquiry would be nullified if the classification of the cases was not accurate. It can be stated that all the 5156 cases recorded were truly cases of appendicitis.

RESULTS

In 1934–37, when the main attack on the acutely inflamed appendix depended, for its effectiveness, on surgical technique alone, 1844 patients with acute appendicitis were admitted to the hospital, and of these 101 died, giving a mortality-rate of 5·4%.

In 1940–43, when chemotherapy was beginning to be used to supplement surgery, there were 1461 patients, and of these 64 died, giving a mortality-rate of 4·3%.

In 1947–50, when to surgery and the wider use of chemotherapy there were added antibiotic drugs and decompression of the small bowel, there were 1851 patients with acute appendicitis, of whom 42 died, giving a mortality-rate of 2·3%.

It has already been shown from the Registrar-General's figures that fewer people die of appendicitis in England and Wales now than died in 1934, and that the decrease through the years has been progressive (fig. 1). The hospital figures now show that the mortality-rate in a large modern general hospital has also decreased in the period under review, and that the prognosis for acute appendicitis is at least twice as good now as it was in 1934.

Thus the figures are complementary, the one series supporting the other to indicate that both in absolute numbers (Registrar-General) and in mortality-rate (hospital) there has been a great improvement in the prognosis in acute appendicitis.

Now the hospital figures, unlike the Registrar-General's, can be broken down and examined by dividing the cases into their groups according to the severity of the inflammation, using the simple classification (described above) based on the surgeons' findings at operation.

Group I

Cases where the inflammation was confined to the appendix wall, accounted for a little more than a third of the total in each period The figures were remarkably constant, being 39% in 1934–37, 36% in 1940–43, and 39% in 1947–50.

The mortality-rate for group I is also constant, varying by only 0·1% in the three periods. In 1934–37 there were 3 deaths in 721 cases, giving a mortality-rate of 0·4%; in 1940–43 there were 2 deaths in 502 cases, giving a mortality-rate of 0·4%; and in 1947–50 there were 2 deaths in 735 cases, giving a mortality-rate of 0·3%. Thus in a total of 1958 cases of acute appendicitis in this group there were 7 deaths, giving a mortality-rate of 0·35%.

This is a very significant figure since it represents the true mortality-rate from appendicitis as distinct from the mortality-rate of appendicitis complicated by peritonitis. This figure of 0·35% has remained constant since 1934, unaffected by any advance in surgery in this hospital, technical or therapeutic.

Of the 7 deaths in this group 6 were due to pulmonary embolism, and the 7th took place on the operating-table from the patient's reaction to the anæsthetic. All these deaths were unforeseeable tragedies, not any more related to appendicitis than to any other abdominal operation. The figure 0·35% must be near the irreducible minimum, not only for appendicitis but also for any abdominal operation under present conditions.

Of the dead patients 5 were women and 2 men. One was aged 23; 2 were in their thirties, and the remaining 4 were in their fifties.

Thus in this group of nearly 2000 cases not 1 patient *died of appendicitis* or even the complications special to appendicitis. There were no deaths among children and adolescents, who made up a third of the group.

Group II

Here the inflammation, though not necessarily localised to the right iliac fossa, was still limited. This practical grouping may not be microscopically accurate, yet it is a workable measure indicating the next extension from group I. There were 1933 of these patients, of whom 43 died. As with group I, the proportion of these cases in each period corresponded closely, being about a third of the total cases.

In 1934–37 there were 630 patients and 22 died, giving a mortality-rate of 3·5%; in 1940–43, there were 562 patients, of whom 16 died, giving a mortality-rate of 2·8%; and in 1947–50 there were 741 patients, of whom 5 died, giving a mortality-rate of 0·7%. This reduction is tremendously worth while. The mortality-rate of group II has been brought down to the same region as that of group I.

A further interesting fact comes out of the hospital records. In group II the average time of the patient's stay in hospital was reduced by three days over the total period under review. In 1934–37 the average stay was eighteen days, whereas in 1947–50 it was fifteen days. To give some indication of what this means, a reduction of three days in the stay in hospital of 741 patients is a saving of 8892 meals, quite apart from their other needs. A general freeing of beds and services makes way for other emergencies, the supply of which seems inexhaustible.

It must be accepted that in the years 1947–50 there was much improvement in the prognosis for cases of appendicitis with peritonitis which had just begun to spread from the right iliac fossa. The mortality-rate was reduced, and so was the average stay in hospital.

Group III

There were 935 patients who had appendicitis complicated by an abscess, and 81 of them died. In 1934–37 there were 404 patients, of whom 44 died, giving a mortality-rate of 10·8%; in 1940–43 there were 292 patients, of whom 18 died, giving a mortality-rate of 6·1%; and in 1947–50 there were 239 patients, of whom 19 died, giving a mortality-rate of 7·9%. In group III there has not been much improvement over the whole period: the difference between 10·8% and 7·9% is not statistically significant. There is need for improvement here. This is a surprising finding, since the prognosis in appendicitis when a tender palpable lump appears in the right iliac fossa is generally held to be good. The surgeon tends to be pleased when he finds a lump. The figures indicate that a different attitude might well be adopted towards this dangerous condition. Here is a veritable surgical wolf in sheep's clothing. The reason why it had such a good reputation in the past is discussed below.

Since group III is more than twice as large as the other death-dealing group, general peritonitis (935 cases against 330), a reduction of its mortality-rate would do more than an equal reduction in any other group to reduce the general mortality-rate for appendicitis. Although there is a larger percentage mortality-rate with general peritonitis, the absolute figures show that more people die of appendix abscess. It is stated above that 81 patients died of appendix abscess in the whole period under review. In the same period 76 died of general peritonitis.

Group IV

In this group, where general peritonitis complicated appendicitis, there were 330 patients, of whom 76 died, an appalling over-all mortality-rate of 23%, but one which has improved through the years. In 1934–37 there were 32 deaths in 89 cases, a mortality-rate of 36%; in 1940–43 there were 28 deaths in 105 cases, a mortality-rate of 27%; and in 1947–50, with all the modern surgical advances up to 1950 at the disposal of the surgeons, there were 136 patients, of whom 16 died, giving a mortality-rate of 12% (fig. 2). Thus group IV, dangerous and difficult though it may be, has shown a response to modern treatment. The mortality-rate has been reduced to a third of the 1934–37 figures. In addition the average stay in hospital was shortened from twenty-nine days in 1934–37 to twenty-four days in 1947–50.

DISCUSSION

There has been a progressive decrease in the mortality-rate from appendicitis since 1934. From the results of the present investigation it is possible to indicate which types of appendicitis have an improved outlook.

Where the inflammation is limited to the appendix and surgical treatment is promptly applied, the mortality-rate approaches the bare irreducible minimum for abdominal operations generally, and has been steady at this figure since at least 1934. If all the cases were operated on at this phase, the problem would almost be solved so far as appendicitis was concerned. The mortality-rate remaining applies to abdominal operations generally and not specifically to appendicitis.

I suggest that, to emphasise the importance of the removal of the appendix in the early stage of appendicitis, such terms as "expectant treatment" and "conservative treatment" of appendicitis should never be used, and this for several reasons. It must be agreed that the treatment of appendicitis in group I is appendicectomy, because when the inflammation is limited to the appendix wall the mortality-rate cited above can hardly be improved on by any form of non-operative treatment. If these figures mean anything, they mean that there should be no such thing as the conservative treatment of *appendicitis*, since the conservative treatment, when it is applied, is directed at the associated peritonitis, which is a different matter. It may or may not be desirable to apply conservative treatment to the associated peritonitis, but it is almost never justifiable, in the light of the above-mentioned figures, to deny operation to *appendicitis without peritonitis*. Yet, if we continue to talk about the conservative treatment of appendicitis, doctors may feel it to be reasonable, under conditions where arrangements for appendicectomy, though available and adequate, are difficult to fix up, to treat early appendicitis conservatively and to await the outcome, hoping either for resolution of the inflammation or abscess formation; which is the same as converting group-I cases with a superb prognosis into group-III or even group-IV cases with the bad prognosis indicated above. If we more accurately talk about the conservative treatment of peritonitis, there is no doubt that patients under conservative treatment should be in hospital; such dangers could not normally be faced in a private house. To restrict the term to its more correct usage would underline the seriousness of the position whenever conservative treatment is even considered. It may lead to more group-I cases coming to operation and fewer patients entering hospital with peritonitis. In 1947–50, 1 in 5 of all the patients operated on for acute appendicitis had either an abscess or general peritonitis.

In group II, where the inflammation was limited to the appendix and the peritoneum of the right iliac fossa, where there was local peritonitis not amounting to abscess formation, the advent of chemotherapy, antibiotics, and decompression of the small bowel has reduced the previously considerable mortality-rate to levels approaching those in group I. If groups I and II are considered together for 1947–50, there were 1476 cases with 7 deaths, giving a mortality-rate of 0·5%. The combined mortality-rate for group III and group IV in the same period was 9·3%.

Consideration of group III and group IV is very important because here we can find where the new advances in surgery have been effective and where they have not. The death-rate from appendix abscess has not greatly altered since 1934. In 1947–50 the presence of a tender lump in the right iliac fossa, associated with a history of appendicitis, carried with it almost as high a mortality-rate as did proved diffuse peritonitis. It was not always so. In the earlier periods diffuse peritonitis was a much more lethal complication of appendicitis than was appendix abscess. Advances in surgery have reduced the dangers of diffuse peritonitis while leaving untouched those of appendix abscess. It seems that, in the past, surgeons were content to accept a mortality-rate of about 8% for appendix abscess, because it contrasted favourably with that of about 36% for diffuse peritonitis. In those days, if a diffuse peritonitis localised into an abscess, the prognosis was improved greatly, and it was a favourable sign to feel a lump in the right iliac fossa. It was from those days, long fled, that appendix abscess derived its good reputation. But now, when the mortality-rates are 12% for diffuse peritonitis and 7·9% for appendix abscess, the difference in prognosis is hardly statistically significant. The satisfaction when a tender lump becomes palpable in the right iliac fossa should give way to sterner feelings. It should be realised that a condition is present which accounts for more deaths than does any other type of appendicitis, that no impression has been made on these figures since 1934, and that this sign does not now warrant any clinical complacency. Rather should it be considered that the lump in the right iliac fossa signifies the hard core of the death-rate from appendicitis, and an improvement in the outlook of this condition would do more than anything to reduce the general mortality-rate from appendicitis, which, being more than 100 a month in England and Wales, is in greater need of attention than other and more publicised methods of dying.

CONGENITAL ABSENCE OF THE COMMON BILE-DUCT

H. L. DURELL
M.B. Lond., D.C.H.
PHYSICIAN TO CHILDREN'S DEPARTMENT

A. C. HALLIWELL
M.B. Camb., F.R.C.S.
SENIOR SURGEON

GENERAL HOSPITAL, JERSEY, CHANNEL ISLANDS

CONGENITAL obliteration of the biliary tract is rare and usually fatal. The published cases have been fully reviewed by Ladd (1935), Ladd and Gross (1940, 1941), and Gray et al. (1948), and surgical intervention has been successful apparently in only 21 cases up to 1949.

Pathology.—One or more parts of the external biliary tract are either absent or exist as fine fibrous threads. Various abnormalities have been reported—e.g., the gall-bladder may be present but does not communicate with the ducts; or the gall-bladder may communicate direct with the duodenum, but there are no hepatic ducts.

Diagnosis.—There is no absolute rule for the diagnosis of congenital obliteration of the biliary tract, because some cases so diagnosed have cleared up spontaneously without operation, and it is assumed that they may have been caused by inspissated bile. Woolley (1948) says: "I believe we can conclude that we must be chary in reaching a diagnosis of congenital atresia of the biliary tract and depend upon a history of progressive jaundice for at least three months." Hæmolytic and infective conditions having been excluded, the diagnosis must be confirmed by laparotomy; otherwise the condition is fatal within the first year.

Treatment depends on the presence of at least one hepatic duct. 8 of the successful cases have followed the anastomosis of the gall-bladder to the stomach, 6 that of the gall-bladder to the duodenum, and 1 that of the gall-bladder to the jejunum. Choledochoduodenostomy and hepaticodochoduodenostomy account for the remaining 6.

CASE-RECORD

A boy, aged 3 months, was first seen on Oct. 25, 1947, with a history of increasing jaundice since birth. He appeared otherwise well, and had been born at full term. Delivery had been normal, and the baby was bottle-fed. He was an only child. Nothing relevant was found in the parents' histories. A Kahn test on the mother's blood was negative.

On admission the baby weighed 12 lb., and was well nourished but deeply jaundiced. No other abnormality was found. A blood-count was normal. The blood belonged to group A, and was rhesus-positive. The urine contained bile, and the fæces were white. Congenital atresia of the biliary tract was diagnosed and laparotomy was done five days after admission.

At operation under open ether the liver was found to extend two finger-breadths below the costal margin. The gall-bladder was 2 in. long and $^1/_2$ in. across; on aspiration it was found to contain bile. A common bile-duct could not be identified, so the gall-bladder was anastomosed to the pyloric antrum over a rubber tube with a double row of fine catgut sutures.

Postoperative recovery was uneventful. The stools became coloured within two days, and the urine cleared more slowly. The tube was passed in five days, and the jaundice cleared in six weeks. The child was discharged six weeks later, well and gaining weight, his weight then being 11 lb. 5 oz.

Subsequent progress was that of a normal child, apart from a small ventral hernia which is decreasing in size. In 1949 a cholecystogram showed no concentration of dye in the region of the liver. In 1951 barium-meal radiography showed no regurgitation into the gall-bladder, but traces of the meal could be seen in the gall-bladder area in the straight film.

COMMENT

The absence of any concentration of dye in the cholecystogram, and the presence of flecks of barium in the gall-bladder area after a barium meal, seem to establish the diagnosis of congenital obliteration of the biliary duct cured by cholecystogastrostomy.

Our thanks are due to Sister D. Fishwick, of the children's department, for her skilful postoperative care.

THE TREATMENT OF PNEUMOCOCCAL MENINGITIS SINCE THE INTRODUCTION OF PENICILLIN

COUNT DILLON GIBSON
M.D. Emory
ASSISTANT PROFESSOR OF MEDICINE, MEDICAL COLLEGE OF VIRGINIA, RICHMOND, VIRGINIA

D. GERAINT JAMES
M.B. Camb., M.R.C.P.
SENIOR MEDICAL REGISTRAR, MIDDLESEX HOSPITAL, LONDON

From the Department of Internal Medicine, Columbia University College of Physicians and Surgeons, and the Medical Service, Presbyterian Hospital, New York

No condition better reflects the advances in the field of antibiotic therapy during the last fifteen years than pneumococcal meningitis. Until 1936 this disease was almost always fatal. During the following two years a few cases were treated with type-specific rabbit antipneumococcal serum; but this was soon to be supplemented by sulphanilamide, and in turn by sulphapyridine, and eventually superseded by them. Hence, the specific antiserum treatment of pneumococcal meningitis will never be evaluated in its true perspective.

In 1940 Coleman reviewed in this journal the treatment since the introduction of 'M & B 693' (sulphapyridine) and concluded that the mortality-rate had been reduced from nearly 100 to 35%. This is in accord with Steele and Gottlieb's (1941) recovery-rate of 57% and Finland's (1938) 60% survival-rate. Waring and Weinstein (1948), reviewing published reports, placed the recovery-rate with sulphonamides at about 30%.

We report here the results in 31 cases of pneumococcal meningitis treated at the Presbyterian Hospital, New York, since the introduction of penicillin. The series is unselected, except that in all but one of them the invading pneumococcus has been isolated from the cerebrospinal

TABLE I—AGE-INCIDENCE OF PNEUMOCOCCAL MENINGITIS

Age-incidence (yr.)	No. of patients

fluid (C.S.F.) and typed. The period covered is from 1944 to 1950. Of the 31 patients 30 received intrathecal as well as intramuscular penicillin; 27 received sulphonamides also; 7 received the appropriate antiserum; 2 were given aureomycin; and 1 received streptomycin in addition to penicillin. In 4 cases simple mastoidectomy was also performed. This combined therapy makes it impossible to assess statistically the value of penicillin therapy alone. Jackson (1950) indicates the superiority of combined therapy; and Waring and Weinstein (1948), from an analysis of the literature, suggest that it is of greater value.

In the present series there were 3 deaths and a recovery-rate of 90%. The 3 deaths took place within twenty-four hours of the start of treatment, and if such cases were excluded, as was done by Smith et al. (1946), the recovery-rate would be 100%. If this is compared with the cure-rate of 43% where penicillin alone was used and that of 62% where combined therapy was used (Waring and Weinstein 1948), it can be concluded that every effective therapeutic measure should be used in the treatment of this severe infection.

CLINICAL AND BACTERIOLOGICAL FINDINGS

Table I shows that half the patients were under two years old, and the rest over twenty. This preponderance in the first two years of life is well recognised as a reflection of the frequency of middle-ear disease at that age. It is therefore surprising to note that only 1 of the 15 children had attributable ear disease, compared with 7 of the 16 adults.

TABLE II—ORIGIN OF PNEUMOCOCCAL MENINGITIS

Origin of infection	No. of cases
Respiratory Tract:	
Bronchopneumonia	7
Upper respiratory tract	5
Nasal septectomy	2
Nasal polypectomy	1
Trauma to posterior pharyngeal wall	1
Total	16 (*50%*)
Ear	8 (*26%*)
Sinus	2 *
Primary	5 (*16%*)
Total	31

* One case due to multiple face and skull fractures.

Length of Illness before Admission to Hospital

In 1 case the illness began when the patient was already in hospital recovering from nasal septectomy. At the other extreme, 1 patient was not admitted until six days after the onset. On the average the interval between onset and admission was two days.

Origin of Infection

In half the cases the respiratory tract harboured the infecting organism (table II). Aural infection was the origin in 8 (26%) of the cases; and, surprisingly, only 1 of these 8 patients was a child, though the series contained equal numbers of children and adults. The 5 cases of primary pneumococcal meningitis represent a fairly large proportion (16%) in which an original focus of infection was excluded beyond reasonable doubt.

Pneumococcal Types

The serological typing of pneumococci shows a wide scatter (table III), but, in accord with previous reports, half of them are seen to belong to the first eight types. In 1 case the type was established as that of type 1 by a polysaccharide precipitation test of the C.S.F. This was the only case in which the actual offending pneumococcus was not isolated.

Blood-cultures

Blood-cultures were made in 27 of the 31 cases, and a pneumococcus of the same type as in the C.S.F. was recovered in 11 cases (41%). Of these 11 cases in which a septicæmia was demonstrable, positive cultures of the same type of pneumococcus were also obtained from the nose, throat, ear, or mastoid in 9 cases (table IV). These 9 cases thus yielded the organism from the original focus, blood, and C.S.F. simultaneously. Only 1 of these 9 patients died—a male diabetic, aged 53, with bilateral bronchopneumonia *and bilateral otitis media.* Type-2 pneumococci were isolated from his upper respiratory tract, left ear, blood, and C.S.F. He died after his initial dose of penicillin.

Return to Normal Temperature

In the 28 recoveries the temperature returned to normal and stayed normal on about the eighth day in hospital. This figure did not change during the years, despite the increasing dose of penicillin.

PENICILLIN THERAPY

During 1944–50 the dosage of intramuscular penicillin altered considerably, climbing steadily from the average of 200,000 units daily in 1944–45 to 1,600,000 units daily in 1950 (table V). The average length of treatment did not alter; it remained fifteen days throughout these years. Intrathecal penicillin was given for an average of seven days, with daily injections of 15,000–50,000 units, usually about 25,000 units. The intrathecal dose remained steady throughout the years and did not follow the climbing intramuscular dosage. Infants tolerated the intrathecal dose of 50,000 units of penicillin with no ill effects, and there were no residual neurological lesions.

It seems that the dangers of intrathecal penicillin have been overemphasised in the literature: in

TABLE IV—RELATION OF BLOOD-CULTURES TO OTHER CULTURES

Blood-culture	Nose and throat positive	Ear and mastoid positive
Positive *	8	1
Negative	3	1

* Altogether there were 11 positive blood-cultures. The 2 positive blood-cultures not recorded here had negative nose and ear cultures.

so serious a disease early sterilisation of the C.S.F. outweighs any doubtful complications due to penicillin. In this series early sterilisation of the C.S.F. was accomplished in 27 of the 28 recoveries. In 23 of the cases pneumococci were not recoverable from the C.S.F. at the second lumbar puncture twenty-four hours after admission, whereas in 4 other cases sterilisation of the C.S.F. was accomplished within forty-eight hours of admission.

In the 1 case in which positive C.S.F. cultures persisted for a month the C.S.F. culture reverted to positive on each of three occasions in which the intrathecal penicillin was stopped (see figure).

Enough reports on the treatment of pneumococcal meningitis have been published to show two grossly divergent views on the use of intrathecal penicillin. Advocates of only intramuscular penicillin emphasise the toxic reactions to intrathecal penicillin; many such examples have been published. But in the present series there were no toxic reactions, even when 50,000 units were given intrathecally to infants under two years old. The crystalline preparations of today need give no anxiety to the clinician compared with the anxieties of the undertreated case.

Dowling et al. (1949) considered intrathecal injections unnecessary if massive intramuscular therapy is maintained. Using 1,000,000 units of penicillin every two hours they reported a fatality-rate of 36%, excluding patients who died within twenty-four hours.

Compare with this the results obtained with the use of intrathecal plus intramuscular penicillin. Smith et al. (1946) reduced their mortality-rate to 10%. They emphasised the value of free access of adequate penicillin to all parts of the C.S.F. pathways, and its maintenance there for an adequate length of time. It has been said that their results are not representative, because most of their patients were adults and treated by a highly skilled team. Such criticism cannot be levelled against the present series, in which half the patients were under two years old, and none was admitted to a special neurosurgical unit. Even so, the recovery-rate is 100%.

TABLE V—INCREASE OF DAILY INTRAMUSCULAR PENICILLIN DOSAGE THROUGH THE YEARS

Year	Dosage (units)
1944 1945	200,000
1946	600,000
1947	700,000
1948	800,000
1949	1,500,000
1950	1,600,000

The controversy about intrathecal penicillin may be summarised as follows:

(1) The results of therapy in cases treated with intramuscular penicillin only have not surpassed the results in the present series.

(2) No damage to the central nervous system from intrathecal penicillin has been observed in the present series.

(3) Intrathecal penicillin can exert a beneficial effect on meningitis.

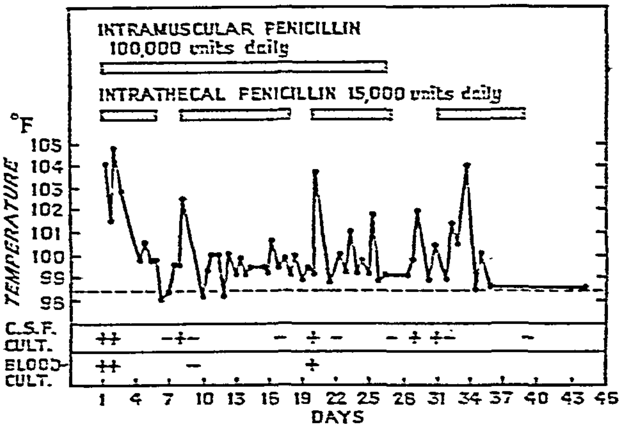

Chart of woman, aged 61, with type-9 pneumococcal meningitis following pneumonia of left lower lobe, showing that, whenever intrathecal penicillin was withheld, C.S.F. cultures reverted to positive.

For pneumococcal meningitis it is recommended that intramuscular penicillin be given in a dose of 2,000,000–4,000,000 units daily for two weeks, and that intrathecal penicillin in doses not to exceed 25,000 units dissolved in 10 ml. of physiological saline solution be given daily until definite improvement is noted. The preliminary observations of Lepper and Dowling (1951) suggest that the addition of aureomycin to this regimen increases the mortality-rate; so this combination is probably contraindicated. These workers treated alternate cases with penicillin and with penicillin plus aureomycin. Their mortality-rate in the penicillin-treated group was 30%, compared with 79% in the penicillin-aureomycin group. Further, recovery seemed to be slower in the penicillin-aureomycin group, as judged by the return of temperature to normal and by decrease in the number of leucocytes in the C.S.F. Since aureomycin alone can cure pneumococcal meningitis, it is probable that penicillin and aureomycin are mutually antagonistic in combination. This may well be a function of the differing modes of action of the two drugs, penicillin being bactericidal, whereas aureomycin is chiefly bacteriostatic.

DEATHS AND COMPLICATIONS

As already stated, there were 3 deaths.

In the case already described, meningitis complicated bilateral bronchopneumonia and otitis media in a diabetic. He died after the initial penicillin injection, and so cannot really be called a penicillin failure. He would probably have died in any case.

Another patient who died was a woman of 39, whose meningitis complicated severe injuries sustained in an automobile accident. There were multiple fractures of the skull and face, and there was serosanguinous discharge from eyes and nose. She died twenty-four hours after admission.

The third death was that of an infant aged 10 weeks, who died sixteen hours after admission. His meningitis followed an infection of the upper respiratory tract.

In the 28 patients who recovered there were no complications from either the meningitis or the penicillin. In 4 cases a simple mastoidectomy was done, in each case within three days of admission.

SUMMARY

In 1944–50, 31 cases of proven pneumococcal meningitis were treated with penicillin at the Presbyterian Hospital, New York. In 5 cases the pneumococcal meningitis was primary.

The daily dosage of intramuscular penicillin increased from 200,000 to 1,600,000 units.

The value of intrathecal penicillin is emphasised.

If 3 deaths within twenty-four hours of the start of treatment are excluded, the recovery-rate was 100%.

We are indebted to Dr. Yale Kneeland, jun., and to Dr. H. M. Rose for their helpful advice, and to Dr. D. Larson for performing the polysaccharide precipitation test.

GOWN FOR INCONTINENT PATIENTS

A. ARNOTT S.R.N.
N. H. NISBET M.B. Glasg.
From Foresthall Hospital, Glasgow

ALL enlightened hospitals aim at keeping their elderly patients active as far as possible, but a few who are too weak or apathetic even to sit up in a chair must spend their days lying motionless in bed, doubly incontinent and having to be fed. Each of these irremediably bedridden patients constitutes a serious nursing problem; some of them develop the habit of contaminating their hands with their excreta, and this may necessitate a complete change of bed-linen several times a day.

A simple modification of the ordinary hospital nightgown has been devised to prevent these patients' hands becoming soiled. The gown is easy to make and to fix; it can be laundered with the rest of the bed-linen; it keeps the patient warmer than the short gown that incontinent people usually wear in hospital; and it does not alter the appearance of the bed. It allows the patient to move the arms freely and to be propped up in bed when necessary. The object is not to restrain bodily movement but to prevent access of the patient's hands to the perineum. The gown is put forward as a useful development in nursing management and not as a substitute for full collaboration between nurse, doctor, and physiotherapist in the task of rehabilitation, which is the best approach to the problem of incontinence.

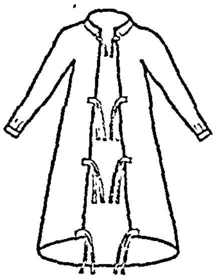

Fig. 1—Modified gown, showing position of tapes.

DESCRIPTION

A very large and strong long gown, with long sleeves, is opened completely down the front and its edges hemmed. Tapes are attached to tie at the neck 1½ in. below the usual neck-line and at three points on each side of this new opening (fig. 1). The gown is put on back to front, over the usual short gown. The top tapes are then tied behind the neck, but the rest of the gown is spread out over the patient, and the other three pairs of tapes are tied to the bedstead on each side, the first of these being high enough to prevent the patient inserting an arm below the gown (fig. 2). The lower edge of the gown should extend well below the knees. Finally, the patient is covered with sheet and blankets in the usual way.

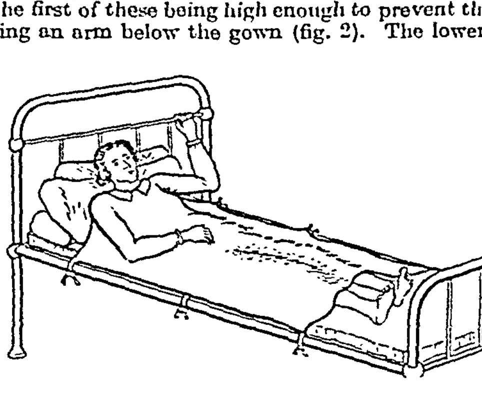

Fig. 2—How the gown is worn in bed.

No difficulties have been encountered in the use of this gown. It makes the patient feel much warmer as well as keeping the hands clean. It is also an exceedingly useful adjunct to the Brocklehurst bed (Brocklehurst 1951), designed for the same type of patient.

We are grateful for the encouragement and advice of Prof. Stanley Alstead.

Preliminary Communication

THE BACTERIOLOGY OF CHRONIC BRONCHITIS

PERHAPS the most striking feature of the published reports on the bacteriology of chronic bronchitis is the great variety of organisms that can be isolated from th sputum in this disease, as described, for example, b Marshall[1] and Southwell.[2] In fact it seems true to say tha all the organisms commonly found in the upper respirator tract are frequent inhabitants of the bronchi in chroni bronchitis. In addition to noting this variety of organisms, Howell [3] pointed out that the predominant organis in any given case of chronic bronchitis may sho considerable variations over comparatively short interval of time. For example, *Neisseria catarrhalis* might predominate in the sputum of a patient on one occasio while a week or two later the predominant organis might have changed to, say, Friedländer's bacillus, whic in turn might be superseded later by the origina *N. catarrhalis* or even by some other organism. Th purpose of this communication is to draw attention to a phenomenon which has come to light as a result of a investigation into the variations described by Howell.

It seemed possible that the apparent variations in th predominant organisms might in fact be due to irregula distribution of the organisms throughout the sputum so that if single cultures only were made the predominan organism might well be determined largely by chanc according to the portion of sputum cultured. *Preliminary* investigations showed that in many cases the distribution of organisms in the sputum was in fact far from regular, and a more detailed study has indicated that the organisms that are distributed most irregularly are those which often seem to be responsible for the infective element of the disease.

VARIATION IN THE DISTRIBUTION OF ORGANISMS WITHIN A SINGLE SPECIMEN OF SPUTUM IN CHRONIC BRONCHITIS

Culture no.	Pus or mucus	Percentage of colonies in each culture			
		H. influenzæ	*Strep. viridans*	Non-hæmolytic strepto-coccus	*N. catarrhalis*
1	P	99	1	0	0
2	P	0	50	45	5
3	P	99	1	0	0
4	P	0	56	24	20
5	M	0	79	19	2

DIFFERENTIAL COLONY COUNTING

In order to determine the amount of variation in the distribution of organisms within a specimen of sputum, a system of "differential colony counting" has been developed. This is applied to cultures made from several different parts of the sputum, the parts being selected by a random sampling method. The relative numbers of the colonies of each type of bacterium present are determined by counting a total of 300 to 500 colonies on each culture plate. The counting is simplified by using a modification of an electric counter devised by Dr. W. D. Linsell. This counter and full details of the counting technique will be described elsewhere.

Initially cultures were made from some thirty parts of each sputum specimen, but it has been shown that, with the random sampling technique employed, this number may be reduced to five. Findings for a single specimen of sputum in which extreme variations are present are shown in the table. This specimen consisted of about 1 ml. of mucus with a lump of pus embedded in it. It was washed in physiological saline solution before cultures were made, in order to minimise risk of salivary contamination. It may be concluded, therefore, that no explanation other than uneven distribution of the organisms within the sputum itself can account for the variations observed.

RESULTS

Sputa from 44 cases of chronic bronchitis have now been investigated by this technique; and detailed results will be published in due course. The following is a summary of the main findings:

(1) The organisms which show the most frequent and startling variations are *Hæmophilus influenzæ* and the pneumococcus. Variations have also been observed with *Staphylococcus aureus*. In some cases, especially those with more acute infections, these organisms may be distributed evenly throughout the sputum.

(2) The variations are not necessarily related to the presence or absence of pus. The table shows the results of four cultures from purulent parts of one specimen of sputum. *H. influenzæ* was present in only two cultures. In other mucopurulent sputa this organism has been found in large numbers in cultures from some of the mucoid parts and has been absent from purulent parts.

(3) The relative numbers of such organisms as *Streptococcus viridans*, non-hæmolytic streptococci, and *N. catarrhalis* throughout any specimen of sputum are fairly constant, suggesting that these organisms have colonised the bronchial tree in a regular manner. This constancy is usually also apparent if comparisons are made between consecutively produced specimens of sputum or specimens obtained on consecutive days, whereas the appearance of *H. influenzæ* and pneumococci may be quite irregular in different sputum samples. The relative proportions of the "stable flora" reflect closely those of the same organisms in cultures of throat swabs from the same patient.

EFFECT OF CHEMOTHERAPY

In addition to the purely bacteriological studies, the clinical and bacteriological response to chemotherapy in 6 patients with chronic bronchitis has now been studied in detail. In all cases the sputum contained a mixture of several different organisms. In 4 cases *H. influenzæ* or pneumococci or both organisms were present, each showing a considerable degree of variation in its distribution in the sputum. In the remaining 2 cases *H. influenzæ* was distributed evenly throughout the sputum. Chemotherapy designed to eliminate these two organisms produced a significant improvement in each case, even though the stable flora—e.g., *Strep. viridans* and non-hæmolytic streptococci—remained unchanged or returned soon after treatment was stopped. In those patients who later relapsed it was found that *H. influenzæ* or pneumococci had reappeared in the sputum. It seems likely, therefore, that these two organisms will prove to be the most important pathogens in chronic bronchitis with secondary infection.

FURTHER WORK

Studies of this kind are continuing in order to establish which organisms are of importance and which may be ignored in the chemotherapy of chronic bronchitis. In routine bacteriological laboratories the need is also apparent for a method of liquefying sputum without destruction of the organisms it contains, so that a homogeneous suspension can be obtained from which only one culture need be made. Such a method has been developed, and is at present being tested in this laboratory by Mr. G. A. Rawlins, who will report on his work in due course.

Medical Societies

ROYAL SOCIETY OF MEDICINE

Chronic Otitis Media

THE section of otology of the Royal Society of Medicine, under the chairmanship of Air Vice-Marshal E. D. D. DICKSON, president of the section, discussed chronic otitis media at a meeting on Dec. 5.

Mr. F. McGUCKIN said that one of the common misconceptions about chronic otitis media was that it was always secondary to manifest otitis media: this was not always so. A patient would put up with a discharging ear for many years before seeking advice, and we must ask ourselves why he should consult the otologist after, say, fifteen years. What was the main trouble? Was it discharge or deafness or discomfort? The patient should be told as soon as possible of the best results that treatment could achieve. Could he expect a dry ear, a safe ear, an ear with which he could hear, or what? He would be disappointed if he did not know what to expect. He should also know, when an operation was advised, whether it was being done to stop the discharge or to give him a safe ear. Chronic otitis media was always a potentially erosive disease, which might spread locally to the facial nerve or the inner ear, or intracranially. In the latter case the patient was probably "ill," in the former probably not. Mr. McGuckin recognised three categories of chronic suppurative otitis media. The first he called the "accessible" group, in which there was a perforation with an exposed promontory (on the inner wall of the middle ear); in the second, or "inaccessible," group, cholesteatoma or granulations were present; a third group was "uncertain" and carried with it all the hopes of the first group and all the fears of the second. Experience and time were necessary before an ear could be transferred from the uncertain group to one of the other categories. The accessible cases required only minor interference, with mopping of the ear and antibiotics; but the inaccessible ones must be treated by some means that would make them accessible, and this always meant some form of surgery. In long-standing cases surgery included the excision of nutritionally defective tissue, either soft or bony; but operation was only one stage in the treatment, and postoperatively the patient was transferred to the minor-treatment group.

Mr. J. ANGELL JAMES said that chronic otitis media always arose from an acute infection of the middle ear. Three months could be taken as the dividing-line. He also classified his cases into three groups. In the first there was a healed perforation; and syringeing, diving, sudden nose-blowing, and pressure changes should be avoided in these cases. In the second group there was a patent perforation, through which recurrent discharge could occur. Here there was a risk to the inner ear from exposure to noise, and to the middle ear from dust in the external meatus. Any primary focus of infection in the nose should be removed—infected sinuses, deviations of the nasal septum, adenoids, and, rarely, neoplasms in the nasopharynx. The third group had an active discharge, more or less continuous but perhaps with slight remissions. Here the aim must be to preserve function. Again, any primary cause of infection must be removed, the threat of dangerous complications warded off, and steps taken to relieve the pain and discharge.

If an intracranial extension was present, operation would be necessary, and surgery was also indicated in the case of cholesteatosis and polypi. Under these circumstances X-ray examination may help to demonstrate bony destruction. Discussing the cause of polypi, Mr. Angell James said that he had felt for some time that aural polypi may have an allergic basis, but it had not yet been possible to demonstrate an eosinophilic reaction in them. When complications were not imminent and cholesteatosis and polypi were absent, conservative treatment could be adopted. The organisms should be identified and their sensitivity to the antibiotics tested. The appropriate antibiotic was then used, preferably in powder form unless the discharge was very profuse or the meatus stenosed (lactose was a suitable base). Careful toilet was an essential preliminary. A dry ear should now be attained after 90% of mastoid operations, so that we could recommend the operation more often than in the past.

Mr. Gavin Livingstone said that the decision whether to operate or whether to continue with conservative treatment was always a difficult one. Chronic otitis media was common in poorer people, and careful cleansing was very important and should be done daily if possible. But the working man could not easily attend hospital every day, and therefore he rarely came to the otologist until his deafness had increased or complications had arisen. Suction was an ideal method of cleaning the ear, and it should be carried out under skilled supervision; but syringeing could be done by less experienced people. Mr. Livingstone distinguished a further three groups of chronic otitis media. The first was the "safe" ear with a mucoid discharge: the postnasal space must be kept healthy, sinusitis must not be overlooked, and septic foci in the nose and mouth must be removed, particularly bad teeth. The second group he called the "mastoid" group, where the discharge was persistent and unpleasant and the hearing was greatly affected. Infections in the attic formed the third group. Whatever surgery was indicated in chronic otitis media, the guiding factor in each case was the particular pathological lesion present. This must be removed entirely, and the aim must be to produce a safe, hearing, and dry ear.

Air Vice-Marshal Dickson agreed with Mr. Livingstone about the importance of trained people treating these ears. It should not be left to the patient.

Mr. A. Tumarkin discussed the evolution of mastoid surgery, and compared his own operation of permeatal atticotomy with the techniques of Lempert, Popper, and others. He emphasised the association between chronic otitis media and the poorly pneumatised mastoid. He felt that "frustration of pneumatisation" occurred because air was unable to circulate in the pneumatic system. The cause was to be found in the nose—or, more specifically, in nasal catarrh. Chronic nasal catarrh was a disease of the whole upper respiratory tract, and led to blockage of the eustachian tube. Diamant (an otologist) and Dahlberg (a statistician) had recently revived Cheatle's theory which attributed the type of pneumatic system to inherited characters. They denied the importance of environmental factors such as eustachian block. Acceptance of their theory, thought Mr. Tumarkin, would paralyse any further research into this aspect of the problem.

Mr. T. B. Layton thought that all cases of chronic otitis media were due to a primary inflammation. There should be no new cases nowadays. The primary organisms were present for the first six weeks of infection; secondary organisms appeared after eight weeks. The infection was then chronic, and therefore mastoid infection should be cleared up between the sixth and eighth weeks. The three-month borderline which Mr. Angell James had suggested was too long. He agreed with Mr. Tumarkin in doubting the hereditary nature of the dense mastoid, but he felt that failure of pneumatisation was caused by an osteitis resulting from minor non-suppurative attacks of otitis media.

Mr. R. Scott Stevenson thought that too many radical mastoid operations had been done before the first world war. Between the wars we had tended to over-emphasise the importance of conservatism; and he wondered whether we were not now tending to swing again towards too much radical surgery. He agreed with Mr. Livingstone that skilled supervision was the ideal to be aimed at in conservative treatment, but he could not accept Air Vice-Marshal Dickson's suggestion that the patient should never be allowed to carry out his own aural toilet—sometimes he had to.

Mr. S. W. Allinson said that 90% of the children that he saw breathed through their mouths and could not blow their noses gently, one nostril at a time. He thought that many cases of the "catarrhal" type of chronic otitis media would settle down if the patients were taught to do this properly.

Mr. Terence Cawthorne said that 70% of cases of chronic otitis media in children cleared up with regular daily treatment. In the Services, Banham and others had shown that a similar or greater proportion would clear up in this way; and Johnston had shown the same for civilians in factory clinics. Surgery was needed for the 20 or 30% that failed to respond to conservative treatment. Recent work on chronic otitis media had given prominence to the teaching of Cheatle that anatomy determined pathology. All these cases started as acute infections: if the mastoid was cellular, acute mastoiditis resulted; if it was acellular, the infection would "tend to lapse into chronicity."

Mr. McGuckin said that chronic infection might sometimes be discovered by accident and that this insidious type was sometimes missed. Coliform organisms were present in about two-thirds of his cases.

Mr. James agreed with Mr. Tumarkin's views on the acellular mastoid in so far as he was convinced that it was acquired and not inherited. When patients with chronic otitis media were examined radiologically, one was amazed how often there was a cellular mastoid on one side and an acellular one on the other. He believed that there was some inherent characteristic in the lining of the middle-ear cleft which was responsible for pneumatisation. Failure of pneumatisation resulted from acute otitis media and could be compared with the changes sometimes seen in the paranasal sinuses, particularly the maxillary antrum.

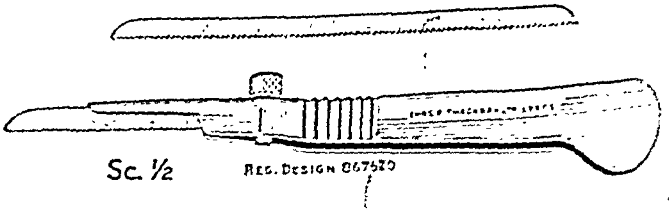
New Inventions

A NEW SURGICAL SAW

There has long been a need for a light-weight general-purpose saw for smooth, easy, and accurate cutting of bone or metal. The saw illustrated can cut bone or steel equally well and uses interchangeable miniature hacksaw blades $^1/_4$ in. wide. These blades cost very little and are available in two types—standard and high-speed steel. The latter are most suitable for sawing stainless steel but are slightly thicker than the standard blades.

The handle is of very simple construction, being made of stainless-steel sheet pressed to a shape which enables it to be held comfortably in the hand. The length of the exposed saw can be easily adjusted by means of the milled-head screw, which clamps the saw blade in position. The blade being reversible, the teeth can be faced to cut on either forward or backward strokes.

The saw was evolved for the accurate shaping and morticing of bone grafts in plastic surgery, where it has been well tried. It should find a wider field of usefulness



in other types of bone surgery, since the blade is always sharp and is not blunted by cutting bone or steel. No special sterilising precautions are necessary.

The saw is made by Chas. F. Thackray Ltd., 10 Park Street, Leeds.

Reviews of Books

Hamey the Stranger

John J. Keevil. London: Bles. 1952. Pp. 192. 21s.

The Royal College of Physicians of London owes much to Baldwin Hamey, son of the subject of this book; for he was one of its chief benefactors. He and his father were both confirmed letter-writers; and their letters, mostly in Latin, are in the archives of the college and the University of Leiden. Dr. Keevil, former library keeper of the college, has drawn on these letters in compiling this biography.

Baldwin Hamey the elder—Hamey the Stranger—was born at Bruges in 1568, the year in which Roman Catholic Spain sentenced to death, as heretics, all the inhabitants of the Netherlands. Things became so bad that in 1584, or soon after, the Hamey family migrated to Leiden, where Baldwin received his university education, first in philosophy and letters, and later in medicine. Through the influence of his teacher, Joannes Heurnius, he was appointed, two years after qualifying, as physician to the Czar of Russia; and found himself plunged into a world of murder and intrigue, where the vast figures of Czar Fedor, Boris Godunow, and the rest of the Godunow family moved in a drama much larger than life. Elizabethan England, to which Hamey soon fled with his promised wife, Sarah Oeils, must have seemed tame in comparison; and indeed the book partakes of the anticlimax. His graphic account of the Essex rebellion, and his own courage in various plague, smallpox, and typhus epidemics, stand out; but much space has to be given, unfortunately, to his struggle to persuade the college to examine him and give him an English diploma. It was achieved at last, but not without some undeserved humiliation for him. His son Baldwin, whose life is to form the subject of a second volume, *The Stranger's Son*, became M.D. of both Leiden and Oxford, as well as a fellow of the college.

This first tale is well told and worth reading, and we look forward to the second.

Surgery of the Chest

A Handbook of Operative Surgery. Julian Johnson, M.D., D.SC., professor of surgery, school of medicine and graduate school of medicine, University of Pennsylvania. Charles K. Kirby, M.D., associate professor of surgery, school of medicine, University of Pennsylvania. Chicago: Year Book Publishers. London: Interscience Publishers. 1952. Pp. 387. 68s.

The authors set out to provide an atlas of thoracic operations, and have adopted the general pattern of a page of illustrations to a page of text. The book is straightforward and easy to read and understand, since the illustrations are clear and precise. For anyone likely to become interested in thoracic work it gives a very good idea of the scope of the subject.

Almost every routine thoracic operation is described briefly and illustrated from the technical aspect, and the reader is given the choice of studying the operation of lobectomy in the supine, lateral, and prone positions, with special reference to the important anatomy of the lung root. In addition, such unhappy incidents as hæmorrhage from the aorta are considered, with the appropriate method for dealing with them. There is little to criticise, though it is strange that an elaborate plastic form of treatment should be described for cardiospasm in preference to the more simple Heller's type which is hardly mentioned. These clear descriptions and the apparent simplicity of modern heart operations should not, however, encourage the inexperienced surgeon to embark on them, thinking they are necessarily easy.

There is an attractive lack of pretension about this well-produced and well-illustrated book.

Microbial Growth and its Inhibition

First International Symposium on Chemical Microbiology. World Health Organisation Monograph Series No. 10. Geneva: World Health Organisation. 1952. Pp. 285. 15s.

In June, 1951, an international symposium was held in Rome on chemical microbiology, with particular reference to antibiotics and the various problems concerned with their inhibition of bacterial growth. It was organised by the Instituto Superiore di Sanità in collaboration with the Council for the Coördination of International Congresses of Medical Sciences and the World Health Organisation. The papers, read by leading specialists, have now been published in book form.

They cover a wide range, including the origin and nature of drug-resistance in bacteria, vitamin-B-group substances in bacterial metabolism; the liberation of nucleic acid when cells are heated, penicillin-fermentation, the chemistry of terramycin, antibiotics against fungi and antibiotics as stimulants of animal growth, the biological standardisation of antibiotic preparations, the lag-phase in bacterial growth, and similar subjects. The papers are mostly short reviews of subjects in which the authors were particularly interested, but the references are chosen with discrimination.

Each of the articles thus presents the considered opinion of a well-known authority. They are lucid and easy to read, and so should stimulate those working on chemical microbiology, and inform those not conversant with this field of research.

Refresher Course for General Practitioners

By various authors; reprinted from the *British Medical Journal.* London: British Medical Association. 1952. Pp. 486. 25s.

This volume is a "first collection" of articles which appeared in the *British Medical Journal* under their present title between October, 1949, and December, 1950. Their publication in book form should be welcome to many practitioners, whether or not they read them as they came out. The authors, drawn from many hospitals and teaching centres in London, the provinces, and beyond, have maintained a remarkably high level not only in the content but in the presentation of their matter. The articles are informed, readable and to the point, and well calculated either to supplement the reader's knowledge of the subject or to stimulate him to consider it afresh. They are illustrated where necessary with diagrams and photographs, well reproduced. The subjects of the 55 articles, though all relevant to general practice, cover no defined field and are arranged in no logical order. This makes for easy reading, but the random selection limits the usefulness of the book for reference.

Metabolism of Protein Constituents in the Mammalian Body

S. J. Bach, PH.D., F.R.I.C., department of physiology, University of Bristol. Oxford: Clarendon Press. 1952. Pp. 272. 40s.

In this book Dr. Bach has confined himself to a review of our knowledge of some aspects of the metabolism of alanine, glycine, serine, threonine, valine, leucine, isoleucine, methionine, cysteine, and cystine. There are sections on the formation and reactions in vivo of hæm pigments, bile pigments, porphyrins, uric acid, glutathione, and other metabolites; and an interesting account of cystinuria is included. The nutritional value and use of these amino-acids for glycogen formation are considered, and there is an exhaustive account (about 53 pages) of "biological methylation." On this subject Dr. Bach is evidently a scholar, and his review—including as it does references to pathological consequences, in man and other species, of deficiencies in methylating processes—could hardly be bettered.

In other respects, the book is less satisfactory, for in spite of the many references to original papers the treatment of some subjects is scrappy and inadequate. Thus the account of conjugated bile acids is inaccurate, and would not do for a student's textbook: and Dr. Bach does not mention the recent work of Friedman and Byers on the excretion of uric acid by dalmatian dogs. Again his references to detoxication do not include any to the work, or to the comprehensive review, of R. T. Williams. It is disturbing to find major deficiencies of this kind in a learned monograph.

Nevertheless, the book does contain some valuable surveys, especially of recent work with isotopes, and it should be useful to the biochemist and the (appropriately critical) advanced student.

Précis de Mycologie

M. LANGERON, Chef de la Section de Mycologie de l'Institut de Parasitologie de la Faculté de Médecine de Paris. 2nd ed. Revised and enlarged by R. VANBREUSEGHEM. Paris: Masson. 1952. Pp. 701. Fr. 5400.

THIS book, when first published in 1945, proved so popular with microbiologists, and particularly with medical mycologists, that the edition was quickly exhausted. Work on the second edition, which began immediately, was interrupted by the death of Dr. Langeron in 1950, and it was eventually completed by his former pupil, Dr. Vanbreuseghem.

The new book is in three sections: general mycology, technique, and medical mycology. The section on general mycology, representing the entire original book except for the descriptions of technical methods and a chapter on fungus diseases, has largely been rewritten with many additions; but it retains all those features which made the first edition so valuable. Descriptions of mycological technique, scattered throughout the text in the first edition, have been collected together in a comprehensive section on laboratory methods. The section on fungus diseases by Dr. Vanbreuseghem is entirely new and replaces the single chapter on mycoses in the first edition. In it the diseases are arranged in alphabetical order and the descriptions follow the plan adopted by nearly all textbooks on medical mycology. This section, which makes the book more attractive to the general medical reader, could with advantage be expanded in a future edition.

Anurie bei Chromoproteinurie (Hämolyseniere, Crush-Niere)

HANS U. ZOLLINGER. Stuttgart: Georg Thieme. 1952. Pp. 138. DM. 14.70.

THE author of this monograph has been interested for many years in the problem of the pathogenesis of the renal lesion associated with myolysis or with hæmolysis, primarily from the viewpoint of the pathologist.

In this study, however, he includes a good account of the clinical aspects of this syndrome, dealing briefly with the signs and symptoms and the mechanism involved in their production, the course, and the prognosis. The section on treatment is not so well balanced, dealing mainly with paravertebral block and decapsulation—therapeutic measures now largely abandoned. High-calorie, low-nitrogen diet is mentioned very briefly but without reference to Borst: avoidance of overhydration and electrolyte intolerance is stressed and there is a brief mention of dialysis methods.

It is, however, the sections dealing with the anatomy and pathogenesis of hæmoglobinuric or myoglobinuric nephrosis that the interested reader will find of most value; here Professor Zollinger speaks as an expert. He has surveyed in detail 55 cases of this condition coming to necropsy in Zürich in ten years (from roughly 17,000 necropsies). They include groups with hæmolysis due to mismatched transfusion, bad conservation of blood, or sensitisation; post-transfusion cases associated with pregnancy, operation, or infection; a group due to exogenous hæmolytic agents such as chlorate and soap; a group with muscle necrosis due to crush, carbon monoxide poisoning, or electrical accidents; one case of burns; and a final group of miscellaneous cases. Illustrative case-histories are given. The pathological findings are given in considerable detail and are well illustrated. A full discussion of pathogenesis reviewing the blockage, ischæmic, and toxic theories leads the author to the conclusion that this is a syndrome of multiple factors. There are 486 references, most of which are recent; and, unlike many monographs with large bibliographies, the references are used critically.

This will be standard reading on the subject for a long time.

After-Treatment (4th ed. London. Oxford: Blackwell Scientific Publications. 1952. Pp. 338. 30*s*.).—Mr. H. J. B. Atkins has thoroughly revised this popular book on the care of patients after operations, which he designed for general practitioners, house-officers, ward sisters, and dressers. Methods in surgery change quickly and are often ephemeral; but this book successfully reflects current views and practice, and the author has used discretion, judgment, and experience in presenting his subject. He has deliberately excluded all descriptions of technique—for such things as spinal puncture, the making of plasters, and so on—holding that these practical procedures can only be learnt at the bedside. Though there is much to be said for this point of view, it is nevertheless helpful for a resident to be able to refresh his mind with the important practical details and pitfalls of these small operations. He will need a small practical book to supplement this excellent guide to after-treatment.

Child Health. *The Practitioner Handbooks* (2nd ed. London: Eyre & Spottiswoode. 1952. Pp. 264. 21*s*.).—This, like the first edition, consists of 22 chapters, each written by a different authority, and covers many subjects not dealt with in textbooks of pædiatrics or public health. There is a section on feeding, and a good chapter on the control of common fevers, by Dr. C. M. Smith; but in general the book aims to give an account of the public-health services available in this country, rather than guidance to the practitioner on the application by himself of preventive medicine. For this edition Prof. Alan Moncrieff and Dr. W. A. R. Thomson, the editors have revised all the chapters. No new subjects have been added, however, and it is disappointing to find no mention of the problems of homeless children, which have aroused much interest recently, and which led to the Children Act of 1948. Nevertheless, this is the most up-to-date book on the subject of child health in this country, and it will continue to be a valuable guide to all concerned with the medical care of children.

New Dictionary of Psychology (London: Vision Press & Peter Owen. 1952. Pp. 364. 35*s*.).—He is a brave man who sets out to define psychological terms; so many writers use them with different meanings. This compilation by Philip Lawrence Harriman is useful but far from complete, and too many not so important American psychologists are listed at the expense of other nationalities. One American is listed merely because he was the first that ever burst into print in U.S.A. with *Mental Hygiene* as the title of a book; Lord Kelvin appears as "William Thomson Kelvin" instead of "William Thomson"; and Napoleon is included for opposing phrenology. Moreover some of the definitions sound wholly incorrect to English ears; but this may be due to American usage, for this book has been made and printed in America and had an English title-page stuck on to it. But there can be no such excuse for the statement that *lapsus calami* is a "psychoanalytic term referring to the unconscious wish for a disaster."

Permeability of Natural Membranes (2nd ed. Cambridge: University Press. 1952. Pp. 365. 30*s*.).—The first edition of the book was sold out within a year and it has been accepted as a standard work in its own field. Since 1943, however, there has been a considerable shift of emphasis in our whole way of thinking about the distribution of ions and other substances across natural membranes; the properties of the membranes themselves are less emphasised, and more importance is attached to active processes of ion extrusion which are linked to cell metabolism. Moreover, active cell processes probably prevent any formal thermodynamic equilibrium of the type treated in chapter III. It is obvious from their candid preface to the new edition that Mr. Hugh Davson, D.SC., and Prof. J. F. Danielli, D.SC., the authors, recognise the need for a more complete revision than they have in fact been able to make: "reprinting of this book with a few minor additions" is an accurate description of what has been done. The "minor additions" consist of a paragraph at the end of most of the chapters, giving references to work up to 1950. The book remains an authoritative summary of the older work in this field, but we hope that the authors will not be content to leave it at that, but will proceed to a full discussion of the subject, with a critical survey of the results of isotope studies and the effect of cell metabolism on the distribution of ions.

THE LANCET

LONDON: SATURDAY, DEC. 20, 1952

College of General Practitioners

As a Christmas present this year our profession is to be given a new college. When the suggestion came up, some of us hinted that, having several colleges already, we should prefer something rather different[1]; but Mr. Willink's committee has decided that a good useful College of General Practitioners is what we really need. The committee was a strong one[2]; its decision was unanimous; the college is all wrapped up and waiting for us; and there is therefore no point in thinking any more about possible alternatives. Some of these were theoretically preferable, but it may well be true that nothing short of a college would now serve the purposes that so many of us have at heart. Certainly, in its report published in this week's *British Medical Journal*, the committee has explained very convincingly why the project that failed 107 years ago must now be realised, and it is able to give a clear account of the functions proposed for the new college, of the initial structure, and of the stages by which the founders will gradually transform themselves into a representative academic organisation.

The purpose of the college is to work towards a renaissance of general practice, and its promoters declare that general practitioners, in the future as in the past, ought to be "good doctors practising medicine in their own right." They regard general practice as "fundamentally as important as the specialties."

> The general practitioner, they say, "must be prepared to assume some degree of responsibility in any and every illness, in people of all ages, over long periods of time; he must play his part in preventive medicine; and he must help in many social difficulties. His deliberate aim should be to achieve breadth of vision rather than great depth in any particular sphere. It is from him that patients first seek advice; to him they should have direct and continuous access; it is his duty to coördinate their whole medical care, to ensure that this is of the highest possible quality, to interpret his patients' needs to specialists and hospitals, and to interpret the specialists' opinions back to them. . . . His medical responsibilities are widespread and he must be equal to them; and the social problems with which he has to deal are widespread too."

On this basis, and on the broad definition of a general practitioner as a doctor "who does not limit his practice to a particular field of medicine or surgery," it is held that general practice embraces the work of many doctors in institutions, such as schools, factories, and prisons, and of general-duty officers in various services, military and otherwise. Hence, in selecting its foundation members, the college will be catholic in its range though eclectic in its insistence on experience or enthusiasm and on a financial act of faith. From New Year's day applications for foundation membership will be acceptable from doctors whose names appear in the Medical Register and who have one of the following qualifications:

1. Twenty years in general practice, or its equivalent as a general medical officer (with primary charge of patients) in a school, factory, or other institution, in H.M. Forces, Colonial Medical Service, Merchant Navy, &c.
2. Five years in general practice (or its equivalent) and an undertaking to accept postgraduate instruction for 3 days (or a corresponding number of hours) each year, or for $5^{1}/_{2}$ days every two years.
3. Five years in general practice (or its equivalent) and the possession of a higher postgraduate medical degree or diploma.

For foundation members the entrance fee will be ten guineas. Doctors who have not yet completed five years in general practice, and newly qualified men and women who contemplate entering general practice, are invited to join as foundation associates on payment of one guinea.[3] The foundation council of the college, which will receive these applications, will at first consist of the 10 members of the Willink Committee who are in general practice. In the New Year, after a circular letter has been sent to practitioners who are known or believed to be actively interested, this council will be enlarged to 21 and will proceed to draft provisional by-laws dealing, inter alia, with qualifications for ordinary membership and fellowship of the college. At a general meeting sometime in 1953, at which the by-laws will be presented, it will retire in favour of a new council; and at a second general meeting in 1954 the whole council will again retire and the constitution and by-laws will once more be re-examined.

So much for the machinery: what is the college going to be and do? It is to be "the headquarters of general practice in Great Britain"; it is to be "academic and educational, not political"; and, in supplementing (not competing with) the work of existing bodies, it is to provide "leadership of practitioners by practitioners." This leadership is to be both central and peripheral, and "one of the early duties of the college will be to establish regional faculties in the university cities and other large centres of population." In seeking the development of general practice on suitable lines it will consider and correlate the conclusions and proposals of the various committees and bodies that have concerned themselves with general practice and will plan and pursue an agreed policy. This will include encouragement of (1) the entry of practitioners into hospitals for more consultation and closer contact with specialists, (2) the restoration or establishment of general-practitioner beds where this is for the benefit of patients, and (3) direct access for all practitioners to laboratory and radiographic facilities; and the college will want its members to play their part in the development of health centres and clinics. Emphasis is rightly laid on the need to give medical students more understanding of practice, and it is thought that more liaisons could be arranged between medical schools and individual practitioners, on the lines of what has already been done successfully in several places.[4] To doctors newly entering practice advice on equipment might usefully be offered: "young men and women will be able to come to the college for help—perhaps as associates in their postgraduate year—to an academic home of their own, with a staff specially interested and experienced in their problems." The college might also have a contribution to make over trainee assistantships; and it would of course want to play a big part, with the universities and the British Postgraduate Medical Federation, in the arrangement of lectures and refresher courses for doctors established in practice, as well as perhaps sponsoring special lectures and exchanges of visits with colleagues overseas. The report pays close attention also to the possibilities of research by practitioners and speaks of a college research organisation which could aid individual doctors and study groups by advice or analysis of data: "ideas which arise from the problems of practitioners in their surgeries and in their patients' homes will, perhaps, become the inspiration of important and widespread investigations." In concluding their account of the functions that need to be performed, the writers add a statement on examinations, hypothetical and actual:

---

[1] *Lancet*, 1951, ii, 1071.

[2] The members were: The Rt. Hon. Henry Willink, Q.C. (chairman); Dr. G. F. Abercrombie; Prof. Ian Aird, F.R.C.S.; Dr. G. O. Barber; Mr. John Beattie, F.R.C.O.G.; Dr. D. M. Hughes; Dr. J. H. Hunt (hon. secretary); Sir Wilson Jameson, F.R.C.P.; Prof. J. M. Mackintosh, F.R.C.P.; Sir Heneage Ogilvie, F.R.C.S.; Dr. R. J. F. H. Pinsent; Dr. A. Talbot Rogers; Dr. F. M. Rose; Dr. Richard Scott; Dr. J. D. Simpson; and Dr. J. C. Young.

[3] Forms of application for foundation membership and associateship may be had from the secretary of the College of General Practitioners at 14, Black Friars Lane, Queen Victoria Street, London, E.C.4. The Society of Apothecaries is allowing the college the use of this address and has also offered accommodation for meetings.

> "A college should be able, before long, to improve the quality—the art and the skill—of general practice by setting a high standard and by encouraging and helping general practitioners to reach and maintain it, in the same way that the Royal Colleges have raised and maintained the standard of specialised practice. If, in the course of time, a diploma is to be granted by a College of General Practitioners it will in no way interfere with the present qualifying examinations. For those who have been long in practice it will probably be obtainable by election; but if for younger men and women an examination is to be held, later on, this will be in breadth rather than in depth, and only in those subjects which are of particular interest and importance to general practitioners in their daily work. It will always be only one of several portals of entry into the college."

Meanwhile it is believed that the very existence of a college will raise the status and enhance the prestige of the general practitioner among medical students, specialists, and the public.

We share that belief. At the same time it seems right to say that Mr. WILLINK and his associates would have made an even stronger case for their college had they emphasised the remoteness of much of present-day practice from what they lay down as ideal. In admiring their summary of what a family doctor should be, it would be wrong to forget that, as the years of this century have gone by, fewer and fewer practitioners have managed to coördinate the whole medical care of individual patients, let alone families. No doubt it is for diplomatic reasons that the list of 167 references excludes the Collings report,[5] but the main conclusion of that major document is among the strongest arguments in favour of what is now being undertaken. "The over-all state of general practice," said Dr. COLLINGS, "is bad and still deteriorating. The deterioration will continue until such time as the province and function of the general practitioner is clearly defined, objective standards of practice are established, and steps are taken to see that these standards are attained and maintained." The practitioner of today, COLLINGS held, is living *on* the tradition of the 19th-century family doctor; but, except in a minority of practices—most of them in the countryside—he has ceased either to be, or to follow the ideal of, the family doctor. All observers agree that this process has been going on for a very long time, and those of us who seriously want it to be reversed must be deeply thankful to see at last the beginning of a movement within the profession which may prove capable of reversing it. Only from within the profession can this sort of salvation begin; for it is simply not true that all our failures to do the best possible work arise from inevitable circumstance or the errors of politicians. In their penetrating study of the present situation of the profession, LEWIS and MAUDE[6] say bluntly:

> ". . . too many doctors are using the difficulties of the N.H.S. as an excuse for their own unwillingness to render the devoted service which a true profession demands of its practitioners. There are too many doctors who, without the excuse of an excessive list of patients, still rush through their cases with a minimum of time and trouble. There is not, despite all the superficial excuses which are adduced, the slightest real justification for being content to receive sick patients, year after year, in dirty and untidy consulting-rooms. . . . Finally, a doctor who acquiesces in a general agreement to pass on *all* but the simplest routine cases to a *hospital or a* specialist is deliberately leaving unused, and therefore allowing to decay, most of the fruits of a long and intensive training; he is wasting time and public money."

As the Willink Committee truly remark, "if a doctor is discouraged, there is no branch of medicine in which he can deteriorate more rapidly"; and no task is more urgent than to tackle the discouragement evident in so many practitioners and the sources from which it springs. The backing of all of us is needed for what the founders of this new college rightly term their "sincere attempt . . . to improve the efficiency and good name of general practice." We regard the foundation of the college as a powerful psychological fillip for a group of men and women too many of whom have lost heart; and we hope the day will soon come when the specialist will be spared the embarrassment of hearing some equally able colleague describe himself as "only a G.P." Specialist and practitioner alike, we shall do well to keep in mind always LEWIS and MAUDE's conclusion that the main strength of the profession lies in "the confidence of ordinary folk in the doctor's surgery."

Hepatitis

OUR knowledge of the viruses which affect man is still rudimentary; and we know particularly little about virus carriers. The new technique of tissue culture of the poliomyelitis virus has given new zest to work on this disease. Unfortunately this technique is not practicable with hepatitis viruses. These viruses probably multiply in fertile hen's eggs; but they do not give rise to pathognomonic lesions in them, nor do they reproduce themselves in sufficient quantity to provide an antigen for serological tests. The only way to be certain that the virus has grown in the eggs or is present in any form in man and his environment is to inoculate other people with the suspected material. Much can be learnt, however, from accurate observation of the behaviour of the disease, as CAPPS and his colleagues[7] [8] in Chicago have lately shown.

Asked to investigate jaundice in some nurses in an orphanage for infants and children under 3 years of age, they found that hepatitis had been endemic among the nurses for ten years, during which time 72 cases had been recognised. The source of their infection proved to be the infants and children in whom jaundice did not appear and hepatitis was not suspected.[8] Most of the affected nurses had been on duty on certain floors of the institution; and the clinical disease ceased to appear among them a few months after proper arrangements had been made for hand-washing and instructions given on personal hygiene and cleanliness. CAPPS and his associates [2] agree that in infants and young children the clinical picture of infectious hepatitis is relatively non-specific, and only those with clearly positive reactions to at least three different liver-function tests for four weeks or longer were accepted as having the disease; in most cases lassitude, gastro-intestinal disturbances, and hepatomegaly were also present. The validity of the diagnosis was thought to be confirmed by a positive result with a skin-test antigen made from infectious hepatitis virus grown in fertile hen's egg and inactivated by ultraviolet light.[9] Of 42 children who had a clinically recognised illness during twenty-two months of study, only 1 developed bilirubinæmia. The American workers admit they were applying strict criteria, and a very large number of other children classed as doubtful or asymptomatic showed some positive reactions for hepatitis. Isolation of suspected children had no effect in controlling the spread of the disease, presumably because so many infections were not clinically detectable at the onset; also some infants were incubating the disease when admitted. In over one-third of the children with clinical disease symptoms persisted for several months, and in these a positive skin test developed late—another example of tardy immunity to virus infection in very young people. The virus was recovered from the stools of 2 children who had been ill for five and fifteen months. CAPPS and his colleagues suggest that these 2 children were carrying the virus all this time; but reinfection or recent ingestion of the virus might have occurred in this orphanage. The minimum incubation period seemed to be 11–12 days—a shorter period than that usually reckoned for adults. Whether persistent infections with infectious hepatitis virus in childhood are common is still uncertain; but CAPPS et al.[7] raise the question whether the syndrome of infantile diarrhœa may occasionally be produced by this virus. In April, 1950, an epidemic of "infantile diarrhœa" broke out in the institution. Of the 14 affected infants, 12 gave positive skin tests two to three weeks after the onset of this illness (no tests were made before the onset).

Should an epidemic among infants and children be terminated? Perhaps it is well that they should develop immunity in early life if the disease is harmless to them; but can we be sure of this—especially in those with persistent symptoms. Several workers have described severe infectious hepatitis in young children. WYLIE and EDMUNDS,[10] for example, reported that of 12 cases in a London children's hospital, 2 had a delayed recovery, 4 had compensated cirrhosis, and 6 died eleven days to five years after onset with acute yellow atrophy or subacute necrosis plus multiple nodular hyperplasia. Several years ago STOKES and NEEFE [11] and HAVENS and PAUL [12] showed that gamma-globulin could be used to stop epidemics of infectious hepatitis in communities of children, and more recently STOKES et al.[13] have reported observations suggesting that, by some mechanism not yet understood, a single dose of gamma-globulin gave protection for five to nine months despite continued intimate exposure to continuing cases in uninoculated contacts.

When these methods fail, what have we to offer to the patient, young or old, to aid rapid recovery and prevent chronic hepatitis? Most clinicians agree that at present the best they can advise is bed rest and a palatable diet, with plenty of protein and carbohydrate and such fat as the patient can tolerate (though some think that there is a tendency to overwork the tired liver with too much protein). The new antibiotics do not appear to affect the acute process; but possibly in some instances coma or chronic hepatic disease may be controlled by inactivating the intestinal flora. Every new vitamin has been advocated in turn, and B_{12} is no exception. In a rough comparison between one diet with high protein, high carbohydrate, and moderate fat content, supplemented by multiple vitamins and brewer's yeast, and a second diet with high protein, high carbohydrate, and moderate fat content and the addition of 30 µg. of vitamin B_{12} by mouth for five days, the latter seemed to promote a more rapid return to normal appetite and liver size.[14] Further trial should perhaps be made of vitamin B_{12}, and also of cortisone and A.C.T.H.[15] which are known to increase appetite and consequently deposition of glycogen in the liver.

Radium Poisoning

THE dangers of ingesting radium or mesothorium are now recognised. This was not always so; and for a time after the first world war these substances were sometimes treated with a casualness that in retrospect seems shocking. 30 of the survivors from that light-hearted time have been sought out by a distinguished team from Boston and New York who describe in great detail the condition of these patients.[16] Now that the few radioactive elements found in the earth's crust are being supplemented by man-made materials, it is important to chronicle all the information that can be gathered about the long-term effects of radiation on the body.

A few of the patients in this American study were chemists or physicists working with radium or mesothorium; but most were engaged, in girlhood, in painting luminous dials. The risks of this occupation were made clear by H. S. MARTLAND as long ago as 1925. Luminous paint consists of zinc sulphide and a source of alpha particles, which may be either radium or mesothorium or a mixture of the two. Alpha particles striking the zinc sulphide emit flashes of light—a principle now used in scintillation counters for detecting and measuring sources of radioactivity. The mixture was applied to the dial by a paint-brush; and in order to obtain a fine point the girls used to moisten the brush between their lips, thereby ingesting substantial amounts of the radioactive material. In other instances radium or radium-mesothorium mixtures were taken medicinally. 5 patients in the series had consumed commercial nostrums containing radium and mesothorium, for the relief of such varied complaints as backache, low blood-pressure, arthritis, and thyrotoxicosis. Others had been given supposedly pure radium by injection as treatment for arthritis or lymphadenoma, or to aid recovery from pneumonia. Whatever the source, the material absorbed usually consisted of a mixture of radium and mesothorium, in proportions difficult to determine retrospectively. These two isotopes are treated identically by the body; but their decay products behave very differently. Radium, like calcium and strontium, is deposited in the inorganic lattice of bone. Its decay products also remain in the inorganic lattice, apart from the gas, radon, which is excreted in the breath (thereby providing the best method of diagnosing radium poisoning). Mesothorium, too, is deposited in the inorganic lattice of bone; but one of its decay products, radiothorium, tends to settle in the organic matrix of bone and possibly also in the soft tissues. This is especially dangerous since the alpha particles are then in a position to do more damage than they could, with their very limited range of action, when locked up in the less active parts of bone. Moreover, each atom of mesothorium retained in the body gives off, by successive transmutation, five alpha particles—about twice as many as the average for each fixed radium atom. Ingenious physical tests have shown the presence of mesothorium in patients previously thought to have been suffering from pure radium poisoning.

The clinical effects of radium-mesothorium poisoning are now reasonably well understood. The girls using the luminous paint remained free of symptoms until they had been working for one or more years; and symptoms might not appear until one to seven years after the last contact with the paint. The early manifestations were of two types: on the one hand rapid dental decay, followed by loss of teeth and necrosis of the jaw; and on the other hand progressive anæmia with leucopenia and thrombocytopenia. Those who escaped the anæmia, which was always lethal, were liable to the late consequences of having radioactive substances fixed in the bones. These again were of two types: either localised areas of necrosis in any of the bones, often with pathological fractures; or malignant tumours, derived either from the elements of bone (osteogenic sarcoma) or from neighbouring tissues (carcinoma of the nasal sinuses, fibrosarcoma of joints). The bone necroses have not themselves proved fatal, and there is even some indication that partial recovery may occur with time; all the late deaths have been due to malignant tumours. The syndrome of radium-mesothorium poisoning clearly depends on the chemical nature of the elements, which determines the localisation in bones, and on the type of radiation, which determines the amount of damage. Alpha particles, being most easily arrested in the tissues, do most damage per unit of radiation. The radium-mesothorium syndrome may be contrasted with the effects of an atomic-bomb explosion—although this would be complicated by the effects of blast and heat. HEMPELMANN et al.[17] have described what happened to 10 people who were accidentally exposed some years ago to a short intense outburst of fast neutrons and gamma radiation. About a week after exposure those affected developed severe constitutional symptoms with high fever, loss of weight, and gastro-intestinal disturbances; in addition there was gross damage to the more exposed areas of skin. One survivor developed bilateral cataracts three to five years after exposure. In those most severely affected all elements of the peripheral blood were impaired. The neutron bombardment induced radioactivity in elements already present in the body; but this induced radioactivity was thought to be insufficient to cause symptoms.

Exposure to external sources of radiation clearly has quite different effects from exposure to radioactive materials within the body. Basically radiations seem to act on tissues always in much the same way—by arresting mitosis they kill cells—but the clinical picture is diverse, since there are so many variables. Clinicians must be alert to the possibility of radiation damage in patients with unusual syndromes who have been exposed—even in the distant past—to radioactive materials.

Annotations

NO JUNIOR STAFF

To be fruitful the human mind must have time to pause and think. In England now we live lives in which there is little pausing and presumably less thinking. Routine housekeeping chores nowadays whittle down the spare time of most professional men and women in their homes; and even in hospital, as Dr. Ursula Paterson points out on p. 1225, the senior specialist cannot always hand over routine chores to a junior, for often there are no juniors to accept the charge.

A year ago, and again last April, we drew attention to this serious deficit in house-officers.[18] The hospitals most severely affected are mainly in the north, and in the periphery of the regions. Young men who want to specialise, or even young men who want to hear of a good opportunity in general practice, do better to stick to the central teaching hospitals of the region than to lose themselves in outlying parts, where they are apt to be overlooked. Young married men, returning from national service, are already anxious to find their places and settle down: they are in no mood to banish themselves from their homes for six months or a year to seek experience in a hospital which has slender links with a teaching unit. Yet these non-teaching hospitals, between them, deal with the bulk of the patients in the country; and in them, as Dr. Paterson points out, operating-lists are having to be curtailed because there are not the housemen, registrars, or junior anæsthetists to support the work of the surgeon.

It is not possible to say at present how great the deficit is, but this time last year the Manchester Regional Board alone had 157 unfilled vacancies among 570 junior medical posts. Registrars, senior house-officers, and house-officers were all needed, and the deficiency in the last two grades amounted to nearly a third of the total complement. Because their staffs are smaller, the small hospitals suffer more: a deficit of one where the whole staff is only three puts a heavy load on the two appointed. Prof. W. H. Wynn (p. 1225) forecasts a total deficit of 573 juniors in England and Wales next year for posts approved under the Medical Act of 1950, and a surplus in Scotland—available, as he says, for export—of 142. He points out that in teaching hospitals at present there is one resident to 15 beds; in non-teaching hospitals one to 103 beds.

---

[17] Hempelmann, L. H., Lisco, H., Hoffman, J. G. *Ann. intern. Med.* 1952, 36, 279.

[18] *Lancet*, 1951, ii, 973; *Ibid*, 1952, i, 705.

The compulsory year in hospital before registration, which comes into force next year, will doubtless make some difference, but it is generally doubted whether it will end the difficulty. The suggestion has been made that general practitioners could be engaged on a part-time basis to do what is needed; but these doctors, specialists in their own field, should not be expected to deputise for juniors, or to further burden their too-full lives with the routine tasks of their 'prentice days; and they cannot be continuously on call to deal with emergencies, or to give suddenly needed anæsthetics. Their services, too, are relatively (and justifiably) expensive.

A partial solution which we advocated a year ago still seems to us sound, and has already been accepted, at any rate in principle, in organising the nursing staffs of regional hospitals. If each of the outlying hospitals of a region was more closely affiliated to a teaching hospital, young doctors could take posts in such hospitals feeling that they were to some extent sponsored by their parent hospitals—which indeed might take the trouble to mantain special links with them by means of case-conferences, medical meetings, or other devices. Compared with residents in a teaching hospital these juniors would be getting in some ways better experience—more responsibility and a greater diversity of patients. Professor Wynn has two further suggestions to offer: that more use should be made of the hundreds of registrars who will never reach consultant status; and that the period of conscription should be reduced, for doctors, to a year, with the proviso that the second year should be spent in hospital. The Forces, however, have their own staffing difficulties; and to them the young doctor is much more valuable in his second than in his first year of service.

We agree with Professor Wynn that the civilian problem is urgent and requires serious discussion.

ANTHRAX

THE increase in anthrax among farm animals during the past few months was recently the subject of a question in the House of Commons,[1] and the danger of increased risk to man must of course be considered, even if this is not great. There are always a few cases of anthrax among animals in this country; and with the increase in imports of feeding-stuffs, notably bone-meal, it was likely that the incidence should rise. It has, in fact, been rising steadily for some months; in June, 31 new outbreaks were reported among animals, in July 90, in August 123, in September 170, in October 185, and in November a further 209; in all there have been 1051 outbreaks among animals in Great Britain since the beginning of this year. There is no reason to suppose at present that this has meant any increase in the incidence among humans.

Human anthrax is uncommon in Great Britain, though there is always a slight incidence among workers in the bone and hide trades; and dockers, knackers, and agricultural workers may all come into contact with infection at times. The Chief Inspector of Factories, in his report for 1950,[2] mentions that there were 36 cases in that year (with no deaths), as against 21 in 1949. Laboratory workers and students handling stained films of anthrax need to be reminded from time to time that staining does not kill the spores of this organism, and that there is risk in handling such slides. This warning should be given specially to technicians in commercial laboratories who are interested in imported foodstuffs, and making a special study just now of anthrax. These workers may be handling anthrax cultures for the first time, and may not be fully familiar with the precautions necessary for safety. Contamination with live anthrax from stained slides is a risk which must be taken seriously, and those handling cultures should be scrupulous in avoiding contamination of their cuffs, or any other part of their clothing, and in leaving their white coats behind them in the laboratory when they go to meals. The hazards of a bacteriologist's life are sufficient, without adding to them unnecessarily.[3]

The present increased infection among animals certainly derives from feeding-stuffs; but the bones of a single infected animal may contaminate a large quantity of material, and bacteriologists can only report on samples: if these happen to be negative it does not necessarily mean that the main bulk is free from anthrax spores. A negative result thus gives no grounds for a feeling of security. Doctors consulted about macules or vesicles, especially on the hands or face, should have anthrax in mind *at present*, and inquire into the recent history.

LOCAL CHEMOTHERAPY FOR TUBERCULOUS EMPYEMA

WIDER use of pneumothorax therapy and wider employment of chemotherapy and other methods are resulting in a diminishing incidence of tuberculous empyema. Pneumothorax, however, may still give rise to empyema, which occasionally also arises spontaneously. Furthermore, collections of tuberculous pus in the chest sometimes form after major operations—for example, in the Semb space after thoracoplasty, in extrapleural pneumothoraces, and even after plombage or resection. Aspiration and local chemotherapy are of value in treating some of these cases; but often pleurectomy, or surgical intervention to obliterate the infected space, proves necessary.

The substances injected with the object of thinning or sterilising the pus have included 20% sodium *p*-aminosalicylate, thiosemicarbazone, and chloroazodin; streptokinase and streptodornase have also been employed. Streptomycin, applied locally, has proved somewhat disappointing; this is partly because its action is hampered by hydrolytic products of the protein in the pus, and partly because empyema fluid has a neutral or slightly acid reaction (pH 6·8–7·0) whereas streptomycin acts best in a slightly alkaline medium (pH $\geq$ 7·8). This second difficulty has been overcome to some extent by alkalinising the pus; this is rinsed with 2–4% sodium bicarbonate solution or $^1/_{20}$ *N* sodium hydroxide solution buffered with $^1/_{20}$ *M* borax solution, or else a 25% sodium citrate solution is instilled daily. In most cases the increase in pH is only transient; but Posternak [4] maintained a pH of approximately 7·5 by injecting 2·5–4% polyvinyl alcohol buffered with 0·1% borax solution; and this gel also appeared to delay the absorption of streptomycin.

The use of a buffered gel as a vehicle has been further investigated by Ståhle [5] in Sweden. A previous observation by Berkman et al.[6] that 'Cellophane' membranes placed in an aqueous solution of 50 µg. streptomycin per ml. adsorbed up to 30% of the drug suggested that a depot effect in the empyema space might be obtained with streptomycin bound to substances of high molecular weight. Ståhle dispenses with intramuscular streptomycin in his technique: after preliminary aspiration through the second intercostal space anteriorly with a long needle (the patient lying horizontally) the pleura is thoroughly rinsed with normal saline solution ; 300 ml. of the vehicle is then instilled, and 0·5–1·0 g. streptomycin or dihydrostreptomycin is instilled either daily or on alternate days. Comparative experiments revealed, however, that with physiological saline as the vehicle the concentration of streptomycin, even with a daily dose of 1 g., remained surprisingly low, dropping from 2500 µg. per ml. to 50–100 µg. per ml. after forty-eight to seventy-two hours. With a 1% solution of sodium carboxymethyl cellulose ('Cellugel I') as the vehicle, the level was maintained at 500–600 µg. per ml. for about seven days, after which it slowly dropped to 400 µg. per ml. ; the same dose of dihydrostreptomycin yielded an even higher concentration. The pH of the pleural fluid when this gel was used remained about 6·8–7·0—no higher than that when 0·9% sodium chloride was employed—but the same gel, buffered with disodium phosphate (named 'Cellugel II'), maintained a pH of 7·8–8·0 during the whole ten-day period of treatment. (The gel was withdrawn and renewed at ten-day intervals.) Ståhle concludes that dihydrostreptomycin given in cellugel II in doses of 1 g. every second day ought to give a therapeutically optimal effect in the local treatment of tuberculous empyema.

The number of cases treated by Ståhle is small—only 8 in all, including 2 of the extrapleural type—but his results were encouraging. In all but one the result was satisfactory ; 2 which failed to respond to cellugel I later responded to the buffered solution, cellugel II. Before the treatment was terminated the pleural contents, when withdrawn, had to be grossly clear and less in amount than the solution injected ten days previously—that is, the tendency towards absorption had to predominate. In 7 of Ståhle's cases these criteria were fulfilled in ten to ninety (average thirty-six) days ; 1 patient with a persistent bronchopleural fistula failed to respond to the treatment. Ståhle obtained his most satisfactory results in cases of acute recent empyema ; chronic empyemata also responded, but he admits that " secondary surgical treatment is often required to close the pleural space." No ill effects were noted from the alkalinisation or from the cellulose gel itself. The main points are that an optimum pH of 7·8 can be achieved by using a buffered cellulose gel, which has the additional virtue of maintaining the effective chemotherapeutic agent at a high level in the empyema space ; and that in the pleural cavity, and probably elsewhere, dihydrostreptomycin is more effective locally than streptomycin.

HEALTH NEEDS OF THE GOLD COAST

ONE of the first acts of the new responsible government of the Gold Coast was to obtain the services of a commission of inquiry into the health needs of the colony. The commission reported last July[1] ; and the government have already issued a statement[2] in which they approve of the general policies of the commission and accept the majority of its recommendations. So the people have reason to look forward to a period of steady growth in their health services.

An introductory chapter shows that out of a total population of just over 4 million only 574 children are likely to pass the school-certificate examination in 1952, and that by 1960 this figure will have risen only to 1057. Comprehending the dependence of health on education, the commission have realistically fashioned their recommendations according to this educational background.

Malaria, tuberculosis, yaws, trypanosomiasis, leprosy, onchocerciasis, ankylostomiasis, schistosomiasis, and venereal diseases each presents important medical problems. The nutrition of large numbers of the people is unsatisfactory—from the Gold Coast indeed came the first descriptions of kwashiorkor. Ignorance of mother-craft is widespread throughout the colony ; and there are only 152 registered medical practitioners, of whom 89 are in government service. The government have accepted the proposal that the establishment be increased during the next five years to 150. Gold Coast students at present training in this country are too few to fill future vacancies, and overseas recruitment must continue. The number of medical students from the colony is not likely to reach even 20 a year ; and to start a school for such small numbers would be uneconomical. The government will make every endeavour to find places at medical schools in the United Kingdom for all studer qualified to enter and likely to be successful.

An important development is the recommendation f setting up 43 new health centres. These should buildings or groups of buildings suitably equipped a staffed to treat minor illnesses, to offer a limited materni and child-welfare service, and to instruct the local co munity in matters of health and hygiene. In gener the curative aspect of medicine should receive le emphasis than the preventive aspect ; and successf treatment should be a means of gaining the confiden of the people and of securing their coöperation in pr ventive and educational measures. These new heal centres will be under the general supervision of medic officers and will be integrated with the hospital service The person in direct charge of each, with the title clinic superintendent, will be a nurse of proven capacit who has been specially trained for the work. His sta will consist of at least a midwife and a sanitary inspector and it is hoped that in time trained health visitors wi be added. The government has accepted this recon mendation, but states it may not be possible to buil more than 10 centres in any one year.

At present there are 949 nurses on the register : 59 of these, mostly men, are in government service. Th commission consider that to provide normal replacement for these, and to staff new hospitals and extensions, a annual output of 150–175 nurses will be necessary. Thi is based on a ratio of 1 nurse to 2·5 beds. A majo problem, to which no clear-cut solution is offered, is the provision of a suitable number of sister-tutors. Equally important is the training of health visitors, who are needed to supervise the midwives and extend their work. There is a recommendation that the School of Hygiene at Accra should train 12 a year.

Much space is devoted to the question of providing an adequate water-supply. Comprehensive schemes involving a capital expenditure of £3½ million are recommended. This covers both piped supplies to the larger municipalities and the sinking of wells and the development of other small supplies. The principle that the supply of wholesome water should be paid for by the consumer is recognised.

Much of the report is taken up with administrative measures for reorganisation of the medical department. The distinctions between government and municipal functions in health matters are clearly set out. Means for the integration of the government medical services with those maintained by the mining companies are suggested, and a senior medical officer will be appointed for special duty in the mining areas. The recent government policy of assisting financially the work of medical missions is endorsed. In these matters, as in all else, the report provides precise guidance for all charged in any way with responsibility for health.

The success of all the commission's plans ultimately depends on those few hundreds of Gold Coast children who will reach school-certificate standard in the coming years. Could not an illustrated synopsis of this report be prepared which will fire their imaginations ?

TESTOSTERONE AND POSTOPERATIVE LIVER DAMAGE

THE danger of the liver being damaged by volatile anæsthetics has been appreciated since their early days. Before we knew something about the factors which affect the susceptibility of the liver to exogenous toxins, little could be done to prevent this damage, apart from avoiding gross overdosage. It is now firmly established, however, that depletion of the hepatic stores of protein and glycogen greatly increases this suceptibility, and the postoperative recovery of patients so depleted may be much improved by inducing a positive nitrogen balance before operation. However, great difficulties may arise in ensuring a suitable diet, either because of the distaste for food that often accompanies long-standing disease, or because of disease of the alimentary canal itself. The introduction of parenteral feeding with protein hydrolysates, with or without emulsified fat, has gone a long way towards overcoming these difficulties; but in the presence of malignant disease it may be hard to achieve a positive nitrogen balance even with large parenteral feeds. The anabolic effects of some of the steroid hormones, especially testosterone, have proved valuable in such cases.

Hayes et al.[1] have made a detailed metabolic study of 8 patients with œsophageal or gastric neoplasms which prevented feeding by mouth. The patients were men between the ages of 69 and 78, and they had lost from 13 to 28 lb. in weight. They all had a period of preoperative parenteral feeding (which included hydrolysed casein equivalent to about 51 g. of protein daily) during which the nitrogen balance was estimated. Daily intramuscular injections of 50 mg. of testosterone proprionate were given to 3 of them for seven days before operation and throughout the period of the investigation. The other 5 patients acted as controls. The effect of the hormone on protein anabolism was striking. Whereas a negative nitrogen balance persisted despite the parenteral feeding, the giving of testosterone was followed by nitrogen retention within twenty-four hours. This retention persisted throughout the experiment despite the katabolic effect of the operation itself. The corresponding retention of potassium supported the view that the nitrogen retention was actually due to protein formation. Hayes et al. also demonstrated the value of this preoperative treatment in raising the liver glycogen. For this purpose the rise in blood-sugar levels following a standard subcutaneous injection of adrenaline was taken as a measure of the hepatic glycogen reserve. A definite improvement was produced by parenteral feeding, and a further increase in the response to adrenaline followed doses of testosterone.

Liver-function tests were performed before and after operation, to study the effects of the improved protein and carbohydrate reserves of the liver upon its resistance to the stress of the operation and the anæsthetic. There was a sharp distinction between the testosterone-treated cases and the controls. Thus, the serum-bilirubin level, which remained within normal limits in all 3 treated cases, rose above normal in 4 of the 5 controls; bromsulphalein retention after forty-five minutes was less than 10% in all the treated group, and between 30% and 40% in the controls; and the twenty-four-hour excretion of urobilinogen, which remained normal in the testosterone group, was considerably raised in the 4 controls in which it was estimated.

Hayes et al. conclude from these impressive results that the anabolic effects of testosterone are of great value in the preoperative reinforcement of hepatic resistance. Of little less importance to the patient is the simultaneous increase in blood volume and plasma-protein, for this considerably reduces the subsequent risk of shock. They are careful to point out, however, that testosterone may reduce the sensitivity of the pituitary to stress, and delay the secretion of adrenocorticotropic hormone in response to the particular stress of the operation. In this way it may interfere with steroid homœostasis; but this effect may be controlled by regular eosinophil-counts, and by the intravenous administration of aqueous cortical extract when the count shows this to be necessary.

FAINTING

FAINTING is a dramatic event, a death in life. For some, perhaps unaware of what they are doing, this is an avenue of escape from fear, pain, or an unwanted situation. On the other hand, fainting has many purely physical causes. Usually it is accompanied by a decrease in blood-pressure which leads to cerebral anæmia and unconsciousness. In the erect position the force of gravity helps to drain blood from the head; whereas in recumbency loss of consciousness is less usual, though weakness, nausea, and other symptoms may be present. In the common vasodepressor type of syncope[1] the fall of blood-pressure is due, not to bradycardia, but to extreme dilatation of the vascular bed in the muscles, with constriction of skin vessels[2] and no compensatory increase in cardiac output, owing to diminished venous return. Barcroft and Edholm[2] clearly showed the central origin of these autonomic effects, since muscle vasodilatation in the arm was abolished in patients by forelimb sympathectomy, and in normal men by nerve-block. They also found evidence of active vasodilatation, as well as inhibition of constriction, in the blood-vessels concerned. Sometimes heart-block develops just before unconsciousness supervenes,[1] but although atropine prevents the heart-block it does not prevent the unconsciousness. If consciousness is lost for more than 15–20 seconds, and especially if the subject is kept erect, mild clonic convulsions may result.[1] During the period of unconsciousness, but not immediately before or immediately after it, electro-encephalography shows characteristic slow waves.[3] The causes of vasodepressor syncope include intense pain, great fear, neuroses, and occasionally hypersensitivity to cold.[1] Hæmorrhage can induce a similar type of faint; but in those accustomed to being bled it occurs, in the recumbent position, only after 15–20% of the normal blood volume has been removed.[4] Orthostatic hypotension may produce fainting which differs from the vasodepressor type in that the loss of consciousness is often unaccompanied by signs of general autonomic disturbance, such as sweating and pallor.[5] In this type there seems to be an imperfection of those vasoconstrictor reflexes normally activated by pooling or shunting of blood. The condition may be temporary with illness or exhaustion; it is seen in diabetes mellitus[6]; and it may be an inborn inadequacy.

Cardiac asystole is a less common and more serious cause of fainting. Asystole, which is often unheralded,[1] may occur in the Stokes-Adam syndrome or from stimulation of nerve-fibres linked with the cardio-inhibitory part of the vagus nerve—for example, by pressure on the carotid sinus from turning the head or wearing a tight stiff collar. In paroxysmal tachycardia the cause of fainting seems to be cardiac standstill at the beginning or end of the paroxysm, and not a reduction in cardiac output.[7] Death may result if asystole persists. Another cause of fainting is an increase in intrathoracic pressure so that venous return to the heart is seriously impeded. This type of faint may follow violent bouts of coughing (the so-called laryngeal epilepsy [8]); it may also take place in cases of emphysema or of tumours obstructing the trachea. As entertainment it is induced with mistaken lightheartedness by school-children and Servicemen [9] by the simple device of taking a deep breath, closing the glottis, and allowing the thorax to be compressed. The loss of consciousness that occurs in major and minor epileptic attacks is of cerebral origin. Finally, hyperventilation is a fruitful source of fainting. It may occur with exertion in the presence of a failing heart, in states of anxiety, and in hysterical subjects. The mechanism seems to be that the changed blood chemistry so alters brain metabolism, as reflected in electroencephalography,[10] that the vasodepressor reflex is facilitated.

For treatment of repeated fainting correct diagnosis is essential; and for this careful history-taking is important. The subjects of hysterical faints often show no anxiety at their condition, and during the faint the blood-pressure, skin colour, and electroencephalogram remain normal.[11] In most instances the treatment of a faint, particularly an isolated one, is simple—namely, to keep the patient recumbent and prevent him from standing too soon or too rapidly.

BEHAVIOUR UNDER STRESS

IN an Ernest Jones lecture, under the auspices of the British Psycho-Analytical Society, on Dec. 1, Prof. Roger W. Russell spoke of behaviour under stress. He explained his approach by citing some words of Dr. Ernest Jones [12]:

> "The limits bounding the field of knowledge studied by various scientific societies are often jealously drawn, and it is unfortunately not a very frequent event for such a society to show any desire to coöperate with another one. Yet the advantages of interchange of ideas among workers in neighbouring fields are undeniable, and many examples could be given of suggestions proffered by an investigator in one branch of knowledge proving exceedingly fruitful on being taken up and developed by someone whose main concern is with some other branch."

One basic characteristic of life, said Professor Russell, was its constant adjustment to environmental forces. Some forms of adjustment were age-long, concerned with the survival of species or civilisations; others momentary, affecting the response of a given organism at one particular instant. Such adjustive processes occurred in all the organism's activities, from its metabolic functions to its behavioural responses to environmental stimuli. Through all this range homœostasis [13] was aimed at; and if adjustment was not possible, disorganisation ensued.

The concept of stress, borrowed from the physicists, was useful for the analogies it provided between the strain undergone by physical objects from environmental stress, which within certain limits of elasticity was only temporary but beyond those limits resulted in permanent distortion, and the effects of environmental stimuli on the living organism, which also, beyond certain limits of adjustment, caused disorganisation. In organisms capable of responding to symbols which had come to represent environmental forces, response might take the form of symbolic behaviour, such as thought, so that little or no overt response might be observable. Adjustive processes broke down in two situations: when the organism encountered a stress which it had not the skill or capacity to surmount (frustration); and when two or more incompatible response-tendencies competed with one another, preventing suitable adjustment (conflict). In man conflict was the rule rather than the exception when decisions had to be made. In conflict situations disorganisation resulted in three ways. In the first the subject had impulses both to approach and simultaneously to avoid the same goal—the so-called "approach-avoidance" situation, exemplified by the hen-pecked husband who thirsted for a visit to the "local" but feared his wife's reprisals. The second—the "avoidance-avoidance" situation—was shown by the patriotic soldier who feared to advance because of danger from the enemy and also feared to retreat because of being called a coward by his comrades. The third—the "double approach-avoidance" situation—was the dilemma of Buridan's ass, which starved to death midway between two bales of hay, unable to make up its mind to move further away from either.

The effects of stress on the behaviour of animals had been extensively studied during the past fifty years. Disorganisation of behaviour under stress had been observed in species widely scattered throughout the phylogenetic scale. Research technique in this branch of experimental psychopathology had first been put on a sound basis by Pavlov [14] with his description of the "experimental neurosis" of dogs in conditioned-response studies. Professor Russell cited from the wealth of research the work of Masserman [15] on cats, which in situations of conflict between desire for food and fear of a noxious stimulus showed regressive and "neurotic" behaviour, and that of Maier [16] on rats, which in a situation of insoluble choice showed fixation of behaviour and became incapable of learning to solve a fresh, soluble problem even after hundreds of attempts.

Behaviour under stress had also been studied in children, both normal [17] and neurotic and delinquent [18]; such researches should lead to a better understanding of the part played by stress in human development. Many studies had been made of the effects of stress on adult behaviour, especially as regards skilled performance. One study of pilot error [19] showed that breakdown under stress was preceded either by a progressive decrease in precision, or by precision maintained by increasingly rapid, small, corrective movements. In another experiment [20] adults subjected to the stress of an insoluble choice situation, such as had produced fixated behaviour in Maier's rats, showed their frustration by aggressive, regressive, resigned or stereotyped responses. Some subjects reported that they found themselves compelled to go on making the same choice, although they knew it was wrong.

Professor Russell also referred to work being done in neurophysiology, in psychosomatic medicine, and in experimental genetics. He hoped that psycho-analysts would be impressed, as he was, by the important contributions towards understanding behaviour under stress which were being made by workers in many different fields: physiologists, zoologists, anthropologists, psychologists, and psychiatrists.

This lecture, as Prof. J. C. Flugel remarked, was encouraging to all who hoped for a rapprochement between psycho-analysis and academic psychology and other branches of science. Certainly coöperation between workers in these fields should be especially fruitful amid the stress of our atomic age.

Reconstruction

HOSPITAL STATISTICS

FROM A CORRESPONDENT

ONE of the responsibilities that the Ministry of Health assumed at the appointed day was the publication of hospital statistics on a national basis. In the press of launching the National Health Service the Ministry was, understandably, too occupied in other directions to give much attention to this matter, but now it is doing its best to catch up with events. The review of the *Statistics of the Hospital and Specialist Services for England and Wales* for 1949 was issued last June.[1] The review for 1950 has just appeared[2]; and the review for 1951 is promised before the end of the year. Thereafter it is hoped, says the Ministry, to issue the figures "by the middle of the year following the one to which they relate."

STATISTICAL PURPOSES

These reviews cover staff, beds, and patients. They do not deal with the finance of the hospital services, which is covered by the *Hospital Costing Returns*.[3] The separation of the statistical report from the financial report may be inevitable; but at first sight it seems a pity. The hospitals had become accustomed to the presentation of the two sides in the King's Fund's tables and in the *Hospitals Year Book* in a form in which simple comparisons of cost could be made at a glance. The separation will not, however, be all loss if a separate statistical return gives us a clearer idea of what statistics are really needed as a guide to hospital policy.

Hospital statistics have two main purposes; they may be used as an aid to hospital administration, enabling those managing one hospital to see how another hospital of comparable scale saves either pence or pairs of hands; or they may be used, much as the statistics accompanying the *Hospital Surveys* were used, as data for the consideration of the wider questions of hospital policy. Unfortunately these reviews are not well adapted for either of these purposes. But the Ministry has not had an easy task. It took over their publication at a time when the old approach to hospital statistics was already felt to be obsolete or, more accurately, incomplete, but before any new conception of what is really needed had been formulated to take its place.

Historically hospital statistics in this country sprang from the desire of hospital authorities to compare notes, and the need to satisfy the public that the volume of work done by one hospital did not compare unfavourably with others where the expenditure was roughly comparable. Much was taken for granted; it was assumed that all the beds and other facilities were needed, that there lay ahead, on all hands, a great need that could never be met—as the Book of *Ecclesiasticus* would have put it, that hospital work was as a sandy hill to the feet of the aged. The fundamental idea was to allow one hospital to be compared with another, and hospitals were as far as possible listed in comparable groups according to type, size, and so forth. The tables with which we were familiar thus grew up—bed complement, occupancy, totals of new outpatient attendances, and so on. Sometimes to supplement these data lists of medical, nursing, and other staff were added.

WHAT THE MINISTRY OFFERS

The first and main set of figures in the Ministry series of tables are in this tradition. The hospitals are classified in large categories, rather like those used formerly by the larger local authorities, and arranged in decreasing order of size according to the number of occupied beds.

Thus we find at the top of the list Walton Hospital, Liverpool, with a bed complement of 1351; 1200 beds available, 1032 being the average daily bed occupation during 1950; 15,728 inpatients died or discharged during 1950; 24,098 new outpatients during 1950; 83,549 outpatient attendances; 5 consultants, 2 senior hospital medical officers, 7 senior registrars, 10 registrars, 23 junior medical staff, 2 other medical staff, no dental staff, 2 almoners, 2 caterers, 2 dispensers, 2 engineers, 11 laboratory technicians, 1 occupational therapist, 3 pharmacists, 12 physiotherapists, no psychiatric social workers, 10 radiographers, 1 biochemist, 2 chaplains, 56 maintenance and transport workers and tradesmen and craftsmen, 8 male staff-nurses, 75 female staff-nurses and 23 part-time female staff-nurses, 35 male student nurses, 247 female student nurses, 14 female enrolled assistant nurses and 12 part-time enrolled assistant nurses, 21 staff midwives, 13 pupil midwives, 2 domestic-staff supervisors, 3 food supervisors, 1 kitchen superintendent. 13 cooks and assistant cooks, 13 ward orderlies and attendants, 409 other domestic staff, and 79 laundry staff.

Some helpful changes have been made in the figures for 1950, compared with those for 1949, and it would be useful if future compilers would add a note explaining any changes made. There are rumours of improvements about to be made in the official statistical return known as S.H.3., which will help to correct some of the inaccuracies and anomalies which lurk behind the present returns.

Among so many data students of the hospital service will find much of interest; and since this is presumably the best material available it is better that the Ministry should publish it than that it should be locked away in the archives. Thus it is easy to pick out hospital A, compare it with hospital B, and notice how anomalous such and such items appear to be; but such reflections do not take one far. At their worst data of this kind can be grossly misleading, and official quotations about unstaffed beds and waiting-lists would afford a rich quarry for anyone who wished to show how defective such material is.

REGIONAL FIGURES

In salute to the existence of regions summarised information is given about each regional board and teaching hospital. Beds allocated, waiting-lists, discharges or deaths during the year, new outpatients during the year, total attendances, and weekly number of clinic sessions are shown for general medicine, general surgery, and some twenty-seven other specialties. Information is also given about other departments such as the numbers of auxiliaries in pathological departments, physiotherapy departments, and so forth.

Here is the beginning of what is badly needed and what was lacking in the old hospital statistics—an attempt at subdivision into medical categories. But unfortunately the handling of this part follows the traditions devised for the presentation of morbidity statistics, and shows no appreciation of any new approach adapted to evolving hospital needs. These large figures lumped into totals, a page of figures sufficing for a whole region, and unaccompanied by any comment tell little compared with what we could be told. For comparative statistical purposes the region is too large, and the significant variations for which we are all looking are largely lost. Each hospital management committee (or group of several in a large city) needs to be examined separately. The figures in this section of the reports are no more than a glimpse of material on its way into the calculating machine for the National Health Service statistics.

TRENDS

The reports thus contain two main sets of figures: the more detailed set is based on the already more than half obsolete hospital approach; while the other set—the only figures related to the new conceptions of planned hospital services—is so highly summarised as to lose much of its practical value.

To launch these reports as the best that we can do is to admit failure, so far, to come to grips with the statistical

heart is seriously impeded. This type of faint may follow violent bouts of coughing (the so-called laryngeal epilepsy [8]); it may also take place in cases of emphysema or of tumours obstructing the trachea. As entertainment it is induced with mistaken lightheartedness by school-children and Servicemen [9] by the simple device of taking a deep breath, closing the glottis, and allowing the thorax to be compressed. The loss of consciousness that occurs in major and minor epileptic attacks is of cerebral origin. Finally, hyperventilation is a fruitful source of fainting. It may occur with exertion in the presence of a failing heart, in states of anxiety, and in hysterical subjects. The mechanism seems to be that the changed blood chemistry so alters brain metabolism, as reflected in electroencephalography,[10] that the vaso-depressor reflex is facilitated.

For treatment of repeated fainting correct diagnosis is essential; and for this careful history-taking is important. The subjects of hysterical faints often show no anxiety at their condition, and during the faint the blood-pressure, skin colour, and electroencephalogram remain normal.[11] In most instances the treatment of a faint, particularly an isolated one, is simple—namely, to keep the patient recumbent and prevent him from standing too soon or too rapidly.

BEHAVIOUR UNDER STRESS

IN an Ernest Jones lecture, under the auspices of the British Psycho-Analytical Society, on Dec. 1, Prof. Roger W. Russell spoke of behaviour under stress. He explained his approach by citing some words of Dr. Ernest Jones [12]:

> "The limits bounding the field of knowledge studied by various scientific societies are often jealously drawn, and it is unfortunately not a very frequent event for such a society to show any desire to coöperate with another one. Yet the advantages of interchange of ideas among workers in neighbouring fields are undeniable, and many examples could be given of suggestions proffered by an investigator in one branch of knowledge proving exceedingly fruitful on being taken up and developed by someone whose main concern is with some other branch."

One basic characteristic of life, said Professor Russell, was its constant adjustment to environmental forces. Some forms of adjustment were age-long, concerned with the survival of species or civilisations; others momentary, affecting the response of a given organism at one particular instant. Such adjustive processes occurred in all the organism's activities, from its metabolic functions to its behavioural responses to environmental stimuli. Through all this range homœostasis[13] was aimed at; and if adjustment was not possible, disorganisation ensued.

The concept of stress, borrowed from the physicists, was useful for the analogies it provided between the strain undergone by physical objects from environmental stress, which within certain limits of elasticity was only temporary but beyond those limits resulted in permanent distortion, and the effects of environmental stimuli on the living organism, which also, beyond certain limits of adjustment, caused disorganisation. In organisms capable of responding to symbols which had come to represent environmental forces, response might take the form of symbolic behaviour, such as thought, so that little or no overt response might be observable. Adjustive processes broke down in two situations: when the organism encountered a stress which it had not the skill or capacity to surmount (frustration); and, when two or more incompatible response-tendencies competed with one another, preventing suitable adjustment (conflict). In man conflict was the rule rather than the exception when decisions had to be made. In conflict situations disorganisation resulted in three ways. In the first the subject had impulses both to approach and simultaneously to avoid the same goal—the so-called "approach-avoidance" situation, exemplified by the hen-pecked husband who thirsted for a visit to the "local" but feared his wife's reprisals. The second—the "avoidance-avoidance" situation—was shown by the patriotic soldier who feared to advance because of danger from the enemy and also feared to retreat because of being called a coward by his comrades. The third—the "double approach-avoidance" situation—was the dilemma of Buridan's ass, which starved to death midway between two bales of hay, unable to make up its mind to move further away from either.

The effects of stress on the behaviour of animals had been extensively studied during the past fifty years. Disorganisation of behaviour under stress had been observed in species widely scattered throughout the phylogenetic scale. Research technique in this branch of experimental psychopathology had first been put on a sound basis by Pavlov [14] with his description of the "experimental neurosis" of dogs in conditioned-response studies. Professor Russell cited from the wealth of research the work of Masserman [15] on cats, which in situations of conflict between desire for food and fear of a noxious stimulus showed regressive and "neurotic" behaviour, and that of Maier [16] on rats, which in a situation of insoluble choice showed fixation of behaviour and became incapable of learning to solve a fresh, soluble problem even after hundreds of attempts.

Behaviour under stress had also been studied in children, both normal [17] and neurotic and delinquent [18]; such researches should lead to a better understanding of the part played by stress in human development. Many studies had been made of the effects of stress on adult behaviour, especially as regards skilled performance. One study of pilot error [19] showed that breakdown under stress was preceded either by a progressive decrease in precision, or by precision maintained by increasingly rapid, small, corrective movements. In another experiment [20] adults subjected to the stress of an insoluble choice situation, such as had produced fixated behaviour in Maier's rats, showed their frustration by aggressive, regressive, resigned or stereotyped responses. Some subjects reported that they found themselves compelled to go on making the same choice, although they knew it was wrong.

Professor Russell also referred to work being done in neurophysiology, in psychosomatic medicine, and in experimental genetics. He hoped that psycho-analysts would be impressed, as he was, by the important contributions towards understanding behaviour under stress which were being made by workers in many different fields: physiologists, zoologists, anthropologists, psychologists, and psychiatrists.

This lecture, as Prof. J. C. Flugel remarked, was encouraging to all who hoped for a rapprochement between psycho-analysis and academic psychology and other branches of science. Certainly coöperation between workers in these fields should be especially fruitful amid the stress of our atomic age.

Reconstruction

HOSPITAL STATISTICS

FROM A CORRESPONDENT

ONE of the responsibilities that the Ministry of Health assumed at the appointed day was the publication of hospital statistics on a national basis. In the press of launching the National Health Service the Ministry was, understandably, too occupied in other directions to give much attention to this matter, but now it is doing its best to catch up with events. The review of the *Statistics of the Hospital and Specialist Services for England and Wales* for 1949 was issued last June.[1] The review for 1950 has just appeared[2]; and the review for 1951 is promised before the end of the year. Thereafter it is hoped, says the Ministry, to issue the figures "by the middle of the year following the one to which they relate."

STATISTICAL PURPOSES

These reviews cover staff, beds, and patients. They do not deal with the finance of the hospital services, which is covered by the *Hospital Costing Returns*.[3] The separation of the statistical report from the financial report may be inevitable; but at first sight it seems a pity. The hospitals had become accustomed to the presentation of the two sides in the King's Fund's tables and in the *Hospitals Year Book* in a form in which simple comparisons of cost could be made at a glance. The separation will not, however, be all loss if a separate statistical return gives us a clearer idea of what statistics are really needed as a guide to hospital policy.

Hospital statistics have two main purposes; they may be used as an aid to hospital administration, enabling those managing one hospital to see how another hospital of comparable scale saves either pence or pairs of hands; or they may be used, much as the statistics accompanying the *Hospital Surveys* were used, as data for the consideration of the wider questions of hospital policy. Unfortunately these reviews are not well adapted for either of these purposes. But the Ministry has not had an easy task. It took over their publication at a time when the old approach to hospital statistics was already felt to be obsolete or, more accurately, incomplete, but before any new conception of what is really needed had been formulated to take its place.

Historically hospital statistics in this country sprang from the desire of hospital authorities to compare notes, and the need to satisfy the public that the volume of work done by one hospital did not compare unfavourably with others where the expenditure was roughly comparable. Much was taken for granted; it was assumed that all the beds and other facilities were needed, that there lay ahead, on all hands, a great need that could never be met—as the Book of *Ecclesiasticus* would have put it, that hospital work was as a sandy hill to the feet of the aged. The fundamental idea was to allow one hospital to be compared with another, and hospitals were as far as possible listed in comparable groups according to type, size, and so forth. The tables with which we were familiar thus grew up—bed complement, occupancy, totals of new outpatient attendances, and so on. Sometimes to supplement these data lists of medical, nursing, and other staff were added.

WHAT THE MINISTRY OFFERS

The first and main set of figures in the Ministry series of tables are in this tradition. The hospitals are classified in large categories, rather like those used formerly by the larger local authorities, and arranged in decreasing order of size according to the number of occupied beds. Thus we find at the top of the list Walton Hospital, Liverpool, with a bed complement of 1351; 1200 beds available, 1032 being the average daily bed occupation during 1950; 15,728 inpatients died or discharged during 1950; 24,098 new outpatients during 1950; 83,549 outpatient attendances; 5 consultants, 2 senior hospital medical officers, 7 senior registrars, 10 registrars, 23 junior medical staff, 2 other medical staff, no dental staff, 2 almoners, 2 caterers, 2 dispensers, 2 engineers, 11 laboratory technicians, 1 occupational therapist, 3 pharmacists, 12 physiotherapists, no psychiatric social workers, 10 radiographers, 1 biochemist, 2 chaplains, 56 maintenance and transport workers and tradesmen and craftsmen, 8 male staff-nurses, 75 female staff-nurses and 23 part-time female staff-nurses, 35 male student nurses, 247 female student nurses, 14 female enrolled assistant nurses and 12 part-time enrolled assistant nurses, 21 staff midwives, 13 pupil midwives, 2 domestic-staff supervisors, 3 food supervisors, 1 kitchen superintendent, 13 cooks and assistant cooks, 13 ward orderlies and attendants, 409 other domestic staff, and 79 laundry staff.

Some helpful changes have been made in the figures for 1950, compared with those for 1949, and it would be useful if future compilers would add a note explaining any changes made. There are rumours of improvements about to be made in the official statistical return known as S.H.3., which will help to correct some of the inaccuracies and anomalies which lurk behind the present returns.

Among so many data students of the hospital service will find much of interest; and since this is presumably the best material available it is better that the Ministry should publish it than that it should be locked away in the archives. Thus it is easy to pick out hospital A, compare it with hospital B, and notice how anomalous such and such items appear to be; but such reflections do not take one far. At their worst data of this kind can be grossly misleading, and official quotations about unstaffed beds and waiting-lists would afford a rich quarry for anyone who wished to show how defective such material is.

REGIONAL FIGURES

In salute to the existence of regions summarised information is given about each regional board and teaching hospital. Beds allocated, waiting-lists, discharges or deaths during the year, new outpatients during the year, total attendances, and weekly number of clinic sessions are shown for general medicine, general surgery, and some twenty-seven other specialties. Information is also given about other departments such as the numbers of auxiliaries in pathological departments, physiotherapy departments, and so forth.

Here is the beginning of what is badly needed and what was lacking in the old hospital statistics—an attempt at subdivision into medical categories. But unfortunately the handling of this part follows the traditions devised for the presentation of morbidity statistics, and shows no appreciation of any new approach adapted to evolving hospital needs. These large figures lumped into totals, a page of figures sufficing for a whole region, and unaccompanied by any comment tell little compared with what we could be told. For comparative statistical purposes the region is too large, and the significant variations for which we are all looking are largely lost. Each hospital management committee (or group of several in a large city) needs to be examined separately. The figures in this section of the reports are no more than a glimpse of material on its way into the calculating machine for the National Health Service statistics.

TRENDS

The reports thus contain two main sets of figures: the more detailed set is based on the already more than half obsolete hospital approach; while the other set—the only figures related to the new conceptions of planned hospital services—is so highly summarised as to lose much of its practical value.

side of national hospital planning. When for the old medley of hospital services we substituted the new era of regional boards and hospital management committees on a geographical basis, and a planned spread of medical staff considered carefully category by category, we took an immense stride forward. But have we yet devised at the centre a statistical approach to help forward this new world? It is urgent that a new concept of national hospital statistics to match the new, and often very successful, planning that is going on should be worked out and brought into use before the present approach hardens into a routine. Large changes are now taking place in the use to which hospital beds are being put. Pressure on children's wards is, for example, already much lighter; pressure on medical beds is responding to the new drugs; the problem of the chronic sick is yielding to a more vigorous approach; pressure in the mental hospitals has perhaps passed its peak; and before long the need for tuberculosis beds may slacken. Trends of this kind are all-important in planning hospital services; and national statistics must be designed to show what effect they are having upon allocations of beds, area by area, and where we may expect to have to expand or retract to meet a changing situation.

It is fortunate that the regional boards are there to deal with the impact of this revolution in medicine on the hospital services. Could they not also be asked to submit to the Ministry their own arrangement of statistics and accompanying observations, for publication by the Ministry in a single volume together with reports from the boards of governors of teaching hospitals? Some of them have been trying to show graphically what is really happening. It would be necessary only to insist on a minimum of agreed definitions and formulæ to enable the reader to pass from region to region. It is too soon—and indeed it would be a mistaken policy at this stage—to expect a complete uniformity of approach. Figures derived as we have suggested, and accompanied by brief explanations by the officers of the boards, would show the enormous improvement in our hospital services of which we have every reason to be proud, but about which we have little accurate information. It would, too, help to create a knowledgeable public opinion which will allow the Government to consider realistically whether further expenditure on the hospital services is necessary, or whether the time will soon come to curb the expansionist tendencies which we have inherited from the past.

Special Articles

TWO YEARS' EXPERIENCE

A SCHOOL OF SPEECH THERAPY

DEFECTS of speech arise from many causes, and are often associated with much hampering frustration and anxiety. For these reasons children so afflicted cannot easily be treated in outpatient departments. Dr. C. Worster-Drought and his colleagues in the department of speech disorders, which has been in action at the West End Hospital for Nervous Diseases since 1914, decided a few years ago to found a residential school of speech therapy. This would serve, they thought, as an inpatient department where children with such defects could be admitted for accurate diagnosis and treatment, while at the same time going on with their general education. The project was made possible by the gifts of anonymous donors, and a report[1] on the first two years of work at Moor House School has now appeared.

Dr. Worster-Drought, who has edited it, finds that most of the children referred either to the hospital department or the school fall into seven main groups: mental defectives; those with congenital or infantile deafness; maladjusted, psychoneurotic, or prepsychotic children; those with neurological disorders such as cerebral diplegia, bilateral athetosis, congenital hemiplegia, and bulbar poliomyelitis; various forms of juvenile aphasia; functional disturbances such as dyslalia and stammering; and mechanical defects such as cleft palate and dental abnormalities. Not all these types of case are suitable for treatment in the school, and recently a diagnostic unit has been established there to study each child admitted and refer those who are unsuitable to appropriate centres.

It is found, for instance, that children with an intelligence quotient (I.Q.) below about 80 cannot profit from the training given in the school. Deaf children, whether the defect is partial or of the high-frequency type, though they may be admitted temporarily for diagnosis, are ordinarily sent on to suitable deaf schools. Psychoneurotic and prepsychotic children, too, respond poorly to the treatment offered and can seldom be retained. Dyslalia and stammering can usually be treated successfully from the outpatient department, and are admitted to the school only if they fail to respond; the results have then been satisfactory. Those with mechanical difficulties such as cleft palate do well in the school, even though training may be interrupted by operations.

DEFECTS OF EXECUTION

The children admitted are classified into two groups: those with executive speech defects, referred to as E cases; and those with receptive speech disorders having difficulty in comprehending ordinary spoken speech (R cases). These two groups naturally need different kinds of training.

The E cases, after being allowed to settle down for a few days, are given a thorough physical examination which includes the anatomy and physiology of the speech organs. Speech is assessed, hearing tested, and personality, temperament, and intelligence observed. Every child has an audiometric test to exclude partial deafness. Of 29 E children admitted during the two years, 25 had normal hearing. Slight general deafness was found in 4, 3 being cases of cleft palate and 1 a case of bulbar poliomyelitis.

In all cases of disordered articulation, the speech therapist analyses the speech sounds, transcribes them phonetically, and then encourages the child to produce the missing sound from the nearest existing phonetic sound by imitation or from kinæsthetic memory. Pictures are used to keep his interest up, and as he becomes more expert in producing the correct sounds the staff—who up to now have been at pains to understand him, even at his most unintelligible—begin to look uncomprehending when he gets a word wrong. They do not, however, fall into what Dr. Worster-Drought calls the common fallacy of correcting every mistake the moment he makes it: "such a method defeats its own ends by producing anxiety."

By this time the child is using his newly acquired speech habits confidently among his familiar company, though he will not as yet make conversation with strangers; so he is taken out shopping, makes inquiries at the station, and attends tea-parties. Friendly tradespeople and neighbours willingly help at this time. He joins a "talks club" at school, helps to make puppets and supply them with dialogue, and speaks on a home-made broadcasting system. Progress is assessed not only by phonetic records but by letting the child make gramophone records at intervals, and these have the further advantage that the children like to hear them and criticise their own performance.

Apart from speech training, the children are taught other school subjects including reading, arithmetic (in which they are all backward), music, art and handiwork, gardening, and general knowledge. During the two years under review 7 of the original 28 E cases were discharged with improved speech, 9 were making satisfactory progress, 8 were discharged as unlikely to benefit further, and 4 left for other reasons.

DEFECTS OF RECEPTION

The 36 R-group children admitted during the two years presented quite different problems. They were difficult to test by audiometry, and it was assumed that they were unable to appreciate and retain the auditory image of what they heard—to be, in fact, cases of congenital auditory imperception. Some were found to be trying to get a *visual* image by lip-reading, and could use a few isolated words learnt in this way; otherwise they used pantomime, and noises indicative of anger or pleasure. As it turned out, no fewer than 27 of them had been unable to learn to speak because of deafness, either generalised or of the high-frequency type. Only 1 proved to be a case of congenital auditory imperception.

---

[1] Residential Speech Therapy. London: Heinemann Medical Books. 1952. Pp. 150. 15s.

This boy was given special training by means of a "sound alphabet" devised by Dr. W. F. Coningsby: he was taught to copy a sound, as "b-b-b-b," and to end with an explosive shout of a word, such as "bottle." He was helped in this by pictures and by the example of the speech therapist, and he is now able to follow directions and to converse in telegraphic sentences.

The rest of the children in this group, however, have been taught on the lines accepted for the teaching of deaf and partially deaf children. Of the original 36, 4 have been discharged as improved, 9 have been recommended for training in schools for the deaf, 14 were found to be unsuitable for training in the school, either because of mental defect or severe maladjustment, and 4 left for other reasons; 4 of the remaining 5 are making satisfactory progress.

FUTURE PROSPECTS

The school seems as yet to be known to relatively few local education authorities. Up to now the governors have accepted children between the ages of five and eleven, but in the future they hope to take an additional 11 children between the ages of eleven and sixteen. This will enable some of the children already in the school to stay on, but there will be places for several others. One of the most valuable services the school can offer is accurate diagnosis of cases of defective reception, for no effective treatment can be given until the cause is clearly established. Cases of congenital auditory imperception, though rare, are greatly in need of special training; and a scheme is being considered for treating cases of alexia and dyslexia, for which at present no adequate treatment is available. This condition is not at all uncommon, though it is often overlooked or mistaken for mental defect. To pursue this work, and the research which is inseparable from it, and to extend its staff and premises, Moor House School needs more funds than are provided by the fees paid by local authorities. Many benefactors have already contributed to the work, and Dr. Worster-Drought is in hope that their numbers will increase. The school is at Hurst Green, Oxted, Surrey.

KING EDWARD'S HOSPITAL FUND FOR LONDON

PRESIDING over the general council of the Fund on Dec. 9 the Duke of GLOUCESTER said that during the last two years grants to hospitals and convalescent homes had amounted to £342,119. In addition £100,000 had been set aside for homes for the aged sick, bringing the total allocation for that purpose in recent years to £350,000. During these years the management committee had been reviewing policy in the light of reports made to them on visits to hospitals applying for grants. These reports showed how various were the difficulties under which work was carried on in some of the older and outlying institutions.

> "Obsolete plumbing, obsolete standards of staff accommodation, grounds that have for lack of funds been allowed to become half derelict, lack of accommodation for visitors —with some of these things the King's Fund can help, others are beyond its resources; hospitals generally are now alert to the possibility of getting help from the Fund. All our experiences in the last few years show plainly how very necessary periodic visiting is if the Fund is to maintain close touch with hospital affairs."

Referring to the reports on hospital costing lately presented to the Minister of Health by the Nuffield Provincial Hospitals Trust and by the Fund, the Duke said:

> "Most of us are so accustomed to the traditional way of looking at hospital accounts that it is difficult to grasp what a revolution is involved in the recommendations in these reports, and yet how simple they are—nothing more or less than that hospitals should adopt a normal business-like approach towards their accountancy, and abandon once and for all the over-simplified headings which go right back to the accounts of early charitable undertakings."

He added that he hoped the recommendations in the reports would be found to be an acceptable basis for the hospital accountancy of the next generation.

Sir EDWARD PEACOCK, the treasurer, reported that income from investments had reached £320,000, and general legacies during the year amounted to £53,000. There had been in addition, for capital, amounts of £14,000 and £9000 from the estates of Lord and Lady Wakefield. As reported in July last, £50,000 had been received from the Nuffield Trust for the Special Areas, which brought the total to £1,400,000.

Sir ARCHIBALD GRAY, chairman of the distribution committee, said that the amount given for maintenance for hospitals outside the National Health Service was about the same as last year. Subscriptions and donations received by this group of voluntary hospitals had increased slightly and now formed 27% of their income, and they had also received £175,000 in legacies.

Before Our Time

FOOD LORE FROM NURSERY RHYMES

THE rhymes and jingles of our childhood days are often uncertain in origin and difficult to date with any accuracy. It is perhaps for these reasons that the many allusions in them to food customs, habits, likes, and dislikes have not yet found a place in scientific literature. Yet our nursery rhymes are not all so nonsensical as they may appear, and even a quick glance through the Opies' fascinating book* must be stimulating to anyone who is interested in the foods of the past.

The common foods of a few centuries ago were not so different from those we eat today. Stews, sheep's head, haggis, roast beef, veal, giblet pie, leg of lamb, gammon and spinach, peas and beans, bread and cheese, curds and whey, pancakes, all are mentioned, some of them many times over. Ducks were evidently prepared in the well-known way.

> "Mrs. Bond she flew down to the pond in a rage
> With plenty of onions and plenty of sage;
> She cried, Dilly, dilly, dilly, dilly, come to be killed,
> For you must be stuffed and my customers filled!"

The man in the moon wore a hat made of "good cream cheese" and, as all the world knows, he "burnt his mouth with supping cold plum porridge."

So far as drinks are concerned

> "One, two, three,
> I love coffee
> And Billy loves tea,"

appeared about a hundred years ago, but

> "The man in the moon drinks claret,
> But he is a dull jack-a-dandy;
> Would he know a sheep's head from a carrot
> He should learn to drink cider and brandy."

dates from the 17th century. Incidentally there seems to be no reference to milk as a drink in any nursery rhyme.

"Parsley, sage, rosemary, and thyme" was a refrain of an 18th century rhyme, and

> "Nutmeg and ginger, cinnamon and cloves,
> That's what gave me this jolly red nose."

---

* Opie, I., Opie, P. Oxford Dictionary of Nursery Rhymes. Oxford, 1951.

comes into a rhyme of two hundred years earlier. The fruits of the country—cherries, apples, pears, and plums—are often mentioned. Oranges and lemons also must have been well enough known in the middle of the 18th century to be coupled with the bells of St. Clements, and, indeed, "Oringes and Lemons" was the name of a dance of the 17th century.

Foods are often promised as treats and punishments for children.

> "When Jacky's a good boy,
> He shall have cakes and custard;
> But when he does nothing but cry,
> He shall have nothing but mustard."

Most of the treats were sweet things, such as treacle, honey, tarts, cakes, plum buns, plum cake, biscuits, comfits and, over and over again, sugar candy.

> "Handy spandy, Jack-a-Dandy,
> Loves plum cake and sugar candy."

Tarts were, of course, the downfall of the Knave of Hearts.

The pie was clearly very popular.

> "A was an apple-pie;
> B bit it,
> C cut it,"

and so on, down to

> "X, Y, Z and ampersand
> All wished for a piece in hand."

Blackbirds entered into the composition of a very famous pie, and

> "Little King Pippin he built a fine hall,
> Pie-crust and pastry-crust that was the wall."

Pie-men and pie-women sold their wares, often mutton pies, in the streets.

> "Simple Simon met a pieman,
> Going to the fair;"

and

> "There was an old woman
> Sold puddings and pies;
> She went to the mill
> And dust blew in her eyes.
> She has hot pies
> And cold pies to sell;
> Wherever she goes
> You may follow her by the smell."

The pudding was something quite different from the pie. It was a boiled concoction made in a bag tied with string. The basis was a cereal of some sort or peas.

> "Flour of England, fruit of Spain,
> Met together in a shower of rain;
> Put in a bag, tied round with a string;
> If you'll tell me this riddle,
> I'll give you a ring."

Puddings evidently formed a substantial part of the meal and the description of the bag-pudding made by King Arthur reads like the dream of a man who knew what it was to be hungry. The basis of the pudding, as described in a previous verse, was barley meal.

> "A bag-pudding the King did make,
> And stuffed it well with plums;
> And put in it great lumps of fat,
> As big as my two thumbs.
> The king and queen did eat thereof,
> And noblemen beside;
> And what they could not eat that night,
> The queen next morning fried."

There were also black puddings, and when the tailor accidentally shot his pig

> "Zooks, quoth the taylor, I care not a louse,
> For we shall have black puddings, chitterlings and souse."

Puddings were eaten either hot or cold

> "Pease-pudding hot,
> Pease-pudding cold,
> Pease-pudding in the pot
> Nine days old."

Fuel was scarce and one good fire probably had to be responsible for several days' food.

The joys of white wheaten bread are brought out in the rhymes again and again. By comparison barley bread was reckoned poor stuff to give to Bonnie Prince Charlie.

> "I'll have none of your nasty beef
> Nor I'll have none of your barley;
> But I'll have some of your very best flour
> To make a white cake for my Charley."

A supper of white bread and butter was something to sing for, and it was worth a journey to Banbury Cross to buy a penny white loaf.

> "Ride a cock-horse
> To Banbury Cross,
> To see what Tommy can buy;
> A penny white loaf,
> A penny white cake,
> And a two-penny apple-pie."

The penny white loaf often crops up in nursery rhymes. By it is meant, no doubt, the penny white loaf which was always listed in the Assize of Bread, an Act which from 1447 fixed the price of bread and ale according to the price of grain.

The drinks people drank, the foods they ate, are in the nursery rhymes for all to read. If only we had the recipes and quantities we might make a dietary survey of the beggars, the children, the old women, and even the man in the moon as they lived in the minds of our great and great-great grand-parents when they were very young.

R. A. McCance.

Public Health

The Fog

First reports indicate that the thick fog which covered London and many other parts of the country from Dec. 6 to 9 produced the customary rise in mortality, notably from respiratory diseases. Last week's fog was particularly fearsome, for it was accompanied by bitter cold; Russell[1] suggested that it is fog and frost combined which especially attack the susceptible chest.

When Logan[2] examined the London mortality figures for the week of the long fog of November, 1948, he found that the number of registered deaths from bronchitis and pneumonia was double the figure for any of the previous four weeks. Deaths from other causes were little affected, though rather more people died from myocardial degeneration and from cancer than in a normal week. Logan's figures showed clearly how the older people suffered most: as far as mortality was concerned, there was no increase at all at ages under 45, and most of those who died from bronchitis and pneumonia were over 65. In the following week, however, an unusually large number of infants died from pneumonia.

Our fogs are undoubtedly cleaner than they were, and less of a "smog" now that electric and gas fires have replaced so many open fires and kitchen ranges. The watch kept on the quality of smokes from factories means that we are unlikely to have such a disaster as happened at Donora, Pennsylvania, in 1948.[3] Nevertheless a further reduction in the output of the country's chimneys would certainly relieve us of much of the distress caused by fogs.

2. Logan, W. P. D. *Ibid*, 1949, i, 78.
3. *Ibid*, 1948, ii, 738.

Meanwhile at least one doctor found London's radio-taxi service of use in the fog last week. In urgent need of oxygen apparatus, he got his message through by radio to a taxi in the neighbourhood of the suppliers. The taxi collected the apparatus and delivered it to the doctor at the patient's home with very little delay.

School Health

Since the school health service was started our children have been steadily growing taller, heavier, and healthier; and now, as Sir John Charles points out in his report for 1950–51,[1] the motor-car is a greater menace to them than diphtheria. Indeed of the 3341 deaths among children in 1950, 851 were due to accidents, more than half of which were motor accidents; and only 16 were caused by diphtheria. The incidence of minor and major disabling diseases has also been reduced. For instance, during 1947–51 the number of children with scabies, impetigo, and ringworm of the scalp dropped from 108,000 to 34,000, and the incidence of rheumatism fell by a third. Admittedly there is still room for improvement; over 4000 children are attacked by acute rheumatism each year.

One of the most important tasks of the school health service is to detect any defect as early as possible so that it may, where possible, be corrected. Among the 4½ million children examined during 1951, medical officers found 157,566 with defects in vision and a further 37,499 who needed treatment for squint—a disturbing increase compared with the 31,189 in 1949. 3 children per 1000-odd were found to need treatment for defective hearing, and 5 in just over 1000 were recommended to be kept under observation.

In addition to inspection the school health service nowadays provides a good deal of treatment. In all, local education authorities and regional hospital boards between them run 2350 clinics, about a third of which are specialist clinics. Some consultants hold that the facilities are better in hospital outpatient departments, and clearly the right place for clinics will vary with local conditions; but in any form this collaboration is valuable both to the child and to the medical student. The National Health Service has also strengthened the relations between school doctor and family doctor. There is now, the report points out

> "no question of clinics 'taking the bread out of the mouth of general practitioners.' . . . There should be full and frank interchange of information between the school doctor and family doctor about children in need of advice or treatment or of special educational provision. The more that general practitioners get to know of the work of the school clinics the more they will be prepared to coöperate."

The progress of our own times has a way of tarnishing the advances of previous decades, and the report ends with a critical survey of open-air schools. These schools, the first of which was opened in 1907, have done much for the health of delicate children; but today the modern school-building is often structurally more open-air than the so-called open-air school, which may have degenerated into a rather draughty ramshackle affair. Some of the schools visited by the four medical officers who made this survey were good, but the standards varied. Many of the residential schools were "bare, cheerless and spartan"; sometimes the hygienic arrangements were defective and the physical education of the children was neglected. The surveyors rightly hold that the great merit of these schools is their small size; and they agree that

> "there is still a place for special schools for delicate children, especially for those who live in industrial areas, but we do not consider that there is justification for much expansion of the existing provision. Indeed, a few day schools have vacant places. With a rising standard of living, better housing, the provision of meals and milk in schools, and with a fuller appreciation in the ordinary school of the varying needs of individual children, it may be that the need for special schools for 'delicate' children will diminish with the years."

Examination of Coalminers

The Coal Mines (Medical Examination) General Regulations, 1952,[1] made by the Minister of Fuel and Power, came into operation on Dec. 10. The regulations place upon the owner of every coalmine the responsibility for making arrangements for the medical examination, by a registered medical practitioner approved by the Minister, of persons under the age of 21 first employed, or about to be employed, in or about a coalmine. The doctor will issue certificates of fitness for mining work to the person examined and to the manager of the mine. Any person who fails without reasonable cause to submit himself for examination, or who is found to be unfit for this particular work, will not be allowed to take up employment in or about a coalmine. Of those engaged in mining work before Dec. 10 only those under the age of 18 must be examined; and in certain Welsh counties all those employed at a mine before this date are exempted.

Cancer of the Respiratory System

The Registrar-General's Statistical Review of the year 1950, published this week,[2] indicates that the increase in the number of deaths from malignant disease of the respiratory system shows no sign of stopping. The crude death-rate from this cause was 312 per 1,000,000 population in 1950—exactly double the 1940 figure. The rate rose from 288 in 1949—the highest rise in any single year in the period 1940–50. The increase has been more rapid among men than women: the crude death-rate for men was 266 per 1,000,000 in 1940 and 536 in 1950; and for women the figure rose from 63 to 104 in the same time.

Parliament

Economy in Hospital Staffing

Mr. ARTHUR BLENKINSOP and some forty other Labour members have tabled a motion criticising the proposed reductions in the staffs of hospitals.[3] The motion expresses alarm at the decision of the Government to impose further limitations upon hospital expenditure by reducing hospital staffs, which must lead to a fall in the standard of care or in the number of hospital beds, and calls upon the Government to review this decision without delay.

QUESTION TIME

Outbreaks of Anthrax

In answer to a question Sir THOMAS DUGDALE stated that outbreaks of anthrax from June to November, 1952, were as follows:

June	31
July	90
August	123
September	170
October	185
November	209

Hospital Waiting-lists

In answer to a question Mr. IAIN MACLEOD stated that during 1951 hospital waiting-lists dropped by nearly 27,000 and the average daily number of occupied beds increased by over 4000. A small reduction in the average length of stay of patients or in the proportion of beds unoccupied would make a considerable difference to waiting-lists.

Supplies of Cortisone

In answer to a question Mr. MACLEOD stated that there was some British production of cortisone and A.C.T.H. The F.O.B. value of Government imports of cortisone during the twelve months ended Oct. 31, 1952, was £105,000; and of A.C.T.H., £111,428.

In England Now

A Running Commentary by Peripatetic Correspondents

ONE of the reasons I look forward to 1953 is that it will bring a new calendar. Not that I have anything against the handsome one now on my desk, but I have tired of the verse that surmounts it. This consists of eight lines, of which only the second rhymes with the fourth and the sixth with the eighth. The remaining alternate lines do not rhyme. This savours to my mind of shoddy workmanship. The poem leads off with an admirable sentiment:

"May the Web of your Life be woven
"In strands of the finest gold."

Fair enough. One could wish for nothing better. But it goes on:

"As the Pathway of Life you travel
"May joys that are new unfold."

Now I can't help feeling that there are better rhymes to woven than travel. How about this for an alternative couplet?

"May your soup be shŏved in the ŏven,
"And never served up half cold."

The second quatrain runs:

"May your Christmas be Bright and Happy
"And oncoming Years be Free
"From the clouds of Trouble and Sorrow
"And Blessed with Prosperity."

Nothing to quarrel with there, of course; but happy and sorrow clash a bit surely? Let's see what we can do:

"From calls to parturient wŏmen
"Or other emergency—
"E.g., an acute abdomen—
"May your Christmas Dinner be free."

An improvement, I fancy. But could I sit opposite even that for twelve months?

* * *

What unknown seas of knowledge are spread before us on first looking into the new *World List of Scientific Periodicals*. One wonders what conscientious doctor can afford to be without the *Journal of Successful Medicine*; what surgeon dare ignore the *Surgical Supervisor*; what obscure subjects are brought to light by the *Medical Searchlight*; what secrets are guarded by the *Medical Sentinel*? The *Medical Mentor* will be just the thing for membership candidates and the *Medical Counselor* for those in difficulties of other kinds. *Medical Life* and *Médecine chez-soi* sound as if they deal with the society (not social) aspects of medicine. Alas, we shall probably never know what is published in *Suomen Lääkariliiton Aikakauslehti* because no library in this country takes it, but at least copies of *Oogst* and *Skýrsla um St. Josep-spitala i Reykjavik* are available. Readers of the *Sun Bathing Review* and the *Survey of Thunderstorms* are probably sharply divided in their interests, but surely everyone will enjoy the pastoral serenity of the *Guide to Experiments conducted at the Station Farm, Little Snoring.*

* * *

In our manic phase recently we determined to buy a house. After a preliminary study of the form in the local newspaper and some dickering with agents we finally discovered the only house in England we could afford to buy. Even to our untutored eye it was not in the best of condition, and we timidly approached a local builder to give us an estimate of the necessary repairs before we put in our offer.

The builder, a small active man of a despondent turn of mind, threw himself about the house in a frenzy of estimation. On several occasions he drew sparks from the end of his foot-rule. He peered into the attic and rapped the cistern with his knuckles—"Iniquitous, doctor!"; he stamped on the floorboards—"Neglect, doctor, neglect!" and inspected the fireplaces—"That's a thing I cannot *bear*, doctor!" Outside, the standpipes moved him deeply—"Horrible, doctor!"; and he buzzed gloomily around the drains—"It's illegal, doctor, completely illegal!" He mentally knocked down and rebuilt several walls, lowered the washbasin and raised the sink, and finally squeezed himself through a small bedroom window to inspect the scullery roof. What he saw confirmed his worst suspicions—"Ah, the scoundrels, doctor, the scoundrels!" The garage rendered him speechless, and only after walking away did he find strength to shake his head and mutter "Oh dear, doctor, oh dear!" He brightened at the unmade driveway—"What you want there, doctor, is a load of gravel, not *our* gravel, you understand, doctor, stuff you can roll," but the garden fence shook him again, and he left enveloped in brisk businesslike gloom.

We are once more making a preliminary study of the form in the local newspaper, and have reverted to our depressive phase.

* * *

Like most medical graduates of the University of London, I had several times had occasion to visit the Royal College of Surgeons in Lincoln's Inn Fields, but it was not until last weekend that I went into Sir John Soane's museum, on the opposite side of the square. I struck lucky, for though I only hoped to fill the gap between lunch and tea on a rainy Saturday afternoon I found that half-past two was the precise time for the weekly conducted lecture tour by the museum's curator.

Soane (1753–1837) was a distinguished and successful architect, who spent the last forty years of his life in collecting and arranging furniture, antiquities, and drawings of architectural interest, and some excellent pictures. These are all looked after by trustees under the terms of a private Act of Parliament which he obtained in 1833. The museum is thus a collection chosen by one man, and maintained according to his taste. The house has a striking façade, with the incised ornamentation peculiar to Soane. Its interior also shows his highly individual architectural style, designed to create the feeling of space, vista, and insubstantiality. Among the varied collection I was most taken by a fine pre-Chippendale mahogany chair, probably built for the ample bulk and dignity of a governor of some prosperous City firm, by the famous *Rake's Progress* and *Election* series of William Hogarth, and by the fine sarcophagus of Seti I. This reposes in a domed recess named the Sepulchral Chamber, and there are also catacombs and a "monk's parlour" down in the crypt—evidence of Soane's liking for the Gothic and, perhaps, of his lonely and embittered old age. Despite the numbers of casts and fragments of Roman statuary, the building itself, with its sense of space and airy hollowness, put me in mind of modern sculpture by Henry Moore or Barbara Hepworth, as though I had crept in under the ribs of a mastodon's skeleton out of the raw December weather.

* * *

It is now some weeks since our hamsters were installed. They live in a glass-fronted case in one of the bedrooms, where they may be seen, dim shapes behind the murky glass. Their presence, however, permeates the house, and they are consulted on all domestic affairs and also on matters of more general interest, such as the probability of snow on Christmas Day.

Even more imminent than their own corporeal existence are the countless generations of unborn hamsters due to spring from their loins, and so many of these have been given away already that the market is saturated. Their slightest gesture is interpreted as a sign of incipient maternity, as, for example, when one of them bit a too-familiar visitor to the effusion of blood, and the action was held to show its highly nervous state; or when the other was observed to demolish three cheese biscuits in rapid succession and its perverted appetite was assumed to demonstrate its delicate condition.

Though surrounded by every luxury, they are determined to escape, and spend the watches of the night in scratching holes in odd corners. They have already spent one night at large, and we await with some trepidation their next eruption. A large notice has in fact been erected on the case which reads "Hamsters, John and Mery. Pleese be ceful."

Letters to the Editor

SHORTAGE OF JUNIOR HOSPITAL STAFF

SIR,—The large number of hospitals with vacancies for house-officers that they are unable to fill is a matter of concern, and provides a problem that may endanger the whole hospital system.

The major cause is the great expansion of hospitals that has taken place since 1936. Entirely new hospitals have been built; old public assistance institutions have been upgraded and enlarged; war emergency hospitals have become permanent; many infectious-disease hospitals have been converted to other uses; and provision for chest diseases, maternity care, mental deficiency, &c., has much increased.

It is difficult to obtain exact figures for pre-war hospitals to compare with the recently published statistics of the hospital and specialist services for 1950. The P.E.P. report on the British Health Services gives some figures for 1936. In that year there were 2688 hospitals with a total of 260,829 beds. These include voluntary hospitals of all kinds, public hospitals, and institutions for tuberculosis, maternity, smallpox, and infectious diseases. Apparently they do not include the 107 mental hospitals with 150,000 beds. In 1950 the total beds in hospitals of all kinds numbered 504,321. The figures are not strictly comparable but do reveal the great expansion that has taken place. The number of pre-war house-officers is not ascertainable; but in 1950 there were 5824 (this includes whole-time registrars, senior hospital officers, and junior hospital officers, but not senior registrars); and 1622 of these were in teaching hospitals.

At one time it was thought that there would be a difficulty in providing sufficient posts for the compulsory preregistration year of residence; but in England and Wales 2104 posts in 456 hospitals have been approved. In 1951 there were 1531 new registrations; so assuming that a similar number register next year there will be an excess of 573 approved posts. In Scotland 557 posts have been approved, and in 1951 new registrations were 699 so that the balance of 142 should be available for export. In Ireland posts and registrations are more evenly matched. It appears therefore that in England and Wales about 1670 of the 2104 approved posts may be filled. This would leave 4154 out of the total of 5824 available posts to be filled from other sources. This is a measure of the problem to be faced.

In pre-war days resident posts in non-teaching hospitals were filled either by the newly qualified who had failed to get a post in their own teaching hospitals, or by those who after holding posts in their own hospitals desired further experience before entering general practice. Such posts were desirable, for they gave opportunities of becoming acquainted with local practitioners and a chance of filling any vacancy in general practice which might arise. They were often held for two or three years. Now these posts are less desirable, especially if situated in a "closed" or "restricted" area. The position has been aggravated by the two years of national service. On their return men do not seem willing to return to hospital life. They may be married and anxious to settle down, and married quarters are not usually provided in hospitals.

It is clear that the hospital services have increased beyond the means of staffing them adequately, and the National Health Service has become unbalanced. Owing to the difficulty of entering into general practice, it has been suggested that the number of students entering our medical schools should be reduced to prevent unemployment. But the number who qualify is far short of that necessary for hospital requirements. If the number is increased to meet this need, what is to become of them when hospital days are over?

There cannot be any one solution of the problem. Much could be done by making better use of the hundreds of registrars, most of whom will not reach the grade of senior registrar and be trained for consultant status. Many will enter general practice and could give valuable assistance in taking over duties now performed by resident officers. I foresee a new type of keen practitioner who will spend half his time in hospital and half in general practice. A major contribution could be made by reducing the conscription period to one year. This is a thorny subject but it is hard to be convinced that it is necessary for a fully qualified man, who has spent a year in residence in a hospital, to have two years intensive training to fit him for military requirements. Reduction to one year, with the proviso that the other year should be spent in hospital, would be a great help. Failing this the proportion of those allowed to take a third hospital post before conscription should be increased. Medical women are free to take further posts and should be encouraged to do so, and some contribution may be possible from the Dominions.

Regional boards are naturally jealous of the large proportion of residents in teaching hospitals and on the face of it they have some justification. In teaching hospitals there is one resident to 15 beds and in non-teaching hospitals the proportion is one to 103 beds.

It is important that the high standard of the teaching hospitals should be preserved and that much emphasis should be placed on scientific method. But scientific method should have been inculcated through the whole period of a student's training, and it may be argued that a newly qualified man who is eventually going into general practice may get a better all-round experience in a non-teaching hospital where he will have greater responsibility and see a greater range of cases than with a highly specialised firm in a teaching hospital.

The problem is an urgent one and requires serious discussion and major decisions at high levels if a breakdown of the hospital service is to be avoided.

Birmingham. W. H. WYNN.

SIR,—It is time that someone spoke again of the difficulties of some hospitals that are not attached to a teaching hospital or unit. At these hospitals, which deal with the bulk of all hospital patients, operating-lists are sometimes having to be curtailed or cancelled because there is neither a resident to deal with postoperative care nor a junior anæsthetist for what are termed "registrar lists." Commonly senior specialists have to do, as well as their own work, that of registrar and houseman. This is not fair to the patient, economical, or good medicine.

As we know, after the Appointed Day registrar posts in all three grades were filled wholesale and often unnecessarily, with the result that there have been drastic cuts in both senior and middle grades in an attempt to make the numbers correspond with future consultant appointments. Unfortunately the number of consultants remains below the proposed national establishment; and thus the number of junior posts is correspondingly low. Even though the number of such posts is now more in keeping with consultant vacancies, there is still little incentive for young doctors to take registrar appointments outside a teaching unit; for efforts to specialise by those not in touch with a teaching centre are foredoomed to failure.

The young doctor who proposes to enter general practice no longer feels a need first to do several house-jobs. Thus the outlying hospitals have lost both grades of registrars; and many cannot get enough house-surgeons or house-physicians or junior anæsthetists. These hospitals have been placed at a further disadvantage in that a salary is now offered by all hospitals, whereas before the war junior appointments in non-teaching hospitals were unpaid.

Another difficulty is that increasing specialisation has changed the attitude of residents, so that they are less willing to fill gaps. Gone are the days when a houseman crammed into his days all possible medical experience. Now he hesitates to take responsibility outside his own particular field. In big hospitals this may matter little; but in the not so big hospital the loss is great.

Possibly the introduction next year of the compulsory preregistration twelve months in hospital posts may bring some relief. But can outlying hospitals, even if given an allocation of interns, be sure of obtaining them? Will not the demand continue to exceed the supply?

Sidcup, Kent. URSULA HAMILTON PATERSON.

HOSPITAL COSTS

SIR,—The proposals described in your leading article of Nov. 29 would lead to great improvement in the system of hospital accounting, but might work out to the apparent disadvantage of hospitals with a quick "turnover" of patients. The more quickly investigations and treatment are carried out, the higher will be the cost per patient per day; yet it is obviously in the interests of both patients in hospital and those awaiting admission that the stay should be as brief as is compatible with good treatment. For this reason it would perhaps be better to relate the cost both of inpatient and of outpatient treatment to the total number of patients of each type treated per year.

Paris. K. W. LOVEL.

DIAGNOSIS OF MIXED PAROTID TUMOURS

SIR,—In their very interesting article of Aug. 16, Mr. Patey and Mr. Hand refer to the difficulties which surround the clinical diagnosis of mixed parotid tumours. Certainly these difficulties are especially important now that ideas on the treatment of these tumours are changing. I am, however, only concerned with their statement that "Redon (1952) now incises as a routine all parotid tumours as a first stage of the operation and to excise a small piece for microscopy."

The histological classification of parotid tumours is uncertain; and it would, I believe, be a retrograde step if biopsy came to be accepted as an accurate guide to treatment. Few workers can have had such extensive experience of the histology and prognosis of salivary tumours as McFarland. From an analysis[1] of 421 cases of salivary gland mixed tumours he concluded:

> "From the present study it appears that something more than a simple microscopic examination of a section of tissue will be required before an accurate prognosis of a mixed tumour of the salivary glands becomes possible. At present our methods are no more accurate or scientific than the flipping of a coin."

Ahlbom,[2] too, who also studied a large series, found that the histological approach alone was unsatisfactory and believed that accurate classification must be based on macroscopic, microscopic, and clinical characteristics. On this basis he divided tumours into benign, semi-malignant, and malignant.

Redon's views were expressed in a personal communication; and his reasons for favouring immediate biopsy are not given. Unless his evidence is very weighty, it would surely be unwise to attach too great importance to biopsy findings and to base therapy on histological criteria which are open to such fallacies. In any case there may be other risks associated with biopsy of salivary tumours. There may be, however, as Mr. Patey and Mr. Hand point out, a place for immediate microscopy after preliminary enucleation of a parotid tumour.

London, W.1. REGINALD T. PAYNE.

DANGER OF PHENOL WITH PENICILLIN

SIR,—We wish to call attention to a risk attached t the common practice of using 0·5% phenol as a preserv tive in penicillin solutions. This amount of phen injected into muscles, or even into veins, appears to b innocuous; but the intrathecal injection of even ver small quantities of such a solution may be highl dangerous. We have recently had reason to suspec that the accidental employment of a penicillin solutio containing phenol may have been the direct cause c convulsions in an infant with meningitis, and we hav learned of at least one other case in which an eve more minute quantity of phenol injected into the thec was the probable cause of severe damage to the nervou system.

The necessary precautions are simple, but need to b rigidly applied. Firstly, every bottle of penicillin solutio issued by a dispenser, and containing phenol, must b distinctively labelled as such, and as suitable only fo intramuscular injection. Secondly, all hospital medica officers should be reminded that when it is necessary t give penicillin intrathecally the solution should be mad by themselves, at the time of injection, from unopene containers of crystalline penicillin.

Children's Department,
Farnborough Hospital, Kent.

PORPHYRIA TREATED WITH DIMERCAPROL

SIR,—Clinically there are two types of porphyri —acute and congenital. The following case seems t belong to the congenital group, for no suggestion of a toxic cause could be found by careful interrogation and examination of the patient.

History

A married woman, aged 28, had been very fit until the last three months of her first pregnancy two years ago. She then had some albuminuria, followed by two eclamptic attacks immediately before delivery, which was completed by forceps. She was never jaundiced, and the albuminuria stopped two weeks after delivery.

In March, 1952, a month before the delivery of her second child, she noticed that her urine was a peculiar bright-red colour. At this time three bullous eruptions developed on one finger. The bullæ contained a clear liquid, and the surrounding skin was normal. Gradually new eruptions of the same kind appeared on the face and the exposed parts of both arms. There were no symptoms related to the gastro-intestinal tract or nervous system. She had taken no drugs which could account for the condition.

By the end of June the bullæ involved a much wider area, including the neck and the medial aspect of the knees. In some areas the appearances were those of epidermolysis bullosa. New eruptions were constantly breaking out, and the skin on the dorsal surface of both hands finally broke down, leaving large ulcers, 6 to 8 cm. in diameter.

Laboratory Investigations

Urine.—Dark red in colour. Concentrated HCl gave a distinct green colour, changing to yellow after some drops of 3% H_2O_2 were added. Acidified urine gave the characteristic absorption spectrum of porphyrin.

Blood.—Erythrocyte-sedimentation rate (three successive occasions) 67, 60, and 25 mm.; Hb 98%; red cells 4,420,000 per c.mm.; colour-index 1; reticulocytes 0·1%; fragility of red

URINARY ANALYSES BEFORE AND AFTER DIMERCAPROL

—	Before dimercaprol	After dimercaprol	
	June 13, 1952	July 31, 1952	Aug. 4, 1952
Coproporphyrin (µg. per 100 ml.)	65	20	20
Uroporphyrin (µg. per 100 ml.)	2025	930	715
Porphobilinogen	None	None	None

The analysis gives a figure correct to the nearest 5µg.

cells 0·40–0·32% NaCl; icteric index 6; platelets 320,000 per c.mm. Sternal-marrow biopsy was normal.

Liver-function tests.—Normal.

Treatment and Progress

Treatment with dimercaprol (BAL) began on June 25, 1952. 1·8 ml. was given every four hours for forty-eight hours, and then 1·6 ml. four times daily. From June 30 until treatment was stopped on July 5 only 1·5 ml. was given twice daily. New skin lesions appeared on July 22; and a second course, with reduced doses, was given from July 23 to 30.

After two days' treatment, the patient felt definitely better. No fresh bullæ developed after July 22, and the urine became brighter in colour, especially during the afternoon and evening. The skin lesions regressed after a few days, and finally healed completely, though deep scars remained. The amount of coproporphyrin and uroporphyrin in the urine decreased (see accompanying table of analyses kindly performed by Dr. S. L. Sveinsson in the Central Laboratory of the Ullevaal Hospital, Oslo).

At the outset the prognosis seemed poor, and we felt justified in trying the effect of dimercaprol, because a good response has been observed in hæmosiderosis due to multiple blood-transfusion,[1] and hæmosiderosis has been found in several organs, especially the liver, in cases of porphyria at necropsy.[2] The distinct improvement after a few days, the regression of the skin lesions, and the urinary changes suggest that dimercaprol may be of benefit in porphyria. They certainly seem to justify its further trial.

St. Joseph's Hospital,
Porsgrunn, Norway. A. SCHRUMPF.

SUFFERING FROM PERNICIOUS ANÆMIA

SIR,—A patient complained that she had suffered from pernicious anæmia for 20 years.

When asked how she had suffered, it was apparent that she had ascribed all her aches and pains, headache and giddiness, indigestion, weakness, and palpitation to her ailment, which she clearly believed to be most pernicious. When told that a recent examination showed that her blood was in every way perfect and that she could not have been anæmic for 20 years (for she had attended a most efficient hæmatological clinic at a large hospital during the whole period) she refused at first to accept the good news. Evidently, no-one had ever told her that the blood of those with pernicious anæmia can be kept normal indefinitely.

Many patients with pernicious anæmia have similar beliefs. During the late war they would attend hospitals with requests that they be given certificates to excuse them from fire-watching and other public duties, and in other circumstances they may ascribe any symptoms to their disease.

The most enthusiastic devotees of the psychosomatic theory of disease have never suggested that pernicious anæmia has a psychological basis. But these considerations suggest that even in treating those with this disease attention should be paid to their minds. This attention need only be of the simplest kind; the doctor has only to tell the patient at the beginning of treatment that within a few weeks his blood will be normal, and, when this time has passed, that his blood is now normal and will always remain normal provided he attends for his regular injections and an occasional blood examination. From time to time in later years these statements may occasionally be repeated, and it be emphasised that if ever the patient does not feel well some other cause than pernicious anæmia must be sought for his complaints.

It may be argued that patients who suffer from pernicious anæmia must be of hypochondriacal temper, and if they are deprived of the opportunity of ascribing their symptoms to this disease they will still continue to get symptoms and ascribe them to something else. No doubt there is some truth in this, and those of sound personality do not become invalids when they develop pernicious anæmia, even if their medical advisers never tell them the facts about this condition. But this does not excuse the physician who does nothing for his pernicious-anæmia patients except to order them injections and blood-counts. By remembering that they have minds as well as bodies, he can surely do something to discourage them from becoming invalids.

Farnham, Surrey. J. W. TODD.

SPLENOMEGALY IN SCARLET FEVER

SIR,—During a recent appointment at an infectious-diseases hospital in the north of England, I had to deal with a large number of patients with scarlet fever—some 200 cases in three months. Most of these were mild attacks, but I was interested to find that no less than 18 of them showed a moderate splenomegaly.

In most patients the spleen was palpable on admission, but in some it was not palpable until a few days later. The spleen was usually firm, and in no case was it tender.

The duration of the splenomegaly generally varied from 4 to 16 days; but in one or two patients the spleen was still palpable on discharge after 21 days.

None of the patients had enlarged lymph-glands, other than the enlarged and tender tonsillar glands so commonly found in scarlet fever.

Unfortunately, a total and differential white-cell count was carried out in only 6 cases. In 5 of these the differential lymphocyte-count varied from 34 to 50%; the 6th had only 12% of lymphocytes; and the highest total white-cell count was 14,600 per c.mm. In none of the cases did the pathologist note any abnormal lymphocytes or an absolute mononucleosis.

I have not seen enlargement of the spleen mentioned in any textbook as a clinical feature of scarlet fever, and I would be glad of your readers' opinions on the incidence and significance of this finding.

The Radcliffe Infirmary, Oxford. S. O'REILLY.

HEALTH VISITORS

SIR,—Some weeks ago, during a discussion in the correspondence columns of the *Spectator*, a general practitioner deplored the activities of "ubiquitous health visitors, usually in the form of smart young women who visit our patients in shining cars. . . ." It was obvious from the letter that the "health visitors" referred to were officials of the Ministry of National Insurance. A letter from the secretary of the public health section of the Royal College of Nursing later pointed out that the designation "health visitor" was wrong and misleading in this instance. The Ministry of National Insurance itself directs the members of its staff who visit insured persons in their homes to use the title "visiting officer." These visiting officers do work similar to that of the old "sick visitors" of the approved societies who, prior to 1948, were responsible for the administration of sickness benefit under the National Health Insurance Acts which were the forerunners of the present Act.

There seems to be some confusion in the minds of both general practitioners and the public between the very different functions of the visiting officer and the health visitor, and there is little appreciation of the nature of the training of health visitors. The health visitor is employed by the local health authority, and has no connection with the Ministry of National Insurance. Her qualifications are prescribed by regulations of the Ministry of Health. She is a State-registered nurse with an additional qualification in midwifery and with the health visitor's certificate of the Royal Sanitary Institute. Her total training occupies a period of at least four and a half years (and it may extend to over five and a half years). She is a health teacher with an expert knowledge of the care of children and of expectant and nursing mothers. Her work now includes the care of the aged, and advising on the health of the family

2. Berglund, H., Paul, K. G. *Ibid.*

as a whole and on the measures necessary to prevent the spread of infection. Many health visitors in addition carry out the duties of the school nurse or of the tuberculosis visitor.

While in the past the health visitor has in general had little contact with the family doctor, it is hoped that in future she may work in closer contact with him, so that he can readily call upon her services should a family require them.

London, S.W.1.

A.C.T.H. IN OIL AND BEESWAX

Sɪʀ,—During the past eight months the department of rheumatism of the Royal Free Hospital has treated 17 patients, suffering from active rheumatoid arthritis, with ᴀ.ᴄ.ᴛ.ʜ. made up in an oil and beeswax base. Bruce and Parkes,[1] as a result of experiments on rats, have suggested that this preparation will act for several days.

In 12 of the 17 cases pain relief and increased freedom of movement resulted from injection of 100 mg. twice a week; the improvement lasted one to three days after each injection; and of 10 outpatients who received this treatment for three to six months, 8 have maintained their improvement during this period. In 4 cases the erythrocyte-sedimentation rate has fallen to normal levels; and in patients who were anæmic the hæmoglobin has risen. The urinary 17-ketosteroid output and the eosinophil-count have not been significantly altered by this dosage.

We have warned patients to attend the hospital if any untoward symptoms arise; but so far no complications have appeared, and we find it a convenient and satisfactory method of using the hormone. Patients attend the follow-up clinic every month. In addition to the convenience of reducing the number of injections, there is also a saving in material.

The only difficulty we have encountered with ᴀ.ᴄ.ᴛ.ʜ. in an oil and beeswax medium is that it has to be used at the right temperature (about 60°C); for otherwise it is difficult to inject. We believe, however, that this preparation effectively prolongs the action of ᴀ.ᴄ.ᴛ.ʜ. and is therefore useful. It may be that in the future some base which is easier to handle will be found more satisfactory, but so far this is the best method we have used.

Mrs. V. David, ʙ.sᴄ., performed the biochemical investigations. Mr. J. W. Hadgraft, ᴘʜ.ᴄ., ᴀ.ʀ.ɪ.ᴄ., prepared the suspensions of ᴀ.ᴄ.ᴛ.ʜ., and is willing to send details to those interested.

GONORRHŒA IN ANCIENT ROME

Sɪʀ,—Can anyone give me a reference to gonorrhœa in Latin literature of the classical period? It is always taught that this disease was known to the Romans in the palmy days of Rome, but I have come to doubt the truth of this assertion.

It is strange that Ovid in his treatise on love has nothing to say on the dangers of promiscuous amours; stranger still that Catullus is silent on a subject that he could hardly have resisted, and equally strange is it with Petronius; but most strange that the satirists should have ignored so obvious an opportunity to point a moral. An acquaintanceship with Juvenal that extends for forty-six years convinces me that he, had he known of gonorrhœa, would have made good use of his knowledge. Then, there is the medical authority of the period, Celsus; but in his work I can find no mention of venereal disease. Again, the Roman system of morals seems to depend upon immunity from this disaster, for the use of prostitutes was defended on the ground that thereby the chastity of wives was less likely to be assailed. If gonorrhœa had been endemic, surely, since there were no means of protection, we should have heard of the terrible results?

Authors of books on gonorrhœa do not cite the passages nor give the texts or translations from writers who are supposed to support their view that the disease existed in Rome of the classical period.

Orpington, Kent.

TOXIC DOSES OF ADRENALINE

Sɪʀ,—Scant attention is given in our textbooks to the toxicology of adrenaline.

The latest annual report of the Medical Protection Society describes a case in which 5 ml. of a solution from a bottle marked "adrenaline 1/1000" caused rapid death when injected subcutaneously into the neck of a presumably healthy man. Nine years ago I witnessed the death of a young man after more than twice this dose had been injected into the muscles of the anterior abdominal wall. This man, who had a large kidney abscess, survived several hours—significantly longer than the man who received 5 ml. In neither case was there cerebral hæmorrhage; in both instances the mode of death was abrupt failure of the heart's action.

I do not know of any case in which less than 5 r
of a 1/1000 solution of adrenaline hydrochloride h
caused death. I do know, however, of a man w
survived the injection into a ruptured quadriceps mus
of 10 ml. of 1/1000 adrenaline hydrochloride. It
apparent, therefore, that the distance from the vi
centres, as well as the amount, of the accidental injecti
will determine the outcome. The site of injection w
also determine, to a certain extent, the time befo
death.

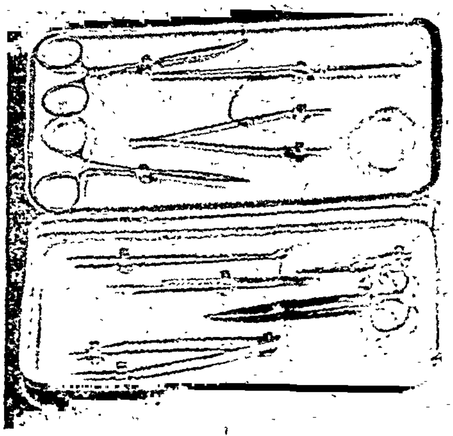
CONTAINERS FOR TRANSFUSION CUT-DOWN SETS

Sɪʀ,—Inside a standard transfusion giving-set box a
two metal plates, each measuring 4 × $9^5/_8$ in. T
lower plate (holding the pair of scissors in the accompan
ing figure) is flat and lies on the bottom of the bo
The upper plate, which is flanged, fits snugly over th
lower plate when the box is closed. These plates a
made into containers, as follows:

Universal-type metal clips, which hold the usual cu
down instruments, are firmly attached to the plates at sui
able levels. Into the flanged plate is let a metal cu
to hold an antiseptic solution. The whole is readil
sterilised.

When the sterile set is required for use the seal is broke
and the colour of the Brown's control tube checked. T
flanged plate is then lifted out and placed in the open
of the box, so that all instruments are readily availab
(see figure). Apart from the usual administration bloo
transfusion set, all that is required is a packet of steri
dressings, catgut, and a bottle of antiseptic solution.



---

1. Bruce, H. M., Parkes, A. S. *Lancet*, 1952, i, 71.

These containers have proved their worth both in hospital and in private practice. They are convenient and relatively cheap.

I am indebted to Dr. A. Jordan for his suggestion about the metal cup. The plates are made by Messrs. D. H. Farley, Union Lane, Sheffield, 1; and I am grateful to the directors of this firm for their coöperation.

Department of Hæmatology,
Royal Infirmary, Sheffield.
E. K. BLACKBURN.

THROMBOPHLEBITIS FOLLOWING INTRAVENOUS INFUSIONS

SIR,—Recent reports[1] in your columns of investigations into the causes of infusion thrombophlebitis have revealed interesting data which warrant some comment the pH of the solutions administered.

It seems a general practice in hospitals to allow a pH of 4·0 or lower in dextrose or dextrose-saline solutions. The habit of buffering such solutions immediately before use is, so far as I can make out, rare. Other precautions against excess of hydrogen ions can, however, be taken.

In the first place the dextrose used should be the finest available. Unfortunately, *d*-glucose of A.R. quality is very expensive; but apart from this, excellent samples can be chosen. Hudson and Tarlowski[2] obtained infusions of varying pH from different samples of monohydrate. The anhydrate, I find, tends to prove more satisfactory; for suitable samples show only half the original acidity set as a limit in the *B.P.* monograph, and yield a 5% solution of pH 6·5 approximately.

Solutions should be made at room-temperature, and filtered and sterilised without delay. Overheating should be avoided by raising the pressure in the autoclave as rapidly as possible, by maintaining the samples at sterilising temperature (115°C) for the minimum period (45 minutes), and by removing the containers to cool rapidly as soon as the pressure has reached that of the atmosphere. Obviously, the smaller the autoclave and the batch, the more effective are these precautions, and it is a practical consideration how far it is possible to reduce the scale of operation. Much trouble arises from an attempt to deal with too much at once. The figures I have quoted above apply only to half-litre containers.

Using this technique, we produce in this hospital dextrose infusions of pH 4·8–5·2 in batches of 50. The period of storage is a most important factor in maintaining this standard. Batches of infusions are given a three-month expiry date, which is quite adequate; there is very little fall of pH over this period, but after nine months to a year the acidity often reaches pH 4·0 or below.

The figures in the accompanying table show titratable acidity in some random samples.

TITRATABLE ACIDITY IN RANDOM SAMPLES OF INTRAVENOUS INFUSIONS

Sample	pH	Ml. of N acid per litre	Age of sample
Dextrose 5%	5·2	0·056	Fresh
Dextrose 4·3% + NaCl 0·18%	5·1	0·090	Fresh
Dextrose 4% + NaCl 0·45% ..	4·2	0·171	1 year
Dextrose 5%	4·4	0·112	6 months
Dextrose 5% + NaCl 0·9% ..	4·2	0·141	6 months

If we take the buffering capacity of normal blood as 28 ml. of N acid per litre, these figures do not appear alarming, and it seems that titratable acidity, per se, is not a menace in infusion therapy (even when venous blood-flow is small), provided the infusion is given slowly. Yet the evidences of local irritation resulting from the infusion of fluids at pH 4·0 and below surely justify an effort to keep the pH of dextrose solutions as far as possible above this figure.

WERNICKE'S ENCEPHALOPATHY

SIR,—In your interesting leading article (Dec. 6) you say that this " disease appears as a sequel to chronic alcoholism, long-continued vomiting of pregnancy, malignant lesions of the gastro-intestinal tract, and primary malnutrition." You certainly refer to papers which are based mainly on cases collected from these categories and, while you do not say so specifically, it is inferred by the authors quoted that the syndrome is met with only rarely, and largely in places like asylums, chronic wards, or prisoner-of-war camps. Indeed, only a few cases of the acute syndrome have been published—e.g., the interesting case described by Jones and Robinson.[1] However, Campbell and Ritchie Russell[2] pointed out that Wernicke's encephalopathy " is a not uncommon condition . . . it occurs as a complication of a wide range of other diseases . . . its incidence in some of these diseases is not generally recognised." The following two case-histories illustrate this statement. (Further details of these and other cases will be published later.)

CASE 1.—A married woman of 43 consulted me during the late war, when she carried on with war work in London. She had a mild hepatitis and symptoms and signs of vitamin-B deficiency (tingling in the limbs and fingers, glossitis, angular stomatitis, scaling of the nasolabial folds, and microcytic anæmia).

I saw her again in August, 1947. For many years she had " turns " at the time of her periods, when she became irritable, quarrelsome, and irrational, and her personality changed completely. Her last period was followed by a sudden " turn " on July 22. On July 24 she had a minor car accident in the grounds of her home and since that time her condition had deteriorated. She complained of splitting headaches, irritability, and a " muddled head." She had previously admitted to taking alcohol, but when I saw her with her husband she insisted that she did not drink even when she had guests.

One day she had laid the table for 8 guests; all the drinks were put out, and she was found semiconscious on the floor. After this she became more and more peculiar and confused, she refused food, and her speech became slurred. As she had fractured her skull at the age of 15, the possibility of a brain tumour was entertained.

She was a well-nourished woman, and lay quietly in bed with eyes closed. She did not recognise her surroundings, and replied incoherently to persistent questioning. She had completely lost her memory, and was severely disorientated in time and place. There was a slight internal strabismus; and abduction of both eyes was incomplete, with horizontal nystagmus. The cranial nerves were otherwise intact. The ankle-jerk was depressed. There was considerable ataxia on standing, and she could hardly walk, even with assistance.

While the husband was collecting some ampoules of aneurine from a chemist about 20 miles away, the servants were questioned. It seemed that the patient had been a secret drinker since April; when guests came along (as they often did) she never touched a drink in their company, but she was often seen in another room drinking a tumblerful of gin or whisky. She would then return to the party and again refuse to touch alcohol. Many empty bottles were found hidden in her wardrobe.

Within two hours of an intravenous injection of 30 mg. of aneurine she recognised the persons present, she could carry on a sensible conversation, and she asked for a meal. The external-rectus palsy became hardly noticeable. The effect did not last long, but another 30 mg. injected next morning was followed by a similar temporary improvement. She was transferred to hospital for further treatment. All the symptoms disappeared within four weeks, the last to go being the ataxia.

CASE 2.—A robust man of 84, with emphysema, bronchitis, and a mild asthmatic state for the past six months, was admitted to hospital with acute retention on Nov. 7, 1948. He had not drunk or smoked for over twenty years. Prostatectomy was performed that night, and the patient's condition was satisfactory for some days after the operation, with the exception of increasing anorexia.

---

1. Jones, F. A., Robinson, V. C. *Lancet*, 1947, ii, 297.
2. Campbell, C. P., Ritchie Russell, W. *Quart. J. Med.* 1941, 10, 41.

On Nov. 12 he was quiet and somnolent, but he answered questions promptly. However, his condition became suddenly worse, and when seen at midnight, he was agitated and talked nonsense continuously for two hours. He pulled the drip needle out, and was restless and confused. He was completely unaware of where he was and unable to answer questions sensibly. He confabulated and was completely disorientated in time and place. The pupils reacted to light and convergence, and there was a moderate bilateral weakness of the external recti. He apparently had diplopia, for he constantly closed one eye. The ankle-jerks were absent and the knee-jerks diminished. Nystagmus was not present and ataxia could not be tested. He had 22 litres of glucose-saline solution in five days, and very little food.

The diagnosis of uræmia was considered; but he was given 100 mg. of aneurine intramuscularly. As the blood-urea level the next morning was 22 mg. per 100 ml., an intravenous injection of 100 mg. of aneurine, 30 mg. of riboflavine, and 200 mg. of nicotinamide was then given three times daily.

His condition improved so much by lunch-time the next day that the glucose-saline drip could be continued, and the doses of aneurine, riboflavine, and nicotinamide were given into the drip for three more days.

On the morning of Nov. 14 he became quite reasonable and clear-headed, though he retained some amnesia about the past two days. All neurological signs disappeared by Nov. 15. Vitamins (50 mg. of aneurine, 20 mg. of riboflavine, and 100 mg. of nicotinic acid intramuscularly daily) were continued until his discharge on Nov. 30.

These two cases are representative of certain types of Wernicke's encephalopathy met with as acute emergencies. Dipsomania may sometimes be hidden even from the closest members of the family. The water-soluble B vitamins, especially aneurine, may easily be washed out from the tissues by continuous glucose infusions, particularly in older patients whose stores are usually very low.[3] [4] This was demonstrated exceedingly well in the cases described by Phillips et al.[5] Their patients received, for the first few days only, glucose-saline infusions which were followed by an intensification of all neurological symptoms and signs.

The condition may easily be mistaken for uræmia or arteriosclerosis, especially where Wernicke's syndrome presents itself with apathy, somnolence, and loss of consciousness. If it happens postoperatively, as in case 2, the continuation of infusions will soon deepen the coma and lead to fatal lesions of the hypothalamus.

London, W.1. Z. A. LEITNER.

PLASMA-UREA LEVELS IN WEST AFRICA

SIR,—In the course of a metabolic investigation on West African subjects, unexpectedly low concentrations of plasma-urea were consistently encountered. An investigation of the "normal" level of plasma-urea, undertaken on a larger series of subjects, confirmed our observation.

The subjects, ten in number, were male West Africans who were employed in the laboratory and who gave no history of renal disease. The estimations were made in samples of heparinised plasma by the method of Karr[6]; the final colorimetric determination was made in a 'Coleman Junior' spectrophotometer set at a wave-length of 5000A°. A number of standard solutions of urea were treated simultaneously and the unknown concentrations read from the standard curve so prepared. As controls a smaller number of plasma samples from European subjects resident in the unit were treated alongside the African samples. A number of the estimations were confirmed by means of the manometric hypobromite method of Van Slyke; good agreement was obtained between the two techniques.

The values obtained, each the mean of determinations on two plasma samples, are recorded in the accompanying table.

PLASMA-UREA CONCENTRATION IN AFRICANS AND EUROPEANS

Africans		Europeans	
Subject no.	Plasma-urea (mg. per 100 ml.)	Subject no.	Plasma-urea (mg. per 100 ml.)
1	15·0	1	31·0
2	13·5		
3	12·7	2	31·8
4	10·6		
5	10·2	3	25·6
6	10·7		
7	11·9	4	24·5
8	16·7		
9	18·8	5	20·6
10	19·6		
Mean	13·9	Mean	26·7

These results may be compared with the finding of Beaudisnet[7] that the average blood-urea concentration of natives of the Cameroons was 17 mg. per 100 ml. There is an indication that these low values may be related to the economic status of the subject operating through the diet; the lowest values observed were in four daily paid labourers, and the higher values in members of the permanent staff.

We would be interested to know whether such low concentrations have been observed in other, similar populations.

CALCIUM CHLORIDE AEROSOL IN CHRONIC BRONCHITIS

SIR,—In patients suffering from chronic bronchitis, wheezing is often a distressing symptom and one which may be hard to relieve. Hitherto such drugs as stramonium, ephedrine, or aminophylline have been given for this purpose by mouth or by injection. The report of Charlier and Phillipot,[8] however, indicated that inhalation of certain preparations in the form of an aerosol might be an effective method of treatment. In particular, the results of these workers with a solution of calcium chloride seemed worthy of further exploration, and a clinical trial was undertaken.

A group of patients with chronic bronchitis and prominent wheezing was chosen: 6 patients were in the geriatric research unit at St. John's Hospital, Battersea; and 12 patients were treated at Queen's Hospital, Croydon. None had any expectorant mixture while under observation; and ephedrine, aminophylline, and other antispasmodics were not used during the experiment. The routine treatment was an inhalation of 3 ml. of a 10% solution of calcium chloride in water three times a day. The fluid was vaporised by means of an oxygen cylinder.

Only 2 of the patients failed to improve, and the remainder gradually lost their wheezing and dyspnœa. On examining the chest, rhonchi and sibili were no longer heard. Most patients began to get relief after the first inhalation, and only one took as long as three days before his wheezing began to go. A woman (who was treated as an outpatient and is not included in this series) stated that she was very short of breath on her way to the hospital before treatment, but could always walk home quite briskly after her inhalation.

As a result of this experiment, several patients with acute exacerbations of chronic bronchitis have been treated with inhalations of either penicillin or streptomycin dissolved in the calcium chloride solution. All responded promptly; and 3, who were treated in the original experiment, lost their wheezing as quickly as before. One of them has had two separate exacerbations cut short in this way. There is at present no evidence to suggest that this technique cannot be repeated time after time without losing its effect. As the solution of calcium chloride is both cheap and easy to prepare, it seems to offer many advantages over other drugs in the treatment of wheezing.

ANOTHER HOT-WATER BOTTLE CASE

SIR,—I should like to add something to the account of this case in your issue of Nov. 29.

The North Liverpool Hospital Management Committee decided to resist this claim after giving the matter careful consideration, although in the present state of the law the prospects of success were not good.

The view of the case which I put before the committee was as follows:

> The patient was admitted to Walton Hospital for her confinement and she was treated with particular care because she had had difficulties over a previous confinement. After delivery there was excessive bleeding which was clearly associated with the retention of a piece of placenta. As soon as this was discovered the midwife in charge sent for the doctors; an anæsthetic was given, and on manual exploration of the uterus a piece of placenta was found and removed. After this there was serious shock, and as a result of hæmorrhage and shock the condition of the patient became very grave. Blood and plasma were administered by intravenous drip; and at one point the doctor in charge, being dissatisfied with the speed of the infusion, asked that additional bottles should be applied with the object of causing dilatation of the superficial veins. The bottles ordinarily used for maternity cases were already in position, and from my investigations it seemed to me that the accepted nursing regulations with regard to hot bottles had been carefully observed throughout. The bottle which caused the burn was one of the additional bottles ordered by the doctor.
>
> In a person with the normal circulation in the skin it is not possible to cause a burn with a bottle used in the way described; but if, for any reason such as deep shock, the circulation is in abeyance the heat is not carried away quickly enough from the part to which the bottle is applied and burning may occur. I regarded the defective circulation as the deciding factor in this case. The patient was suffering from hæmorrhage and shock, and presumably the peripheral circulation was impaired. The burn occurred only at the upper part of the right thigh because this was a relatively resistant part and the weight of the bottle increased the effect of the heat.
>
> The question then arises as to whether the doctor could properly be accused of negligence for ordering hot bottles for a patient in the condition described. Unfortunately he is in Africa and was not available to give evidence; but when I made my inquiries just after the incident he was quite definite in his statement that he had specially ordered the bottles to dilate the veins. Abundant evidence could be called to show that in a patient with a normal circulation this effect will be produced, but it is probable that in a condition of deep shock there will be no such effect and the application of heat will indeed be dangerous. A doctor who is fully alive to this danger may be placed in a difficult position. His patient does not present a static problem: her condition is changing from moment to moment, and whether the change will be for the better or the worse may depend on his treatment. It must be difficult to determine just the point she has reached, and in any case he must give her the benefit of any doubt. If the shock is of a certain degree a burn may easily be caused and the doctor may be faced with an action for damages. It would be deplorable if the fear of possible litigation should interfere with the freedom of his clinical judgment and should deter him from carrying out treatment that he may believe to be the best for his patient.

One of the dangers of a highly organised health service is that methods of treatment may become unduly standardised, and if this should happen any departure from orthodoxy would become grounds for a successful claim for damages.

In the trial of the case expert evidence was called to describe the theory of burning in cases of shock set out above; but it was admitted that this theory was not as yet the view of all the members of the profession; and apparently the judge did not accept it.

In reaching his judgment the judge came to the conclusion that there must have been negligence in the use of the water-bottles by someone, possibly a nurse who had not been called. The defence was unable to prove a negative; and, as you have reported, damages were awarded. In making this assumption the judge was able to make a decision without bringing in the question of medical responsibility for an injury resulting from treatment given in good faith and with every care; so this important issue was left undecided.

HENRY H. MACWILLIAM
Late Medical Superintendent,
Walton Hospital, Liverpool.

SUCCINYLCHOLINE APNŒA

SIR,—Several cases of long-continued apnœa following the use of succinylcholine have now been reported. The following case includes features that have not hitherto been described.

The patient was a man, aged 48, weighing 9 st. 6 lb., who had carcinoma of the rectum. Resection of the growth followed by end-to-end anastomosis of colon to rectum was performed. The premedication was 'Omnopon' gr. $^1/_3$, scopolamine gr. $^1/_{150}$. The preoperative blood-pressure was 120/80 mm. Hg.

The throat was sprayed with 2% amethocaine hydrochloride. A drip was set up comprising a 0·16% solution of succinylcholine chloride in normal saline solution. Thereafter the sequence of events was as follows:

2.23 P.M.—Induction of anæsthesia with 8 ml. of 5% sodium thiopentone solution. The drip was set going at 30 drops per minute. An endotracheal tube was introduced under direct vision and the throat packed off. Gas/oxygen (6 : 2) administered by semi-open circuit without an absorber.

2.26 P.M.—Pethidine 25 mg. intravenously. The patient was put into the Trendelenburg position with a 20° tilt.

2.30 P.M.—Operation begun.

2.34 P.M.—As the muscles were obviously "tight" the drip was speeded to 50 drops per minute for the peritoneal opening. Adequate spontaneous respiration.

2.37 P.M.—Thiopentone 2 ml.

2.39 P.M.—The surgeon complained that the peritoneum was tight. Drip speeded to 70 drops per minute to give adequate relaxation. Small spontaneous respirations present. Respiration assisted.

2.42 P.M.—Self-retaining retractor introduced. Drip slowed to 52 drops per minute. Adequate spontaneous respiration.

2.44 P.M.—As relaxation was adequate the drip was slowed to 44 drops per minute, and this rate was found to give satisfactory relaxation.

2.57 P.M.—Pethidine 25 mg.

3.6 P.M.—Thiopentone 1 ml.

Since the commencement of the resection the blood-pressure and pulse (which were taken at 5-minute intervals) had varied little, the former being 100/70, and the latter 92 per minute. The respiration, except for the period 2.39–2.42 P.M., had been fully adequate to maintain good oxygenation. There had been no undue trauma and the patient had lost relatively little blood.

3.36 P.M.—As the surgeon commenced the anastomosis, it was noted that the respirations had become very small and that the blood-pressure had dropped to 70/50. The drip was slowed from 44 to 22 per minute and the respirations assisted. A few minutes later no spontaneous respirations could be detected. The drip was further slowed to 14 drops per minute.

From 3.38 to 3.58 P.M. the blood-pressure remained at about 65/45, and the patient remained in apnœa from about 3.39 to 3.50 P.M. However, the skin was warm and of good colour, the peripheral veins were full, and the arteriocapillary reflex time remained good.

3.58 P.M.—It was decided to stop the succinylcholine administration, replacing it with dextran, which was run at about 80 drops per minute. (Unfortunately there was no blood available for administration on the lines suggested by Evans et al.[1]) Small spontaneous respirations. Respiration assisted.

4.6 P.M.—Pethidine 25 mg.

4.8 P.M.—Closure of the peritoneum was begun. The peritoneum was a little tight but the closure was managed without undue difficulty; it was considered inadvisable to administer any relaxant.

4.30 P.M.—*Operation ended.*

Between the closure of the peritoneum and the termination of the operation the blood-pressure had gradually risen to 85/40. At 4.25 P.M. the respirations became deeper and no longer required assistance, and at 4.35 P.M. the respirations were of good amplitude, although the rate was only 10 per minute, and the general muscle tone was fairly good. The cough reflex was not present on extubation. The further course of the case was uneventful.

The total amount of succinylcholine chloride given was 384 mg. (240 ml.).

This case has several unusual features:

1. The drip-rate required to produce adequate relaxation for the exploration of the abdomen (70 per minute) is, in my experience, much higher than the average.

2. After maintaining spontaneous respiration for 1 hour 8 minutes the patient suddenly became apnœic without any concomitant acute surgical or anæsthetic reason.

3. After the blood-pressure had remained steady for about 40 minutes it suddenly dropped severely and remained low without any apparent surgical or anæsthetic cause. The pulse, which had remained at about 92 per minute, rose at 3.36 P.M. to 120 per minute, and remained at this rate till the end of the operation.

4. During the period of hypotension the patient's condition strongly resembled that of a patient under hexamethonium.

The events in this case are not easily explained. I have used this technique without any such hazard in a large series of cases, including many where the total dose was much greater and where the duration was considerably longer. It is possible that the production of cholinesterase became exhausted or ceased temporarily, and the consequent rapid build-up of succinylcholine resulted in a high degree of myoneural block and, in addition, gave rise to autonomic-ganglion block.

Bovet et al.[2] and other workers have, however, found no evidence of the occurrence of autonomic-ganglion block with succinylcholine. In any case it is difficult to see why the production of cholinesterase should suddenly become insufficient after being maintained for over an hour in adequate quantity.

Manchester. MARK SWERDLOW.

SIR,—We should now like to report the results of the further work on plasma-cholinesterase levels to which we referred in our earlier note (Sept. 27). The main facts are summarised in the accompanying table, from which it will be seen that the depression of plasma-pseudocholinesterase is much greater in patients showing delayed recovery from succinylcholine ('Scoline') than that estimated on whole blood. This is what we expected, and confirms the work of Bourne et al.[3] and Evans et al.[4] Perhaps we did not emphasise sufficiently in our previous letter that the simple Michel electrometric method is equally applicable to the estimation of plasma-pseudocholinesterase and is not restricted to determinations on whole blood. Our intention was to point out that this simple technique is a sufficiently sensitive measure of cholinesterase activity to confirm the findings of other workers using the more accurate Warburg technique.

Of particular interest is case F. In this case the estimation of cholinesterase activity was carried out nine months after the observation of prolonged apnœa after administration of succinylcholine. We would b glad to hear of any other cases in which the cholinesteras level has been found to be lowered over so long a period Aldridge and Davies[5] cite evidence that after poisonin with organo-phosphorous compounds regeneration o cholinesterase is slow. In this connection it is perhap significant that for three months in the early part of thi year patient F was employed at work which entaile contact with shale-oil distillates.

FINDINGS IN SIX CASES AFTER ADMINISTRATION OF SUCCINYLCHOLINE

Case	Duration of apnœa (min.)	Whole-blood-cholinesterase number *	Plasma-cholinesterase number *
A	<5	139	77
B	<5	126	100
C	<5	112	88
D	10	99	26
E	20	100	40
F	60	108	29

* The "cholinesterase number" is the fall in pH of a buffer syste produced in 1 hour by 0·1 ml. of whole blood or plasma × 10 The normals are given by Aldridge and Davies[5] as whol blood 80–129, plasma 40–100.

Royal Victoria Hospital, Belfast.

J. E. REID
D. W. NEILL.

ŒSOPHAGEAL CONTRACTION AND CARDIAC PAIN

SIR,—Dr. William Evans in his article on this subject (Dec. 6) describes certain changes in the behaviour of the œsophagus during the swallowing of thick barium paste as œsophageal arrhythmia. The phenomenon appears to be identical with a normally functioning phrenic ampulla,[6] from which Dr. Evans gives no differential diagnosis. Furthermore, he states that œsophageal arrhythmia in health is not uncommon, but he makes no reference to the stage of respiration at which the phenomenon was observed.

We believe that this phenomenon, associated with the formation of a phrenic ampulla, can be seen in the majority of normal individuals, if instructed to hold the breath in the inspiratory position as the bolus is passing through the lower œsophagus. The reasons why a phrenic ampulla is produced are not yet full understood.

Radcliffe Infirmary, Oxford.

F. H. KEMP.

DANCKWERTS AWARD

SIR,—The distribution of back pay has given a chance to medical practitioners to help the Royal Medical Benevolent Fund. In fact this letter was suggested by a writer enclosing a cheque for £50; and several other contributions of a similar amount have already been received.

With the rising cost of living there are many old people trying to make ends meet on meagre incomes. The urgent need is for increased grants. I appeal to your readers, who are willing to help this deserving charity, to send their cheques to the Secretary, Royal Medical Benevolent Fund, 1, Balliol House, Manor Fields, Putney, London, S.W.15.

FRANK JULER.
Hon. Treasurer.

Obituary

KAREN HORNEY

M.D. Berlin

Dr. Horney, founder of the American Institute for Psychoanalysis, died in New York on Dec. 5.

She was born in Hamburg in 1885, and she obtained her medical qualification in Berlin, where she also received her psychiatric and psycho-analytic training. She was a member of the Berlin Psycho-analytic Institute from 1920 until 1932, when she went to America and settled there.

K. T. writes: "Dr. Horney's early contribution to psycho-analytic literature already showed that spirit of independent thought and argument which has been the outstanding characteristic of her scientific career. She threw doubt on the validity of Freud's exclusively phallic conception of infantile sexuality, and her alternative views on the psychosexual development of women have since been widely accepted.

"Life in the United States seemed to kindle the spirit of independence in her. She began to examine critically the premises and concepts of psycho-analytic teaching which, she said, had 'come into a blind alley, manifesting itself in a rank growth of abstruse theories and the use of shadowy terminology.' Her declaration of independence was set out in a series of books, appearing between 1936 and 1951—*The Neurotic Personality of Our Time*, *New Ways in Psychoanalysis*, *Self-Analysis*, *Our Inner Conflicts*, and *Neurosis and Human Growth*. In 1941 she founded the American Institute for Psychoanalysis for the teaching and propagation of her views.

"She rejected Freud's biological and 'instinctivistic' orientation and replaced it by a cultural and sociological approach. She held that the main motive force of human behaviour did not, as Freud thought, lie in instinctual urges to obtain satisfaction, but in a universal desire for safety in a world that was considered as menacing. The core of neurosis was not a libidinal conflict, but a basic anxiety about being lonely and helpless in a hostile social environment. To overcome this basic anxiety three kinds of attitude could be adopted in human relationships: a movement towards people, causing 'compliant' personality types yearning for the affection of others; a movement against people, producing 'tough' persons striving for power, prestige, and possessions: and a movement away from people, causing 'detached' and emotionally distant personalities.

"Karen Horney has sponsored new ways in psycho-analysis which have run close to the modern trend of thought in social psychology. Her emphasis on the importance of cultural differences and on the significance of interpersonal relations in the moulding of character and personality has appealed to many who were unable to follow more orthodox psycho-analysts into the labyrinthine recesses of intrapsychic conflicts."

Births, Marriages, and Deaths

BIRTHS

ALLEN.—On Dec. 6, at Farley House, Farnborough, Hants, to Edna (née Browne), wife of Dr. P. L. Allen—a son.

HARVEY.—On Dec. 7, to Jean (née Jeffery), wife of Mr. Thomas G. Harvey F.R.C.S., of Upper Basildon, Berks—a daughter.

MATTHEWS.—On Dec. 9, at Lambeth Hospital, to Mary (née Dendy), wife of Dr. Michael Matthews—a daughter.

MARRIAGES

DOW—MILLBANK.—On Nov. 28, at Shoeburyness, James Dow, M.B., to Jean Millbank.

SETH-SMITH—REID.—On Nov. 29, David William Seth-Smith, M.R.C.S., of London, to Jean McClymont Reid, of the Argentine Republic.

DEATHS

BODMAN.—On Dec. 7, at Addlestone, Richard David Bodman, M.A., M.B. Brist., aged 43.

DAY.—On Dec. 9, at Hans Place, London, Bernard Day, M.D. Camb., M.R.C.P., formerly of Kuala Lumpur.

EVE.—On Dec. 7, Frank Cecil Eve, B.A., M.D. Camb., F.R.C.P., of 9, Newbegin, Beverley, Yorkshire, aged 81.

HARTLEY.—On Dec. 6, at Headington, Oxford, Harold Hartley, M.D. Lond., F.R.C.S., aged 79.

ORD.—On Dec. 7, at Dumfries, Gavin Ernest Ord, O.B.E., M.B. Aberd., lieut.-colonel, R.A.M.C. retd.

PIGOTT.—On Dec. 8, at Shrewsbury, John George Glynn Pigott, O.B.E., L.R.C.P.I.

WATSON.—On Dec. 6, George Trustram Watson, O.B.E., M.A., M.B. Camb., F.R.C.S., of Tunbridge Wells.

Notes and News

U.S. HEALTH PLAN

LAST January President Truman set up a commission, under the chairmanship of Dr. Paul Magnuson, to review the health needs of the United States "from an impartial and non-controversial viewpoint." The report of this commission was being published on Dec. 18. Dr. Magnuson has announced (*New York Times*, Dec. 4) that the commission believes that comprehensive health care can be made available to all the people in the United States on an insurable basis without continuing federal subsidies. It believes that any scheme should be started by "the people at the grass roots" by the extension of existing voluntary and industrial health prepayment schemes. "The job can be done by private plans, by the tremendous medical set-ups of industry, by the doctors in the home town," Dr. Magnuson said. "Federal grants in aid can be used to stimulate the growth of private prepayment, but without continuing subsidies." He added that the commission contemplated health centres being set up and run by local communities, all the work being done by local doctors and the nearest group of consultants. Federal grants in aid might be used to stimulate the growth of diagnostic centres, to build up health personnel and facilities, and for large-scale research.

ELIZABETHAN PHYSICIAN

Dr. Walter Baily, physician to Queen Elizabeth I, is known to fame for having tactfully refused to provide the henchmen of Lord Robert Dudley with a bottle of physic for the unhappy Amy Robsart. He thought, not without reason, that poison might be added before it was administered, and he had no wish to be hanged as a cover for someone else's sin. Little else is known about him. Mr. Horton-Smith [1] has traced the descent of the Baily family through seven generations, starting with the physician's father. The text of this book is crowded with detailed bibliographical material. Though it is written in legal language and cannot be read at all easily, it contains a vast amount of detailed research which will be of great value to anyone interested in the family.

ADVERSITY OVERCOME

Dr. Carlson's autobiography [2] which appeared in the United States in 1941, has now been published in this country. It is an inspiring account of how a "spastic" has overcome both poverty and his disability, and has been able to qualify in medicine and devote his life to those similarly afflicted. Perhaps the most striking part of the book is the account of his visit to relatives in Sweden "who found it strange that their contact with members of the family who had gone to America should be resumed through the appearance of the one least fitted for survival." The book would interest any kind of reader, but it can be specially recommended to the parents of children with cerebral palsy, or indeed with physical handicaps of any kind.

University of Oxford

Sir Howard Florey, F.R.S., has been elected to an honorary fellowship at Magdalen College.

University of Cambridge

The Raymond Horton-Smith prize for 1951-52 has been awarded to Dr. D. R. Smith and Dr. J. P. Henry.

Royal College of Physicians of Ireland

On Dec. 5 the following, having passed the final examination of the Conjoint Board of Ireland, were admitted licentiates in medicine and midwifery:

K. A. Beahan, Adrian Blake, M. F. Bonar, Romuald Calo, G. J. Coghlan, A. W. Eldemire, J. E. Fahy, M. B. Griffin, W. W. Kobler, L. G. Meagher, Pawel Michalski, J. A. Moffitt, Dermot MacAlister, Frank McCrystal, Marianne Neumann, William Nolan, Gertrude Shaw, Gustawa Stendig, H. R. Trueman, Audrey Wilkinson.

Welsh National School of Medicine

Dr. H. J. Whiteley has been appointed senior lecturer in the department of pathology and bacteriology. Dr. Whiteley is at present lecturer in pathology in the University of Sheffield.

[2] Born That Way. By EARL R. CARLSON, M.D. Evesham: Arthur James. 1952. Pp. 136. 8s. 6d.

Royal College of Surgeons of England

At a meeting of the council on Dec. 11, with Sir Cecil Wakeley, the president, in the chair, Mr. A. Dickson Wright was admitted to the court of examiners. A Moynihan lectureship was awarded to Dr. Richard B. Cattell, of the Lahey Clinic, Boston. Mr. G. T. Hankey was appointed Charles Tomes lecturer for 1953, and Prof. H. F. Humphreys Webb-Johnson lecturer for 1954. The Begley prize was presented to J. H. Breed (Westminster Hospital).

Diplomas of fellowship were granted to the following:

C. H. J. Rey, E. H. L. Cook, J. R. G. Edwards, J. N. Aston, Francis Glassow, E. A. Malkin, Leslie Turgill, P. S. Jaikaran, D. G. Maurice, Rustam Jehangir Moolan-Feroze, Helen M. Mellor, P. R. French, M. F. Hunt, G. L. Bourne, T. H. Morgan, L. A. J. Evans, M. H. Stroud, W. R. Denny, P. G. Bevan, Irene M. S. Cade, A. J. Harrold, Cyril Havard, D. J. Oakland, R. A. Payne, R. L. Grynoch, D. W. T. Roberts, Hari Ratan Ker, Joyce M. Daws, [illegible] nu Pada Chatterjee, Arun Kumar Gupta, [illegible] Brun, P. D. Blaxland, J. C. FitzHerbert, [illegible] e Panduranga Pai, H. M. Shaw, E. L. G. [illegible] W. B. Law, Cicely Pepler, R. R. Spencer, [illegible] Henley, G. G. McCloskey, D. H. McMillan, [illegible] G. Moffoot, R. K. Newing, L. H. Pimm, [illegible] G. E. Schofield, G. K. Thomas, M. A. Birnstingl, J. E. Blundell, D. J. Crockett, Kathleen A. M. Frith, N. T. Hamilton, T. A. H. Hurrell, R. O. Parnis, B. E. Pierard, Timothy Savage, Mirisse Hewage Gunadasa Karunatilaka Siriwardena, J. B. L. Taylor, J. G. Toakley, D. J. Tuffley, S. E. Wijetilaka, G. G. Wyllie, Robert Alhadeff, Yahya Cohen, J. L. Connell, W. T. Irvine, D. G. Lane, H. K. McComb, B. V. McEvedy, P. D. O'Donoghue, Guan Bee Ong, A. D. Roy, Geoffrey Wilson, A. F. Grant, G. M. Linehan, T. P. Nash, Nemish Ambalal Shah, J. H. Shoesmith, S. R. Young, J. S. Brown, W. D. Friend, Vithal Madhav Kini, R. M. Mitchell, J. B. Self, W. R. T. Turner, J. S. Karanwal.

A diploma of membership was granted to J. A. McHardy.

Association of Surgeons of Great Britain and Ireland

The annual meeting of this association is to be held in London from April 30 to May 2. The following subjects have been chosen for discussion: Management of Cancer of the Breast (opening speakers, Mr. H. J. B. Atkins and Dr. Gwen Hilton); Perforated Peptic Ulcer (Mr. T. Stewart Heslop); Postoperative Strictures of the Bile-ducts (Mr. Rodney Maingot); *Crohn's Disease (Mr. Harold Edwards).*

World Health Organisation

Dr. Brock Chisholm, director-general of W.H.O. since 1948, has announced that he has decided not to accept the three-year renewal of his contract offered him by the World Health Assembly last May. His present term of office expires in July.

Dr. Jerome S. Peterson (New York), who has been chief medical officer of the United Nations Relief and Works Agency for Palestine Refugees in the Near East, has taken up his appointment at W.H.O. headquarters in Geneva as director of the division dealing with the organisation of public-health services. He succeeded Dr. V. Sutter, who is now assistant director of W.H.O., on Dec. 8.

Swedish Health Insurance

A government committee has proposed that compulsory health insurance for all citizens should be introduced in 1955. The scheme would be combined with a system of voluntary insurance and coördinated with the present accident insurance scheme. The annual cost is estimated at nearly Kr. 700 million (£48,200,000), of which Kr. 206 million will be covered by state grants, Kr. 311 million by private contributions, and Kr. 180 million by employers' contributions.

Emergency X-ray Service

A memorandum (M.O. 209/77/1) from the Ministry of Health suggests ways in which hospitals may provide an X-ray service at times outside the normal working hours of the X-ray department. Regional boards and management committees are asked to review their present arrangements, and to consider one of two plans should a change seem advisable. Under "stand-by arrangements" a radiographer is available at the hospital at night and at weekends; and under "on-call arrangements" the radiographer leaves the hospital but is prepared to be recalled for an emergency. With either scheme radiographers should receive time off during the day in place of time spent on duty out of normal hours. The stand-by system is suitable for large hospitals where night and weekend calls are frequent; and the memorandum suggests that such a hospital might provide a service for other hospitals in the group by arranging for patients to be referred to that hospital when other X-ray departments are closed.

Scottish R.H.B. Appointment

Mr. Edward Macintosh has been appointed chairman of the Northern Regional Hospital Board in succession to Mr. James South who has resigned from this office, but who is to continue as a member of the board.

The Company of New Elizabethans

This company has been formed to raise the standard of reading for children and to combat the influence of the "unwholesome publications of low intelligence and doubtful morality" now often offered to them. Further particulars may be had from the secretary of the company, 12, St. James's Place, London, S.W.1.

New Chest Hospital in Northern Ireland

The Northern Ireland Tuberculosis Authority has announced that the ministry of finance has approved *in principle* of the project to build a three-storey 500-bed chest hospital at Brookhill, near Lisburn, co. Antrim, at a cost of £2 million. Work will begin next spring and it is expected that the first patients will be admitted to the hospital in three to four years' time.

Diary of the Week

DEC. 21 TO 27

Monday, 22nd

ROYAL EYE HOSPITAL, St. George's Circus, Southwark, S.E.1
5 P.M. Dr. T. H. Whittington: Astigmatism and Treatment. Factors affecting Binocular Vision.

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5.30 P.M. *Section of Odontology.* Dr. C. H. Tonge: Early Development of Teeth.

MANCHESTER MEDICAL SOCIETY
9 P.M. (University of Manchester) *Section of General Practice.* Prof. W. F. Gaisford: Acute Infections in Childhood.

Appointments

DUDDINGTON, A. J. E., M.B. Lond., D.P.M.: asst., dept. of psychological medicine, St. Luke's Woodside Hospital, London.

GILLIES, HUNTER, M.D. Glasg., F.R.C.P.E., D.P.M.: part-time consultant, psychiatric wards, Stobhill General Hospital, Glasgow.

GREEN, D. L., M.B. Sydney, F.R.C.S.: surgical registrar, Cheltenham General Hospital, Cheltenham.

HARRISON, IRENE, M.B. Cape Town, D.C.H.: asst. M.O., West Ham.

HOBSON, R. F., B.A., M.D. Camb., D.P.M.: asst., outpatient dept. of psychological medicine, Middlesex Hospital, London.

HUTCHISON, ALEXANDER, M.D., PH.D. Glasg., F.R.F.P.S., D.P.H., D.P.A.: M.O.H., Hull.

MCDONALD, CHRISTINA, M.B. Dubl.: asst. M.O., West Ham.

MINOGUE, FRANCES, M.B. N.U.I.: S.H.M.O., Royal Western Counties Institution, Starcross.

PENMAN, AGNES, M.B. Edin., D.OBST.: asst. M.O.H., Kirkcaldy.

RAINSFORD, C. R. C., M.D. Belf., D.P.H.: asst. county M.O. and M.O.H., Retford borough and rural district, Notts.

East Anglian Regional Hospital Board:

ABSON, E. P., M.B. Manc., D.OBST.: surgical registrar, United Norwich Hospitals.

JENNINGS, H. B. N., M.D. Lpool, D.OBST., D.P.M.: consultant psychiatrist, St. Andrew's Mental Hospital, Northampton.

JENNINGS, J. H., M.B. Edin.: surgical registrar, West Suffolk General Hospital.

MACGILLIVRAY, R. C., M.B. Edin., F.R.F.P.S., D.P.M.: asst. psychiatrist, Little Plumstead Mental Deficiency Colony.

MILLER, W. T., M.B. Aberd.: medical registrar, Nayland Sanatorium.

MORLEY, J. S. J., M.R.C.S.: surgical registrar, Norfolk and Norwich Hospital.

O'SULLIVAN, J. G., M.B., M.A.O. N.U.I., M.R.C.O.G.: registrar in obstetrics and gynæcology, East Suffolk and Ipswich area.

Appointed Factory Doctor:

DAMREL, J. R. G., M.R.C.S.: Rocester district, Stafford.

MCGREGOR, A. MCK., M.B. Aberd.: Westray district, Orkney.

MORRISON, JOHN, M.B. Aberd.: Portree district, Inverness.

YOUNG, ANGUS, M.B. Glasg.: Bonnybridge district, Stirlingshire.

Staffordshire County Council:

CAMERON, A. N., M.B. Lpool, F.R.C.S.E., D.O.M.S.: ophthalmic specialist.

PRECISION IN DIAGNOSIS

JOHN W. TODD
M.D. Lond., M.R.C.P.
CONSULTANT PHYSICIAN, FARNHAM HOSPITAL, SURREY

THERE is a widespread assumption that it should be possible to attach to a patient a diagnosis. The perusal of a death-certificate book, for example, makes it clear that people have to die of some definite disease; no provision is made for them dying of "an obscure and baffling illness." Even such comparatively definite conditions as "cardiac failure" are condemned in the introduction, the reader being urged to employ instead some such pathological term as "myocardial degeneration." In the Services, in order to be invalided a man must have a disability; these procedures cannot be justified merely on the grounds that he has been found useless to the Service. In civil life the medical history sheets of hospitals have a small space for the diagnosis. If this is left blank or filled by some vague term an objection may be raised on the ground that the patient's condition cannot be classified properly in the card-index system. And medical students are given the impression that the bewildering diagnostic problems which they study in the wards and outpatient departments are capable of solution.

In an official work, *The Nomenclature of Diseases*, published by H.M. Stationery Office and drawn up by a committee appointed by the Royal College of Physicians of London, is listed a vast number of diagnoses. Although it is not stated that to every patient can be attached one of them, many people seem to act as if this were so, and the fact that a diagnosis appears in the *Nomenclature* gives it official status.

The *British Medical Journal*[1] says:

> "... W.H.O. has published a small booklet that describes the structure of the death certificate; explains the importance of recording the causes of death lucidly, concisely, and in correct order if the certifier's meaning is to be properly understood; and illustrates what is meant by direct antecedent, underlying, and contributory causes of death and how they should be distinguished and recorded. The underlying cause of death, which is the one selected for statistical assignment, is the condition which initiated the train of events leading to death; in a properly completed certificate it would be the last or the only cause to be mentioned in Part I of the form. The booklet also explains why certain terms are considered indefinite or inadequate and lists many of the descriptions that are found unsatisfactory and that lead to requests for clarification or for additional details."

All this seems to imply that if a doctor is shrewd enough and careful enough it is *possible* for him so to complete a death certificate that the statements therein explain just why the patient has died.

Finally, a perusal of medical textbooks gives the impression that patients can be fitted into some more or less definite category. The books are divided into chapters dealing with the diseases of the different systems of the body, with additional chapters devoted to general diseases such as the specific fevers. Even the chapter devoted to psychological disorders may be divided under such headings as "schizophrenia," "anxiety neurosis," and "hysteria," suggesting that in practice patients satisfactorily fit into these categories. With the organic diseases is a section devoted to pathology. Only in a few conditions, idiopathic epilepsy and migraine for example, will it be stated that there is no convincing pathological basis. Similarly, with the psychological disorders may appear a section on "psychopathology," often couched in the most confident terms.

THE NATURE OF DIAGNOSIS

It is apparently taken for granted that everyone knows what diagnosis *is*. At first glance the dictionary definition —"identification of disease by means of patient's symptoms &c." (*Concise Oxford Dictionary*)—may seem satisfactory. But many people with symptoms are clearly not suffering from anything which is usually described as a *disease*—typically those with a condition often given the name "anxiety neurosis." A better definition of diagnosis would therefore be "the provision of an explanation of the patient's symptoms."

The symptoms can never be explained wholly by a single organic cause; the patient's state of mind must also be taken into consideration. The degree of pain felt by an injured man does not depend on the nature of his injury alone. If he is of sensitive temperament he may suffer great pain; if he is phlegmatic and unimaginative his pain may be slight. If the suggested definition is accepted, therefore, a complete diagnosis cannot consist of a single disease entity. Nevertheless, in the case of most acute and recoverable conditions, for all practical purposes the psychological aspect of diagnosis can be left out of consideration. It makes very little difference to the assessment and management of a case of acute appendicitis that the patient is of sensitive temperament and constantly groaning or grimacing, or of phlegmatic temperament and lying impassively in bed without a murmur. In regard to progressively fatal diseases, too, the organic process is so overwhelmingly important that a diagnosis consisting of this alone is adequate.

But when a patient has a chronic and comparatively benign organic process a purely organic diagnosis is sometimes incomplete, and may be positively misleading. If a man with a sebaceous cyst which he is convinced is a cancer is given the diagnosis "sebaceous cyst," he is obviously being diagnosed wrongly. No-one would dispute that this unqualified organic diagnosis is wrong, and few would be so narrow in their outlook as to make it. But when the psychological element is not so conspicuous a purely organic diagnosis can more easily be made and may have disastrous consequences.

Striking examples of this error are those cases in which an improper surgical operation follows upon the mistaken diagnosis. A fruitful field is the chronic orthopædic conditions; and the orthopædic surgeon who ignores his patients' personalities while concentrating his whole attention upon deformities, bones, and ligaments is a menace. He may operate upon complaining hysterics with hallux valgus, pes cavus, or persistent sciatic pain, who subsequently stay in hospital for months and complain far more than they ever did before their operations.

The subjects of valvular heart lesions which do not much impair cardiac function may be diagnosed and managed very wrongly if they are studied from a purely organic angle. Dizziness, aching in the chest, and palpitation, do not justify the unqualified diagnosis "mitral stenosis," since this does not explain these symptoms. This mistaken diagnosis may be followed by the failure of the doctor to explain the true cause of these symptoms, and the patient will probably take it for granted that they are all due to a badly diseased heart. Whereas a correct diagnosis and a full reassurance and explanation may diminish or abolish the symptoms and improve the patient's state of mind.

The diagnosis in a patient with a chronic and fairly innocent organic lesion should, then, consist not merely of the name or description of that lesion. In addition, there should be some reference to the state of mind.

---

[1] Leading article, *Brit. med. J.* 1952, i, 641.

THE DIAGNOSIS OF BODILY SYMPTOMS

If these considerations are ignored, and it is assumed that a single label can rightly be given to subjects with bodily symptoms, it is still often impossible to make a satisfactory diagnosis.

Many syndromes, which appear to be more or less definite entities, such as most varieties of non-articular "rheumatism," have no convincing pathology. But patients who complain of pains in the back, neck, or limbs, "pins and needles" and numbness in the hands, and the other symptoms of this group of disorders may be given such labels as "fibrositis" or "neuritis." Fanciful pathological states may be hypothesised, and even described in textbooks, with descriptions of round-celled infiltration, aggregations of fibroblasts, and œdema around nerve-fibres.

In recent years many symptoms of this type have been ascribed to prolapsed intervertebral disc, especially when pain is severe and there is objective evidence of trouble in the shape of diminished deep reflexes, muscular wasting, and stiffness of the back. No doubt there are good reasons for supposing that prolapsed disc is a real condition which explains many symptoms, but it is well to remember that before it was discovered many of the patients who would now be given this diagnosis were confidently stated to be suffering from "sacro-iliac strain" or brachial or sciatic "neuritis."

A proportion of dyspeptic symptoms can truthfully be ascribed to definite pathological causes, such as carcinoma of the stomach, peptic ulcer, colitis, and pancreatitis. But many dyspeptic subjects who appear to be free of relevant pathological changes may be told they have chronic gastritis, colitis, visceroptosis, hyperchlorhydria, and various other conditions bearing little or no relation to their symptoms. Diagnoses of this kind tend to vary from year to year according to current fashions, and the patient who thirty years ago might have been considered to have visceroptosis would, twenty years later when the gastroscope had become a popular instrument, have been thought to be suffering from chronic hypertrophic gastritis.

It is now widely believed that psychological upsets may cause dyspeptic symptoms, and many dyspeptic subjects have been given—no doubt correctly in some cases—psychological diagnoses. But to diagnose "anxiety neurosis," or even nervous dyspepsia, merely because organic lesions have been excluded is just as mistaken as is diagnosing visceroptosis from the radiological demonstration that the hollow viscera are situated unusually low in the abdomen. There are surely many dyspeptics who can no more be given a psychological than an organic diagnosis, though whatever the main cause of dyspepsia—or equally when there is no definite cause—emotional disturbances will often aggravate the symptoms.

Perhaps the commonest of all symptoms is headache. In medical articles elaborate classification of the causes of headache may be given, including a variety of intracranial states from cerebral tumour to migraine, affections of the skull, cranial air sinuses, and the structures overlying the skull, such as "fibrositis" of the fascii or "neuralgia," prolapsed cervical disc, numerous general or distant disturbances such as fevers, chronic constipation, high blood-pressure, and eyestrain, and "psychoneurosis" and other psychological disorders. But in a high proportion of the common cases of chronic or recurrent headache there is no good evidence that any organic condition is present—or if present is related to the headache. Leaving aside those who complain of pressure on top of the skull and such sensations as numbness and deadness, there is also rarely sufficient reason for diagnosing "psychoneurosis," though emotional stress is often related to individual attacks of headache.

As a rule, therefore, the only diagnosis which can truthfully be given to the subjects of headache is "headache," though in some cases a guarded psychological diagnosis can be added, and in others there is justification for using the term migraine. But the desire to attach definite labels is responsible for many wrong diagnoses. If the blood-pressure of those with headache is high, they may be said to have hypertension; if their cranial air sinuses reveal such radiological changes as thickened lining membrane, they may be said to have sinusitis; and if they have errors of refraction they may be supplied with spectacles, implying that their eyes are responsible. (It is not denied that there is never any association between raised blood-pressure and headache, nor that sinusitis and refractive errors are sometimes responsible for headache.)

PSYCHOLOGICAL DIAGNOSIS

Psychological disorders, since by their nature they lack an organic basis, are less satisfactory to those who like to deal with precise entities than are organic diseases. Nevertheless, even in the psychological field many fairly definite labels are now commonly attached to patients—such as manic-depressive psychosis, schizophrenia, involutional melancholia, conversion hysteria, and anxiety neurosis. Many of these labels may sometimes make genuine progress, by implying a fairly definite mode of behaviour and prognosis. But among that vast mass of humanity who forever remain outside the walls of mental hospitals but provide so high a proportion of the patients who frequent doctors' surgeries, it may well be doubted whether exact labels of this kind often reflect accurately what is happening. Do not such homely phrases as "depressed and worried about himself," "nervous and irritable," and "stupid and self-centred" often give a better understanding of the symptoms?

DISCUSSION

In the wards of hospitals patients affected by gross and often obscure organic lesions tend to be collected. Here it is often possible to reach a more or less precise pathological diagnosis. Should the patient's disease remain in doubt when he is alive, it may become apparent when he is on the post-mortem table—at least, if he dies between childhood and advanced middle age.

It is in the surgeries of the general practitioners that those numerous people with vague complaints without definite pathology congregate, and medical students do not penetrate there. In recent years such cases have increasingly overflowed to the outpatient departments of hospitals, often to the dismay of those medical men to whom an "interesting case" is one with gross lesions and striking physical signs. But medical students may still see comparatively little of them because the chief may select the "interesting" cases, while the others are relegated to the small rooms where registrars and clinical assistants work alone.

The great stress which is laid upon pathology is also illustrated by the frequent references to the practice of "excluding organic disease." It is commonly said that, before labelling a patient with bodily symptoms as neurotic, no effort should be spared to exclude organic disease. But this practice is demonstrably false for several reasons:

(1) The only good ground for concluding that a patient is neurotic is from the positive evidence that his behaviour and symptoms are of a neurotic character.

(2) The patient who has organic disease may also be neurotic, and the disease may be irrelevant to his symptoms, which are of psychological origin.

(3) The patient who is apparently free of any definite pathological state may not be neurotic.

(4) It is often impossible to exclude organic disease by any method short of exploratory operation—and even that may be unsuccessful. How can a cerebral glioma, a carcinoma of the body of the pancreas, a prolapsed disc, or atheroma of the coronary arteries be excluded ?

The most important reason for the great stress which is laid upon pathology in hospitals is no doubt the desire for definiteness. And the discovery of a pathological basis is a clear advance in the understanding of a patient's symptoms. By contrast, a syndrome of the muscular "rheumatism" group, recurrent headache, and the vague symptoms bound up with psychological disturbances appear to many of those with "tidy" minds highly unsatisfactory and hardly real.

Medical and surgical treatment, too, is often effective for cases with known pathology. Whereas the other cases are seldom fatal, may seem trivial, and as a rule can be treated only by symptomatic drugs, physiotherapy (the value of which is highly problematical), and reassurance, explanation, and encouragement—remedies in which many medical men take little interest.

There is, indeed, a profound desire in men's hearts to find a cause for developments. The laity often refuse absolutely to accept a doctor's statement that symptoms have no known cause. They tend to be more interested in ætiology than in actual pathology. While willing to accept the diagnosis "rheumatism" for most pains, they may show no desire to know what rheumatism is, though they will insist, in the face of all statements from their doctor to the contrary, that it is due to a damp house or a change in the weather. And they may have no objection to being told that they are merely suffering from "indigestion," which they confidently ascribe to poor food—if in the Army to the "greasy Army food"—or to bad smells. Some medical men, on the other hand, are unwilling to admit the absence of a pathological cause, while having less objection to an agnostic viewpoint in the ætiological field. But even in ætiology unjustifiable conclusions are often reached in medical circles, as is illustrated by the statements in medical textbooks, usually made on very flimsy grounds, that so many diseases are partly due to such factors as strain, fatigue, and lowered resistance. There have been phases in medical history during which a single ætiological factor has been thought to be responsible for numerous diseases. A decade or two ago, the septic focus was such a factor, and in recent years many diseases have been said to be psychosomatic, on evidence little stronger than that supporting the septic focus theory.

Though the doctor in his heart of hearts may appreciate his inability to make a pathological diagnosis, reasons of prestige may sometimes persuade him to do so. This may be not so much to please patients as to impress medical students, nursing sisters, or physiotherapists. The physician who confidently states that a patient has subacute interstitial fasciitis may seem at the moment more impressive than his more modest colleague who can only say that a similar patient is suffering from a "persistent pain in the back."

The practice of making pathological diagnoses on insufficient grounds is inevitably responsible for erroneous statistics, and consequently for all sorts of other erroneous conclusions. During the recent war, many diagnoses recorded on military hospital record cards, such as coryza, influenza, dengue fever, and clinical malaria, were used quite loosely, according to individual taste. The value even of many of the statements made on death certificates is highly problematical, especially the popular diagnoses given to the very old, such as myocardial degeneration, coronary arteriosclerosis, and cerebral arteriosclerosis.

I suggest, therefore, that those concerned with administrative medicine should ask for precision only when precision is possible. When it is not, they should encourage the doctors who fill the forms to leave their answers vague. If Army medical officers were told to diagnose dengue and sandfly fever only from convincing evidence, to diagnose coryza only when the symptoms are those of the common cold, and when the cause of fever is obscure to diagnose "short fever of undetermined origin," the statistics at the medical directorate would be far more valuable. Similar considerations apply to death certification. If it were laid down that indefinite terms like senility, cardiac failure, and "sudden cardiac death without demonstrable basis" *should* be used when no gross cause of death can be found, the value of the statistics relating to the definite causes of death would be enhanced. It might also be sound to include a small space on the death certificate in which the compiler could fill in the number 1, 2, 3, or 4, to represent the degree of likelihood of his statements. Thus, 1 would mean the diagnosis given is virtually certain, 2 that it is highly probable, 3 that it is fairly likely, and 4 that it is a reasonable possibility. And why should not a similar attitude be encouraged in coroners' courts ? At present, medicolegal pathologists make completely confident statements as to the cause of death, which must often be a severe strain on their consciences. Why should not they be allowed to state that a patient has died of, say, "natural causes of undetermined type" ?

CONCLUSION

In a high proportion of patients it is impossible to make a pathological diagnosis. Many of them complain of symptoms of psychological origin, and in their case some sort of psychological diagnosis can be reached, though it will inevitably lack the precision of a pathological one. Moreover, "anxiety neurosis," "conversion hysteria," and other comparatively precise psychological labels are often best avoided, the true state of affairs being better represented by more indefinite terms. But many more patients—typically those with non-articular "rheumatism"—no doubt have a pathological basis to their symptoms, but a basis whose nature is not at present fully understood. Nothing could be further from my intention than to belittle the importance of pathology, or to suggest that it is not often the right course to attempt to find a pathological basis to symptoms. But I believe that there has been a general tendency to assume that nearly all that matters in medicine can be reduced to pathological terms, and I urge that doctors should view their diagnostic problems with humility, should realise how often they are in the dark, and, if only a vague diagnosis can be legitimately reached, should avoid the pretence of a precise one.

When pathology has advanced as far as it can advance, a bald pathological label will still remain an incomplete diagnosis, even for those patients who have a pathological lesion which is related to their symptoms. For patients with some grave or fatal organic disease, and especially for those with an acute and recoverable illness, the pathological diagnosis usually represents sufficient of the truth for all practical purposes. It is the patients with chronic and fairly benign organic lesions whose diagnoses should indicate more than just these lesions. The man with a sebaceous cyst which he fears is a cancer and the woman with varicose veins which she believes are so ugly that everyone stares at her, should be diagnosed, not by a word or two, but by a sentence. The practice of attaching a single diagnostic label to patients is, therefore, not only wrong now; it will always remain wrong when applied to those with chronic benign lesions.

I wish to thank my father for his help in revision, and Dr. C. C. Thomas for his advice and criticism.

INFLUENCE OF A MERCURIAL DIURETIC ON THE MECHANISM OF DIURESIS IN CONGESTIVE CARDIAC FAILURE

T. E. LOWE *
M.D., D.Sc. Melb., F.R.C.P., F.R.A.C.P.
DIRECTOR, BAKER MEDICAL RESEARCH INSTITUTE AND CLINICAL RESEARCH UNIT, ALFRED HOSPITAL, MELBOURNE, AUSTRALIA

IN a previous paper (Lowe 1951) it was shown, in a series of œdematous patients with congestive cardiac failure, that water is lost from the body during diuresis in a manner which conforms to a uniform pattern. It was concluded from these observations that there exists a mechanism which controls the water content of the body, and some of its characteristics were defined. Subsequently (Lowe and Sayers 1952) this concept was analysed in terms of an "open" storage system, and the mechanism was shown to contain volume-disturbing and volume-restoring forces. It was also shown in the cases discussed, that where diuresis had followed rest in bed and dietary measures these forces were acting in an essentially normal fashion even though the patient was still œdematous. During recovery the major change in the mechanism was an increase in sensitivity.

This paper presents a study of changes in weight and fluid balance in œdematous patients with congestive cardiac failure to whom a mercurial diuretic ('Mersalyl') was given. Several types of behaviour can be recognised, and the six cases described resemble many others seen during our investigations. These observations are discussed in the light of the hypothesis, already enunciated, that there is a mechanism in the body which controls the total water volume and which behaves as an "open" system.

PROCEDURE

After admission to the ward these patients were confined to bed for the greater part of the period of observation. As in the previous series, they were placed on a diet of known and fixed caloric value, the sodium content of which was kept constant throughout the period of observation (see table). The patients were encouraged to drink freely of sodium-free fluids. Digitalis preparations were given only if the patient had been receiving them before admission or for the treatment of an arrhythmia. Intramuscular injections of mersalyl were given in the doses and at the times indicated. The fluid intake and output and, when possible, the weights were recorded daily. From these figures the fluid-balance curve was constructed with the corrections previously discussed (Lowe 1951).

As the weight curve is usually more accurate than the fluid-balance figures, this curve has been differentiated to give a fluid-balance curve. The curve so derived is shown superimposed on the observed fluid-balance curve as a check on the accuracy of measurements.

CASE-RECORDS

Case 1.—A man, aged 88, was admitted to hospital shortness of breath on slight exertion and œdema of his and ankles. Examination revealed tense œdema of lower limbs. Moist sounds were present in the lungs. No gross abnormality was detected in the heart. His blood-pressure was 140/90 mm. Hg. He was treated by rest in bed and with the usual dietary régime, and his weight and fluid balance were observed over 25 days. The weight curve (fig. 1) shows that his weight fluctuated up and down over the first 17 days. This indicated an oscillating fluid balance, at first retention, then loss, and again fluid retention. On the 18th day injections of mersalyl (2 ml.) were begun and they were given on alternate days for 6 days. These led to pronounced diuresis, which was maximal after the first injection and then diminished as indicated in the curve. By the 24th day the patient was free from œdema.

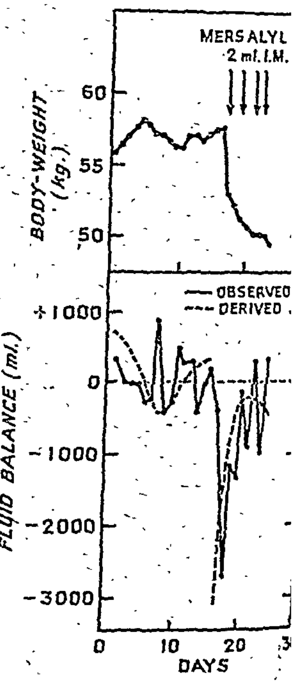

Fig. 1—Weight and fluid balance in case

Case 2.—A woman, aged 42, was admitted to hospital for investigation and treatment of malignant hypertension. She ha had shortness of breath and œdema of the legs for the pas 2 years. Examination revealed an enlarged heart, blood pressure 240/150, no increase in venous pressure, some live enlargement, moist sounds throughout the lungs, and seven œdema of the legs. Her ocular fundi showed gross papillœdem and some hæmorrhages. She was treated at first by rest in be and with dietary régime and digitalis. Over the first 15 day her weight increased although she showed some symptomati improvement. The fluid-balance curve (fig. 2) showed a oscillating fluid retention. From the 15th to the 43rd day sh was given intramuscular mersalyl 1 ml. daily. This produce an increasing loss of weight. Coincident with the first injectio of mersalyl the fluid-balance curve, which had been in a phas of retention, indicated a sudden loss of fluid and then oscillated By the 43rd day she was free from œdema, and her weigh

DATA ON ŒDEMATOUS PATIENTS

Case no.	Sex	Age (yr.)	*Diagnosis*	Excess body-fluid (litres)	Fig.	Sodium intake (g. per day)	Average daily fluid intake (ml.)	Treatment before admission	Treatment during observation
1	M	88	Atherosclerosis, myocardial degeneration	7	1	1	1600	Nil	Routine; mercurial diuretic on days 18, 20, 22, and 24
2	F	42	Malignant hypertension	15	2	1	2000	Rest in bed, digitalis, mercurial diuretics	Routine; *digitalis*; mercurial diuretic daily from days 15 to 43
3	F	53	Hypertension	3·5	3	1·5	1400	Nil	Routine; mercurial diuretic on days 8, 9, and 31
4	M	61	*Chronic rheumatic valvulitis (mitral and aortic) and carditis; auricular fibrillation*	About 11	4	2	1900	Periods of rest in bed, digitalis and mercurial diuretics, intermittently for two years	Routine; digitalis (after 17th *day*); mercurial diuretic as indicated in fig. 4

* Aided partly by a grant from the National Health and Medical Research Council, Australia.

remained constant during the remainder of the period of observation.

Case 3.—A woman, aged 53, was admitted to hospital with a year's history of shortness of breath on exertion. This dyspnœa had progressively increased until at the time of admission she was orthopnœic. She gave no history of any previous illness. Examination revealed distension of her neck veins to 6 cm. above the clavicle when she sat upright. Her heart was grossly enlarged, and a basal systolic murmur was heard. Her blood-pressure was 160/120. Her liver was enlarged. She had moderate œdema of the lower limbs.

She was treated by rest in bed and with the standard diet. On the 8th day, as the œdema was still marked, a small test dose of mersalyl was given, and on the 9th day a dose of 2 ml. was injected intramuscularly. Fig. 3 shows that, although her weight at first increased, the fluid-balance curve indicated a reduced rate of water retention from the start of rest in bed. Then followed an increasing fluid loss which continued until the day after the second injection of mercury. The curve then reversed its direction, showing in order a diminishing fluid loss, an increasing fluid retention, and a cycle of fluid loss and retention.

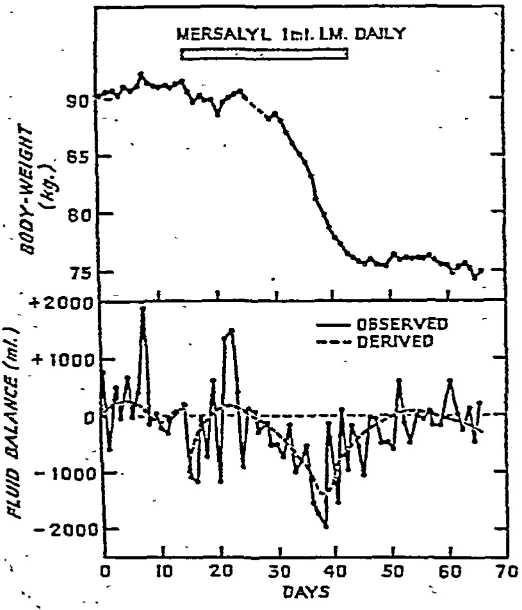

Fig. 2—Weight and fluid balance in case 2.

On the 31st day another injection of mersalyl 2 ml. was given, and this was followed by a rapid diuresis. The balance curve on this occasion revealed a sudden change from fluid retention to fluid loss, which in succeeding days diminished and gave way to fluid retention. By the 40th day she was free from œdema and other signs of congestive cardiac failure.

Case 4.—A man, aged 61, was admitted to hospital with three months' history of steadily increasing congestive cardiac failure. A similar episode a year before had responded to treatment. He had had rheumatic fever in childhood. Examination showed distension of the neck veins to 7·5 cm. above the clavicle when he sat upright, considerable enlargement of the liver, and generalised œdema. Fast auricular fibrillation (ventricular rate 136–150) was present. The heart sounds and murmurs were those of mitral stenosis. (The presence of this lesion was confirmed at necropsy 15 months later.) Moist sounds were present throughout the lungs. He was treated by rest in bed and with the usual dietary régime, and intramuscular mersalyl 2 ml. on alternate days. The fluid-balance curve (fig. 4) shows an increasing fluid loss. The jugular venous pressure fell to 3·5 cm. above the clavicle, but the tachycardia persisted. Rapid digitalisation was then instituted, and the ventricular rate fell to 80 beats a minute.

After the 17th day, as his œdema had almost disappeared, the injections of mersalyl were given at increasing intervals (fig. 4). The balance curve shows that at this stage each injection was followed by considerable diuresis.

Observation of this patient ceased after the 45th day, when he was free from all signs of congestive failure.

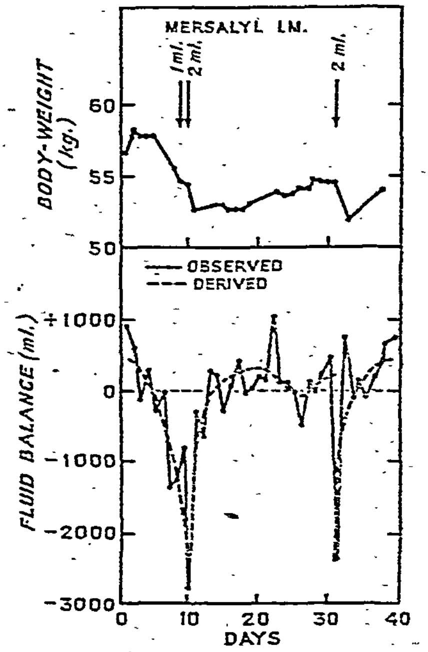

Fig. 3—Weight and fluid balance in case 3.

Case 5.—A man, aged 58, had had hypertension for 12 years. During the 4 months before admission he had become dyspnœic on exertion and his legs had become swollen. Examination revealed an orthopnœic man with neck veins distended to 5 cm. above the clavicle. His heart was enlarged, and moist sounds were heard in both lungs. His liver was considerably enlarged. There was gross œdema of the legs and sacrum. He was treated with the usual dietary régime and digitalis in the same dose as he had had previously. He was given one intramuscular injection of mersalyl 2 ml. on the 7th day. On the 22nd day regular intramuscular injections of mersalyl were started and continued on alternate days to the 36th day. His weight (fig. 5) diminished from the time of admission, and his fluid-balance curve showed an oscillating fluid loss but no sudden disturbances. He was free from œdema and had no signs of congestive failure by the 35th day.

Case 6.—A man, aged 53, was admitted to hospital with a 5 years' history of recurrent episodes of congestive cardiac failure. He had diastolic hypertension (blood-pressure 136/110) and cardiac enlargement. He had been treated by rest in bed and with digitalis and mercurial diuretics. However, over the past 3 months œdema and shortness of breath had become gross.

On admission he was treated by rest in bed and with digitalis in the same dosage as previously, a dietary régime with a sodium intake of 250 mg. a day, ammonium chloride 1 g. three times a day, and intramuscular mersalyl 2 ml. on alternate days. Because his œdema and dyspnœa were so gross it was impossible to weigh him daily, and his fluid balance was computed from his intake and output of water.

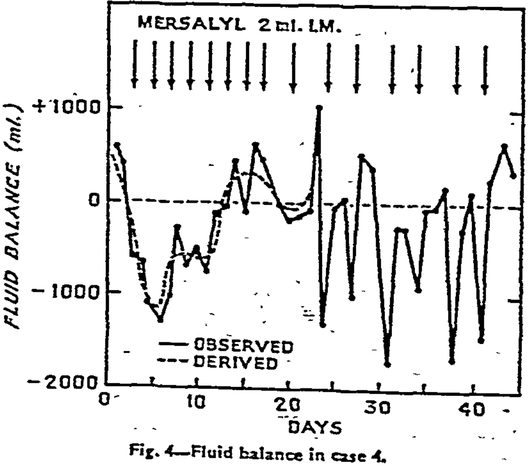

Fig. 4—Fluid balance in case 4.

The curve (fig. 6) indicates that the rate of water retention diminished from the time of admission, and alternating periods of fluid retention and fluid loss occurred. However, by the 34th day there had been no net loss of weight, for the periods of fluid loss were balanced by periods of fluid retention. At this time, in view of his poor general condition and high venous pressure, 500 ml. of blood was removed by rapid venesection. This, however, effected no improvement; so on the 35th day the skin of both legs was incised in many places and a considerable loss of fluid ensued during the next 48 hours. Fig. 6 shows that after this time a diuresis followed most of the injections of mersalyl, and that he was, on the average, losing fluid. By the 55th day he was free from œdema and from signs of congestive cardiac failure although he had little exercise tolerance.

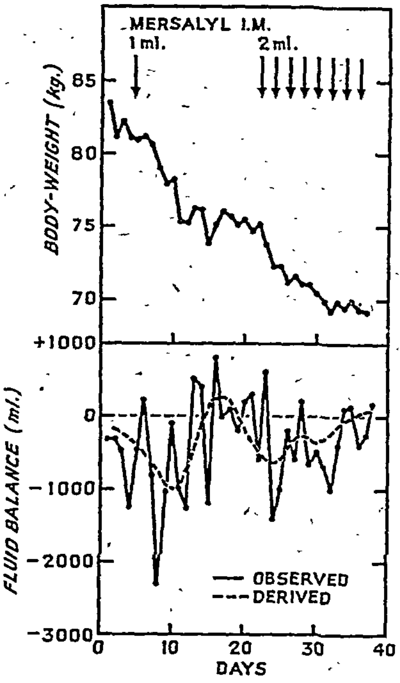

Fig. 5—Weight and fluid balance in case 5.

DISCUSSION

Inspection of the fluid-balance curves of these cases shows that the type of cyclic curve previously described is present in all. Cases 1 and 2 were, at first, treated under the same conditions as in the previous series, and in them the curve executed a typical complete cycle before mersalyl was given. A similar cycle is seen in case 3 between the two groups of injections of mersalyl.

However, two modifications of the curves are seen after the exhibition of mercurial diuretics. In cases 1 and 2, and after the third injection of mersalyl in case 3, there was a sudden change of the curve from fluid retention to fluid loss, and this change coincided with the exhibition of mersalyl. After this sudden upset the curve returned to its cyclic form, even though injections of mersalyl were continued.

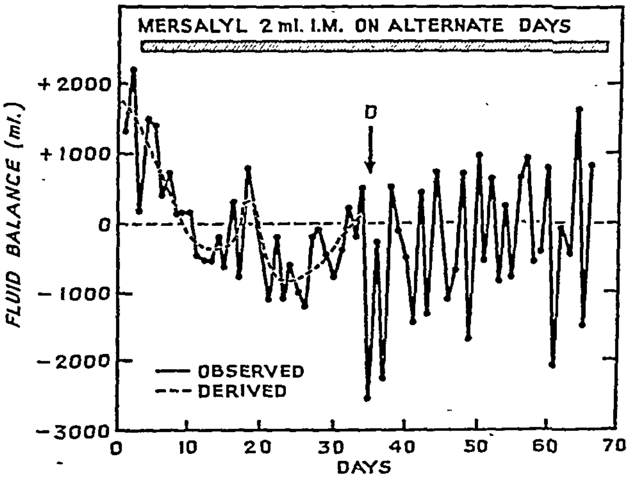

Fig. 6—Fluid balance in case 6, showing response after drainage (D) of œdema fluid from legs.

In cases 4, 5, and 6 the administration of mersalyl produced no sudden change in the cyclic curve, but in cases 4 and 5 the diminishing fluid-loss phase of the cycle was interrupted by a short cycle of increasing fluid loss, giving the appearance of a hump on the rising slope of the curve. In case 6 there is a similar hump near the trough of the curve. Further, in case 4, when the patient was free from œdema and the time between injections of mersalyl was increased, the fluid-balance curve became broken up, with a considerable diuresis following each injection. Between these sudden diureses the curve swung towards or across the zero balance line in much the same manner as is in case 3 after the isolated mersalyl injection. In case 6 the smooth cyclic curve persisted during mersalyl administration until acupuncture was performed, when a sudden dislocation of the curve from fluid retention to fluid loss occurred. Thereafter nearly every injection produced a pronounced diuresis followed by a rapid swing to fluid retention.

It is a matter of clinical observation that the response to mercurial diuretics varies from patient to patient. Sometimes a good diuresis follows each injection; sometimes there is not much fluid loss with each injection but a steady sustained diuresis; and at other times mercurial diuretics produce no diuresis even though their action is augmented with ammonium chloride and correction of blood-electrolyte patterns. These types of response are all illustrated by the cases presented, which, together with other similar studies, afford a possible explanation of the variations in response to this therapy.

In our cases a sudden onset of diuresis was seen only when the cyclic fluid-balance curve was rising and the patient was in a phase of fluid retention. The exhibition of mersalyl then produced a sudden change to fluid loss. If, however, the balance curve was falling, as in the first two injections of case 3 and in cases 4 and 5, there was no such displacement and the only change is a probable exaggeration and prolongation of the fluid-loss phase of the cycle.

The curves presented show also differences in the response of patients to isolated and repeated injections of mersalyl. These differences can be explained by the observations of Burch et al. (1950), who studied the rate of disappearance from the blood of mercurial diuretics in different people. They noticed that in patients with congestive cardiac failure the blood-mercury level often fell more slowly than in normal persons. Further, their results indicated that daily doses of a mercurial diuretic would build up a steady concentration of mercury in the blood-stream, and often in the presence of cardiac failure doses administered at intervals of 48 hours would also do this.

Thus in case 3, where the blood-mercury level was not maintained, it appears that the volume-controlling mechanism soon reverted to its original state and the diuresis diminished rapidly, giving way to fluid retention.

In case 4 administration of mersalyl every second day appears to have produced a continuous mercury effect on the system; but after the 15th day, when the time between doses was increased, probably a blood-mercury level above therapeutic levels was not maintained and the system behaved as though each dose were isolated.

The curves of cases 1, 2, and 5 and portions of the curves of cases 4 and 6 suggest that the repeated injection of mersalyl produced a continuous mercury effect, which once established gave a smooth water-balance curve.

Case 6 is an example of a patient clinically resistant to mersalyl but in whom the smooth cyclic curve can be seen, probably moving very slowly towards an effective diuresis. In this case acupuncture produced a sudden dislocation of the rising curve, and thereafter the system became sensitive to mersalyl in a manner similar to the response of other cases to single doses or widely spaced doses. This suggests that the rate of excretion of mercury had now been increased, and a steady therapeutic concentration was not being maintained in the body.

When considered in the light of an "open" system containing volume-restoring and volume-disturbing forces, these results suggest that mercurial diuretics act on one of the forces, either inhibiting one or enhancing the action of the other. The sudden and obvious change in the system which results when mercurial diuretics are exhibited during a rising phase of fluid retention suggests inhibition of the dominant factor rather than an exaggeration of the recessive one. On the contrary, when the diuretic is given on a falling curve, the relatively minor changes produced suggest enhancement of the dominant factor or blocking of the recessive factor.

If the forces in this system, represented as volume-restoring and volume-disturbing, are biochemical reactions, it is reasonable to assume that a mercurial diuretic inhibits one, for Goth et al. (1950) have shown that mersalyl inhibits an enzyme system in the kidney cells.

Now, if the affected process is dominant at the time of inhibition, the system will be thrown towards the other extreme and the fluid-balance curve suddenly displaced. By contrast, if the process is not dominant, only a small effect will be seen and no change in the direction of movement of the system will occur.

That the affected factor is not kept completely inhibited is shown by the way in which the cyclic curve continues even though the body concentration of the mercurial diuretic is maintained. The system is, however, modified, as is indicated by the "hump" in the cyclic curves. The continuance of a smooth cyclic curve implies the continued action of opposing forces.

The curves of case 6 indicate that a sudden displacement of the system can be produced by agents other than mercurial diuretics. In this instance a cyclic curve, modified by a mercurial diuretic, was suddenly altered by acupuncture which released fluid from the body reservoir. This permitted a readjustment of the volume-restoring and volume-disturbing forces so that an over-all fluid loss continued. Further, it sensitised the system to injections of mercurial diuretics given on alternate days, which then acted as though they were injections isolated by considerable periods of time.

CONCLUSIONS AND SUMMARY

These cases record the various types of response to mercurial diuretics which are seen in patients œdematous from cardiac failure.

These observations support the hypothesis that there exists in man a water-volume-controlling mechanism which has as components volume-restoring and volume-disturbing forces. This mechanism operates at varying sensitivities. These observations also show that it is possible partially to block one of the components with mercurial diuretics. The varying clinical response seen on exhibiting these drugs has a possible explanation in terms of the phase of activity of the system at the time of their exhibition, and of the rate of excretion of mercury by the patient at that time.

It is a pleasure to thank the members of the Baker Institute and Clinical Research Unit for their help in collecting and assessing the data used in this investigation.

CUTANEOUS ARTERIAL SPIDERS FOLLOWING USE OF ADRENOCORTICOTROPIC HORMONE

JAN H. SOLEM

M.D. Oslo

ASSISTANT PHYSICIAN, DRAMMEN HOSPITAL, DRAMMEN, NORWAY

VARIOUS cutaneous reactions and vascular phenomena have been noted after the use of adrenocorticotropic hormone (A.C.T.H.) and cortisone, and these are commonly associated with signs and symptoms resembling Cushing's syndrome (pituitary basophilism). Similar changes, such as brown pigmentation and an increased tendency to bruise, are sometimes seen in normal pregnancy. In the case described here cutaneous arterial spiders (*Lancet* 1946) appeared during treatment with A.C.T.H. I have been unable to trace any previous record of this happening.

CASE-RECORD

A married woman, aged 25, was admitted to Drammen Hospital last May with a diagnosis of rheumatism. There was no family history of hæmorrhagic tendencies or telangiectases, and during a normal pregnancy 8 years earlier the patient had not developed telangiectases. Her health had been good and her periods regular. She had had no liver disease. She now complained of a week's pyrexia, painful swelling of the ankles, and red tender nodes on both legs.

Condition on Admission

Her temperature was 101·6°F (38·7°C) and her pulse regular. She had typical erythema nodosum on the front of both legs. Her skin was moist with some moles on her back and limbs, but otherwise normal except for the erythema nodosum. Both ankle-joints were swollen and tender, with some limitation of motion. Her lungs, heart, and abdomen were normal. Her blood-pressure was 115/70 mm. Hg. A blood-count showed Hb 75%, red cells 3,800,000 per c.mm., white cells 11,200 per c.mm., and eosinophils 203 per c.mm. The erythrocyte-sedimentation rate (E.S.R.) was 86 mm. in one hour (Westergren). Her urine, sp. gr. 1·023, was normal. Meinicke's test was negative. The urinary excretion of 17-ketosteroids during a 72-hour period was 8·9 mg. in 24 hours. An electrocardiogram was normal. Radiography of the chest showed clear lungs. A tuberculin test was negative.

Treatment and Progress

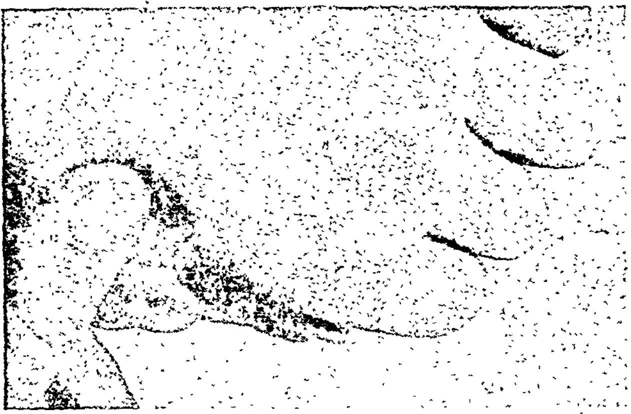
Our diagnosis being acute rheumatoid arthritis with erythema nodosum, A.C.T.H. therapy was started with 'Corticotropin' (Nyco), a preparation of A.C.T.H. made from the frontal lobes of pituitary glands of whales. I am informed that the extraction procedure used yields a product substantially free from gonadotropins and thyrotropin, but regular tests for the presence of posterior-lobe contaminants are made by the manufacturers, who keep the oxytocin content below 0·2 I.U. per 100 ml. The presence of some growth-hormone activity cannot be excluded.

The treatment was started with intravenous infusions of corticotropin 10 I.U. in 1000 ml. of 5% glucose given over a period of 8 hours daily on 5 successive days. The eosinophils immediately disappeared. At the end of this course of treatment the patient felt perfectly well, with normal temperature and no joint pains; and the erythema nodosum had gone leaving only some discoloration of the skin. The E.S.R. was now 30 mm. in one hour. In the next 4 weeks, with the exception of a few days, small doses of intramuscular A.C.T.H. were given daily to a total of 300 mg.

Side-effects of Treatment

After 2 weeks' intramuscular A.C.T.H. therapy the patient's face became rounded, she had sweating and furunculosis of her face and upper thorax, and her limbs tended to bruise easily. She said she felt as though she had a hump on the back of her neck, where a moderate amount of fat appeared. In the 3rd week she had an increased growth of hair over the lower parts of her legs, and her pubic hair extended upwards toward the navel. She developed many pigmented nævi on her limbs, brown pigment appeared at the sites of needle punctures, and her moles became darker.

At the beginning of the 4th week ten telangiectases were found. At the end of the week four more had appeared and those already present had become bigger One was at the root



Arterial spider on patient's hand.

of the nose, one on the left shoulder, two on each upper arm, one on each lower arm, and the rest on the backs of the hands. Two of them were larger than the others and macroscopically resembled cutaneous arterial spiders. They had a raised central pulsating point, from which branching vessels radiated like the legs of a spider (see figure), and they were surrounded by an area of erythema. They did not show any tendency to bleed. The mucosa of the mouth, tongue, pharynx, and nose was not affected.

At this juncture pregnancy was excluded by gynæcological examination and by the fact that the patient's periods were normal. Liver disease was excluded by functional tests, including the thymol-turbidity test, the Takata-Ara reaction, and the prothrombin value.

A.C.T.H. Discontinued and Resumed

A.C.T.H. therapy was then stopped for 10 days, at the end of which the number of telangiectases remained unchanged but some were much smaller. The pulsation of the two arterial spiders was no longer visible to the naked eye.

During the following 10 days A.C.T.H. was again given daily intramuscularly. By the end of this time four new telangiectases had appeared—two on the back of the left hand and two on the volar side of the right fifth finger. The two vascular spiders were distinctly enlarged, and pulsation could once more easily be demonstrated. It should perhaps be emphasised that these changes neither coincided with nor preceded a menstrual period. The urinary excretion of 17-ketosteroids was now increased to 24 mg. in 24 hours. The urinary excretion of corticoids was 4·72 mg. in 24 hours. The excretion of œstrogens was within normal limits—17 M.U. per 1000 ml.

The patient had no complaints and was discharged after being in hospital 33 days. Her E.S.R. was then 15 mm. in one hour.

Follow-up

Since discharge the patient has attended hospital as an outpatient for 5 months. Her periods have been regular and liver-function tests normal. There have been no symptoms or signs of relapse of her rheumatism. 6 weeks after the last injection of A.C.T.H. the urinary excretion of 17-ketosteroids, corticoids, and œstrogens was normal (7·8 mg. in 24 hours, 0·82 mg. in 24 hours, and 56 M.U. per 1000 ml. respectively). The fullness of her face and her excessive sweating have disappeared, but mild acne persists. The hirsutism and pigmentation are unchanged. Seven of the telangiectases have vanished in the week after discharge from hospital, and all the rest are smaller, most being scarcely visible. Pulsation in the arterial spiders could not be detected at the end of the first week.

DISCUSSION

Arterial spiders have previously been observed in patients with rheumatic disease, but apparently only in association with clinical signs of heart-failure and cardiac cirrhosis. Such signs were absent in the present case. The vascular lesions in the present case seemed to be caused by A.C.T.H.; and their number and the size were indisputably influenced by the interruption and the resumption of A.C.T.H. therapy.

The development of the telangiectases and arterial spiders in the present case coincided with that of several features of Cushing's syndrome. It is therefore of interest to recall that two out of twelve of Cushing's patients with this syndrome had telangiectases (Cushing 1932), one of the cases being that published by Friedman (1921). Bean (1945) observed typical vascular spider in a case of Cushing's syndrome where (as in our case) liver disease could be excluded. Bean (1945) held that these vascular alterations may be related to abnormality in the metabolism of certain 17-ketosteroids.

The development of arterial spiders in liver disease and during pregnancy is well known. Alterations in 17-ketosteroid metabolism have been reported in liver cirrhosis (Edmondson et al. 1939), and the period of increased excretion of œstrogens in pregnancy coincides with that during which the vascular spiders tend to appear. This led Bean to administer œstrogens in liver disease. Vascular spiders developed in two of three chronic addicts to alcohol after therapy with œstrogenic 17-ketosteroids (Bean 1942).

In our patient the development of cutaneous arterial spiders after A.C.T.H. therapy, and the considerable increase in urinary excretion of 17-ketosteroids, further supports the hypothesis that these alterations of the small arteries of the skin are caused by a disturbance of the balance and level of the 17-ketosteroids.

Since this article was drafted I have seen a single pulsating arterial spider in a woman treated with A.C.T.H. for colitis; it lasted three days and then disappeared. Liver disease and pregnancy were excluded.

SUMMARY

Telangiectases and cutaneous arterial spiders developed simultaneously with Cushing's syndrome in a woman, aged 25, treated with A.C.T.H. for acute rheumatoid arthritis. These vascular lesions regressed in number and size with the interruption of A.C.T.H. therapy and progressed with its resumption.

None of the usual predisposing causes (pregnancy, liver disease, deficiency disease) were present. The development of arterial spiders seems to be related to alterations in the metabolism of 17-ketosteroids.

The occurrence of protein in the urine of an infant during the first two weeks of life is regarded by many authorities as one of the physiological peculiarities of the neonatal period (Brennemann 1948, Bamberger et al. 1942, Debré et al. 1943–45, Feer 1938, Finkelstein 1938, Grulee and Eley 1948, Nelson 1950, Parmelee 1952, von Pfaundler and Schlossmann 1931; von Reuss 1914, Smith 1951, Tow 1937). Czerny and Keller (1925) give the best and most extensive review of the work on proteinuria of the newborn, most of which is to be found in the German literature before 1916.

Proteinuria was found within the first two weeks of life, on at least one occasion, in nearly all the infants included in the extensive surveys of the more recent German workers (Ewald 1916, Franz and von Reuss 1914, Heller 1913). In older articles the incidence of proteinuria was reported to vary from 41 to 93% (Flensburg 1894, Martin and Ruge 1875, Cruse 1877, Hofmeier 1862), whereas no protein was found by French workers at the end of the last century (Audebert and Arnozan 1896, Parrot and Robin 1876). The work of the latter authors was not well documented and gave neither the number of infants studied nor the method of protein estimation. Greer et al. (1928) observed protein in the urine of only 7 of 66 healthy infants.

Before trying to relate the reported proteinuria to other features of the newborn infant, we thought it desirable to reinvestigate its prevalence by methods more reliable than those used by earlier workers.

Some of the urines obtained from newborn infants were scanty, had a deep colour, contained a large deposit, and gave positive tests for protein. As urinary salts can interfere with the tests for protein when the urine is concentrated (Todd and Sanford 1944), the present work was designed to test the hypothesis that the so-called proteinuria of the newborn is due to excessive amounts of urates interfering with the tests for protein.

METHOD

The approximate specific gravity of the urine was determined in many cases after the specimens had been clarified (Dogramaci 1947). For the purposes of protein determination any deposit or cloud remaining after the specimen had been warmed in a water-bath at 37°C was centrifuged off, and the supernatant fluid was used for the test. Protein was estimated by adding 0·1 ml. of 25% (w/v) trichloracetic acid to 1 ml. of urine and comparing the turbidity with that of standard tubes after two minutes (Grey 1930).

If the urine appeared to contain more than 15 mg. of protein per 100 ml., urates were quantitatively removed by a method developed by Hopkins (1891, 1893a and b). The urine was saturated with ammonium chloride (A.R.), and one or two drops of concentrated ammonia were added to give a white gelatinous precipitate of ammonium urate. After standing for two hours the supernatant fluid was tested for protein by the addition of trichloracetic acid. As the urine had been treated with concentrated ammonia, it was necessary to add up to 0·2 ml. instead of 0·1 ml. of trichloracetic acid (25% w/v) to attain the same pH as before.

Treatment of urine with ammonium chloride and ammonia does not remove any organic physiological constituent from the urine except urates and soaps (Cole 1933), but it was considered necessary to ensure that protein was not affected by this procedure.

For this purpose a solution free from urates—i.e., serum—was diluted to give concentrations of protein varying from 10 to 100 mg. per 100 ml. Part of each solution was saturated with ammonium chloride, and ammonia was added. There was no trace of a precipitate, but there was an increase in the volume of solution from 100 to 125% as a result of the saturation with ammonium chloride. When this dilution is taken into consideration, it is clear from the accompanying table that, within the limits of experimental error, there was no loss of protein when the solutions were put through the process for removing urates. Similarly, when pathological urine from nephritic patients was treated with ammonium chloride and ammonia, the observed decrease in protein concentration was compatible with the dilution from saturation with ammonium chloride.

The murexide test, which is specific for urates (Cole 1933), was applied to the deposit from neonatal urine and proved strongly positive. The precipitate (presumably ammonium urate) which appeared when a urine containing "protein" was treated with ammonium chloride and ammonia gave a positive murexide test. Further, the "protein"—i.e., the precipitate obtained when urine was treated with trichloracetic acid—also gave a positive murexide test.

CONCENTRATION OF PROTEIN IN VARIOUS DILUTIONS OF SERUM BEFORE AND AFTER ADDITION OF REAGENTS FOR REMOVAL OF URATES

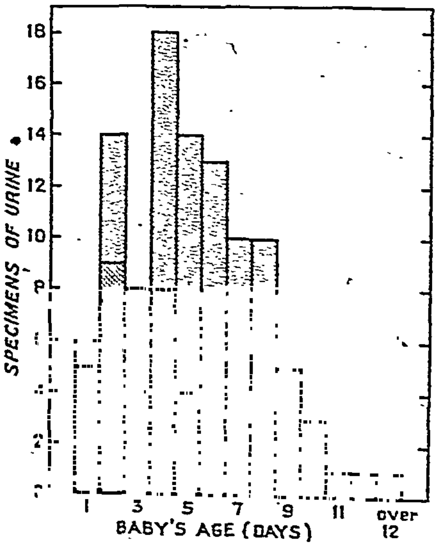
Sample of urine	Protein (mg. per 100 ml.) in diluted serum	
	Before treatment with NH_4Cl and NH_4OH	After treatment with NH_4Cl and NH_4OH
1	95	70
2	80	60
3	70	55
4	65	50
5	60	45
6	50	40
7	40	30
8	30	20
9	20	15

The small decrease in protein concentration is explained by the increase in volume after the addition of the reagents.

If uric acid is dissolved in dilute alkali—e.g., 2% (w/v) sodium carbonate—the insoluble acid can be precipitated again by the addition of one or two drops of concentrated hydrochloric acid. Uric acid can also be precipitated by the addition of 25% (w/v) trichloracetic acid. It is therefore clear that turbidity can be obtained when concentrated urine, obtained from a newborn infant and containing an excess of urates, is treated with the reagents commonly used for estimating protein. The treatment of any protein solution or urine containing protein with reagents which will remove urates does not remove protein but does precipitate the salts of uric acid, which can interfere with the tests for protein in a concentrated urine.

MATERIAL

103 specimens of urine were obtained from 97 clinical healthy newborn male infants, aged 1–21 days, by strapping a 'Pyrex' test-tube to the penis. The mothers of 88 of these children were in good health, whereas the remaining 9 mothers had mild toxæmia. Girls' urine was not studied, because of the difficulty of collecting specimens.



Number of specimens of urine obtained from newborn boys, showing those (hatched) which contained excessive amounts of urates, which gave false positive tests for protein.

RESULTS

Of the 103 specimens of urine 30 had a deep colour and a rather high specific gravity (1·014–1·024), and contained a large deposit which gave a very strongly positive murexide test. It was only the more concentrated specimens of urine passed within the first five days of life which showed these peculiarities and gave a positive test for protein up to amounts of 100 mg. per 100 ml. When urates were removed from these specimens, no protein was detected in the urine from 96 of the 97 newborn infants studied. The urine of 1 infant appeared to contain 70 mg. protein per 100 ml. on the first day and 50 mg. per 100 ml. on the ninth day, but on neither occasion was it possible to exclude the possibility of contamination after collection and before testing it.

DISCUSSION

In this series of observations tests for protein made on clarified urine were positive only in deeply pigmented specimens which had contained a large deposit and had a specific gravity greater than 1·014. No urine with a specific gravity of less than 1·012 gave a precipitate with trichloracetic acid, and it was only during the first five days of life that the more concentrated specimens of urine were passed (Thomson 1944).

When the urates were removed from these concentrated specimens of urine, the test for protein was positive in only 1 case. If urates were not removed before testing for protein, the incidence of "proteinuria" in the present series would have been about 30%, which is not significantly different from that of some of the German workers. As the methods described by previous observers would not distinguish between protein and urates in a concentrated specimen, we can only conclude that their results were fallacious.

It has long been known that there is an increased excretion of urates in the newborn. Schloss and Crawford (1911) found that 7–8% of the total nitrogen of the urine was uric acid within the first few days of life, compared with 1–2% in the adult. Franz and von Reuss (1914) noticed that their tests for "albumin" were more positive when the urine was intensely yellow and contained a large deposit of urates.

Other workers noticed the correlation between "albuminuria" and excessive excretion of urates. Kjellberg (1870) held that the mechanical irritation caused by the excessive amount of urates produced the "albuminuria," whereas Cruse (1877) suspected that the test for "albumin" was fallacious because mucin interfered with the test. Ultzmann (1881) found a close correlation between "uric acid infarct" and "albuminuria." He accepted Virchow's (1856) hypothesis that both manifestations were the result of a local mechanical cause, the presence of a urate deposit in the kidney causing hyperæmia and exudation of protein. Flensburg (1894) studied this phenomenon but concluded that there was not a close correlation between "uric acid infarct" and "albuminuria."

Many authors record a much higher incidence of proteinuria in infants born of eclamptic mothers than in those born of healthy mothers.

Salmi (1935) recorded proteinuria in 6 of 17 infants born of eclamptic mothers and in only 2 of 8 infants born of healthy mothers. Greer et al. (1928) observed proteinuria in 7 of 66 infants born of healthy mothers, in 12 of 13 infants born of pre-eclamptic mothers, in 4 infants where both mother and child had acute infections, and in 3 of 6 infants born after difficult labours. Brash (1949) found albumin in the urine on the third day of life in 1 of 10 infants of toxæmic mothers and in 10 of 25 infants of healthy mothers.

Of the 97 mothers whose infants were included in the present survey 9 had toxæmia. The infant which seemed to have protein in its urine was born to a mother without toxæmia.

It therefore seems that the earlier French workers who did not find proteinuria in the newborn were correct, but it is noteworthy that one of the best-known French pædiatric textbooks (Debré et al. 1943–45) ignores their work. Similarly the most authoritative American textbook (Smith 1951) ignores the work of Greer et al. (1928) and, on the evidence from the earlier German papers, says:

> "Tests for albumin have been so consistently positi especially during the second to fifth days after birth, t albumin is to be considered a more or less 'physiologic constituent of the newborn infants' urine."

The work reported here has shown that neona proteinuria as a physiological phenomenon does exist. We suggest that any occurrence of "tru protein is very rare and may indicate disease.

SUMMARY

The incidence of proteinuria in the newborn infa has been reinvestigated.

A third of the specimens of urine obtained from ne born infants was highly pigmented and contained a lar deposit which gave a strongly positive murexide te and appeared to contain protein.

When urates were removed from the more conce trated specimens, which were produced only within t first five days of life, the "protein" disappeared.

Proteinuria as a physiological phenomenon in t newborn infant does not exist. The fallacy has aris from the excessive excretion of urates in the first few da of life, interfering with the test for protein.

Our thanks are due to Prof. R. S. Illingworth for his advi in the preparation of this paper and to Dr. Thomas Colver f permission to obtain specimens from some of his patients.

PERFORATION OF APPARENTLY NORMAL COLON AFTER A BARIUM MEAL

J. C. B. Serjeant
M.B. Edin., F.R.C.S.E.
SENIOR SURGICAL REGISTRAR

J. A. Raymond
M.B. N.Z.
LATE HOUSE-PHYSICIAN

ROYAL NORTHERN HOSPITAL, LONDON

Several cases of perforation of a diseased colon after a barium meal or barium enema have been published; but we know of no report of perforation of an apparently normal colon after a barium meal.

CASE-RECORD

Mrs. A, aged 67, was first seen on March 26, 1952, complaining of intermittent abdominal pain and vomiting of five or six years' duration. The trouble seemed to consist of retching more often than actual vomiting. She complained of anorexia and loss of weight. She admitted to being a nervous woman but had no domestic worries. There was no relevant previous history.

Apart from a blood-pressure of 220/120 mm. Hg (benign hypertension) no abnormality was found either in the alimentary system or elsewhere. A provisional diagnosis of nervous dyspepsia was made.

Radiography.—A barium meal was given on the morning of April 1, and radiography showed a normal stomach and duodenum. But when the patient returned at 10 A.M. next day for the follow-through examination she said she had had generalised abdominal pain since 7 A.M. The follow-through films were normal, with discrete masses of barium throughout the colon (fig. 1). As, however, she had generalised abdominal tenderness, with resistance of the abdominal muscles, and did not appear well enough to go home, she was admitted to a medical ward for observation.

Condition on Admission.—She was pale and slightly greyish, with a dry tongue. Her pulse-rate was 72, with some extra systoles, and her blood-pressure was 180/100. Her abdomen was tender and resistant in all areas. Rectal examination showed a gross impaction of hard inspissated barium.

The possibility of perforation was not entertained at this time, especially in view of the normal appearance of the follow-through radiographs. It was thought that the pain might well be due to numerous hard masses of barium in the rectum or the colon. Accordingly the rectal mass was removed digitally, this being followed by two rectal washouts, which were rapidly returned with a moderate amount of barium.

Progress.—At 9 P.M. the patient's condition was worse. Her pulse-rate had risen to 100, her tongue was dry, and the abdominal pain and tenderness were more severe. She had evidently developed peritonitis. Further radiography showed, in addition to the previously noted barium masses, a dense collection of barium in the pouch of Douglas, with thinner streaks in the left paracolic gutter and between loops of bowel (fig. 2). A Ryle's tube was passed and the patient was prepared for operation.

Laparotomy (J. C. B. S.).—At 11.30 P.M. on April 2 a left upper paramedian incision was made. There was generalised peritonitis with purulent free fluid mixed with barium. The stomach, duodenum, and small and large intestines were examined in turn, and a perforation was finally found in the pelvic colon about 2 in. above the peritoneal reflexion. Its diameter was about that of an index finger, and the colon showed no abnormality of any sort, either at that point or elsewhere. The perforation was closed and patched with omentum. As much as possible of the paste-like barium in the pouch of Douglas was removed together with the free fluid. The lesion being too low for exteriorisation, a proximal double-barrelled colostomy was performed in the left inguinal region. Two hard balls of barium about 1 in. in diameter at the site of the colostomy were removed through it, and a Paul's tube was placed in position. During the operation an intravenous infusion was begun, and, the patient's condition being poor immediately after the operation, a pint of blood was given by this route.

The barium masses proved to be solid barium, difficult to cut with a scalpel, but able to disintegrate spontaneously in water.

Postoperative Progress.—Penicillin 500,000 units b.d., streptomycin 0·5 g. six-hourly, and intravenous glucose and saline solution were given, and the stomach contents were aspirated. There was complete ileus for five days, after which the colostomy began to act, aided by softening of the remaining barium masses with olive oil run in through the Paul's tube. Oliguria caused the blood-urea level to rise to 102 mg. per 100 ml. by the third day, but this passed off. There was a troublesome infection of the superficial part of the wound, which eventually healed well. On April 19 the patient was sitting out of bed, and had pain in her left hypochondrium. On April 21 radiography showed free fluid present at the base of the left lung, and next day straw-coloured exudate was aspirated from it. Radiography on April 21 also showed residual barium between the loops of bowel, on the under surface of the liver, and round the spleen (fig. 3). An enterotome was applied to the spur of the colostomy on April 24 and removed on May 1. On May 7 the colostomy was closed (J. C. B. S.). Local cellulitis followed this but was soon

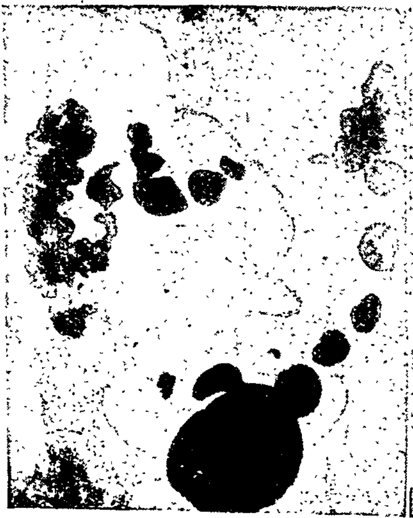

Fig. 1—Follow-through radiograph after barium meal on April 2, showing discrete masses of barium throughout large intestine.

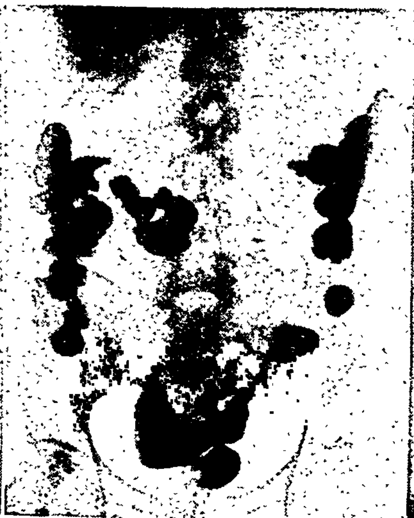

Fig. 2—Radiograph in the evening of April 2, showing collection of barium in pouch of Douglas, and streaks of barium in left paracolic gutter and in between loops of bowel.

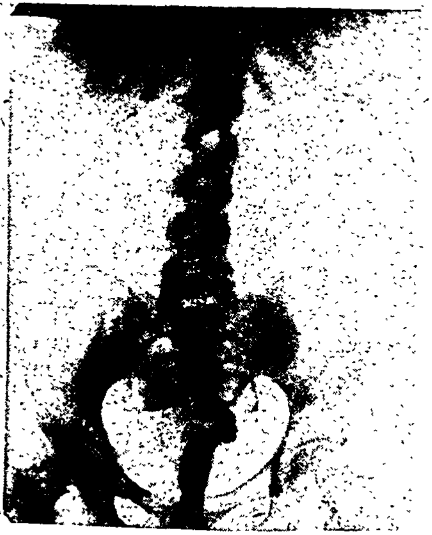

Fig. 3—Radiograph on April 21, showing residual barium between loops of bowel, surrounding spleen, on under-surface of liver, and in rectum.

controlled with chloromycetin. The patient was discharged to a convalescent home on May 19.

Follow-up.—When seen on June 26, her condition was very satisfactory, her only complaints being of general weakness and of œdema of her ankles. The abdominal wounds had healed well, and sigmoidoscopy showed normal rectum and colon. There were no abnormal chest signs. Radiography of the chest on May 20 had shown considerable reduction in the extent of the left basal effusion; but on July 1 the chest was clear.

COMMENT

The original diagnosis of nervous dyspepsia in this case was supported by the absence of any abdominal lesion other than the accidentally perforated colon. There seems to be no clinical doubt that the perforation took place within twenty-four hours of the administration of the barium, which by then had reached the pelvic colon and rectum, where it had formed solid hard masses. Perhaps the patient had previously been a little dehydrated, causing more absorption of water than usual from the barium during its passage through the colon.

The reason for the perforation is unknown. It is difficult to imagine that a necrosing pressure ulcer could develop in so short a time. The subsequent rectal washouts must have contributed to the severity of the peritonitis, but in retrospect it seems clear that the perforation had taken place some hours earlier. Possibly a barium mass was blocking the breach but was forced through it by the enemata. This would account for the normal radiological appearances in the morning.

No comparable case seems to have been published in the last thirty years or so.

Kaulich (1930) reported a case in which, after a barium meal, a barium mass became impacted in the middle of the sigmoid colon and caused obstruction. Twenty-seven days later a barium enema was given, followed by perforation at the site of impaction. In this case there was presumably an ulcer at the site of impaction. The outcome is not recorded.

Scheidt (1950) reported a case in which perforation of the colon above a carcinoma following two barium enemata given at an interval of ten days. The patient was operated on four days later but died of peritonitis.

A case of perforation of the sigmoid colon during the giving of a barium enema is reported by Kleinsasser and Warshaw (1952) in a case of chronic ulcerative colitis. The patient recovered after repeated attacks of obstruction of the small intestine.

Golub (1934) cites three cases of retention of barium masses after barium enemata forming a hard mass of barium, but perforation did not follow in any of them.

Himmelmann (1932) cites colonic perforation due to barium meal in cases of carcinoma of the rectum and stenosis of the colon.

In all these cases there was a lesion of the colon which determined the onset of perforation, but in the present case there was apparently no such lesion.

Isaacs (1952) reports two cases of escape of barium into the peritoneal cavity during the administration of a barium enema. One patient had a carcinoma of the sigmoid colon, and the other a perforation due to sigmoidoscopy the previous day.

SUMMARY

A case is recorded in which, after a barium meal, masses of inspissated barium caused perforation of an apparently normal colon. The patient recovered after closure of the perforation and proximal colostomy.

We are indebted to Dr. E. G. B. Calvert for permission to publish this case, and to Dr. L. S. Carstairs for his coöperation in the radiological examinations.

ACUTE PERFORATION OF A DUODENAL ULCER IMMEDIATELY AFTER BARIUM MEAL

COMPLICATED BY INTESTINAL OBSTRUCTION

C. P. DE FONSEKA
M.B. Ceylon, F.R.C.S.
RESIDENT SURGICAL OFFICER, ST. BARTHOLOMEW'S HOSPITAL, ROCHESTER

Rosenthal, cited by Gross (1941), was the first to record in 1916 a perforation of a peptic ulcer on the X-ray table, when the barium was seen in the lesser sac. Lang (1926) reported the perforation of a gastric ulcer during X-ray examination of a man aged 65. The patient was operated on and made an uneventful recovery. Barium was found only in the vicinity of the ulcer. Singer (1934a), discussing barium meals in the presence of unrecognised perforations, refers to cases where local abscesses were detected during examination. These were no doubt cases of "subacute perforations" with a slow leak. In one case the abscess ruptured during examination. An operation was done, but the patient died. Gross (1941) reported a case of his own where at operation the ulcer was oversewn and parts of the lesser omentum were excised to remove the adherent barium. The patient recovered.

The following case is presented, however, not only on account of its rarity but also because of the most unexpected complication which ensued.

CASE-RECORD

A Greek, aged 34, officer on a tanker, was brought into the casualty department of this hospital at 10.50 P.M. on Nov. 15, 1951, in an extremely shocked state, complaining of agonising abdominal pain. His own doctor, who accompanied him, said that the patient, who forty minutes earlier had had a barium meal, got off the X-ray table and was immediately doubled up with this pain. One of the radiographs already taken showed an ulcer crater in the duodenum. The patient had left Greece three months earlier. About then he started getting attacks of upper abdominal indigestion related to meals. The attacks had become gradually worse and during the past week had been almost continuous. He had lost weight. As soon as the ship docked he sought medical advice.

On examination he was writhing in agony, retching violently, and bringing up small quantities of barium. His extremities were cold and cyanosed, and his pulse was barely perceptible. His abdomen was board-like all over and extremely tender.

Treatment.—Morphine gr. $^{1}/_{4}$ was given intravenously and a dextrose-saline drip was started. An attempt to aspirate the stomach was unproductive, but the Ryle's tube was left in. The patient was left undisturbed. By 2 A.M. he was warm and his blood-pressure was normal.

Operation.—At 2.30 A.M. on Nov. 16, under thiopentone, curare, and endotracheal gas and oxygen, a right upper paramedian incision was made. The parietal peritoneum was found œdematous, and free gas escaped. The entire peritoneal cavity was smeared with barium of creamy consistence intimately mixed with exudate. The surfaces of all the viscera were covered with a fine layer of adherent barium. The whole of the visceral peritoneum showed intense œdema, as much as would be seen in a 24-hour ordinary perforation. The inferior surface of the liver was lightly adherent to the duodenum. On the anterior surface of the first part of the duodenum was a perforation about 3 mm.

across, through which barium and gas were escaping. The perforation was closed with an omental graft. As much as possible of the creamy fluid was swabbed and sucked away, but the adherent barium could not be removed. The neighbourhood of the ulcer was lightly dusted with penicillin and sulphonamide powder. The abdomen was closed without drainage. On return to the ward at 3.15 A.M. the patient's condition was satisfactory, but in view of the extensive œdema a pint of plasma was given and a slow dextrose-saline drip was continued.

Subsequent Progress.—On Nov. 16 there were considerable abdominal pain and restlessness requiring repeated doses of morphine, pethidine, and sodium phenobarbitone. Intermittent gastric aspiration was done. The patient's pulse-rate was 90–100 per min. On Nov. 18 he was still distressed. No flatus was passed. The abdomen was uniformly distended, tender, and silent. Gastric aspiration for the day totalled 36 oz. In the evening the tube was removed, but the patient complained of nausea, and reinsertion was followed by aspiration of 10 oz. of green fluid. The intravenous drip was continued. On Nov. 19 distension was more severe, and the patient was very restless and complaining of pains. A good deal was aspirated from the stomach. No flatus was passed. The pulse was good. Enemata morning and evening were without result. On Nov. 20 the abdomen was still very distended, and distressing pains continued. A radiograph was taken of the abdomen (fig. 1). The insertion of a flatus tube was followed by the passage of a very small quantity of gas, but enemata were without effect. On Nov. 21 4 oz. of olive oil was run into the rectum, and a 3-pint washout had no appreciable effect on the distension. Peristaltic sounds were now audible. Another radiograph was taken of the abdomen (fig. 2). On Nov. 22 a colonic washout was repeated with an excellent result, large quantities of barium and flatus being passed, and the abdomen becoming deflated. The patient was very comfortable, and gastric suction and intravenous drip were discontinued. The patient was allowed up next day, and the sutures were removed on the 10th postoperative day. He was discharged on Nov. 30. A radiograph taken on Nov. 28 showed residual barium. The patient was last seen just before Christmas and was then having no symptoms. He left for Greece by air a few days later and was advised to see his doctor there.

DISCUSSION

The frequency with which peptic ulcers perforate during or after a barium-meal examination has been variously estimated. Hummelman (1932) put it as high as 29·4%, whereas Singer (1934a and b) estimated it as 0·08% of 5000 examinations at the Cook County Hospital. These variations seem to be due to different intervals between the examination and the perforation. This interval in the published cases is between two hours and six days. It therefore appears futile to attempt a statistical estimation of frequency; but one can say that it must be very rare for a peptic ulcer to perforate during or immediately after a barium meal.

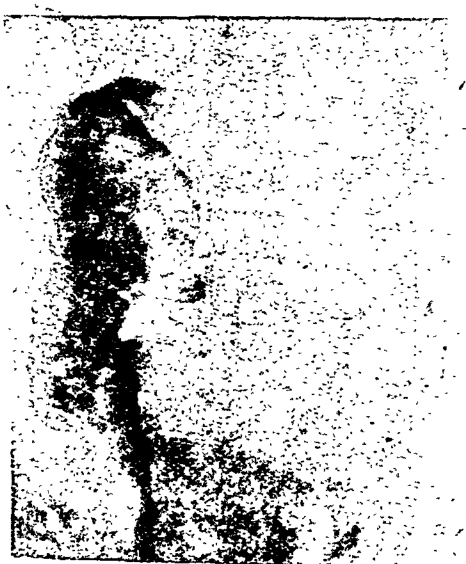

Fig. 1—Full-blown ileus. Head of barium has reached hepatic flexure.

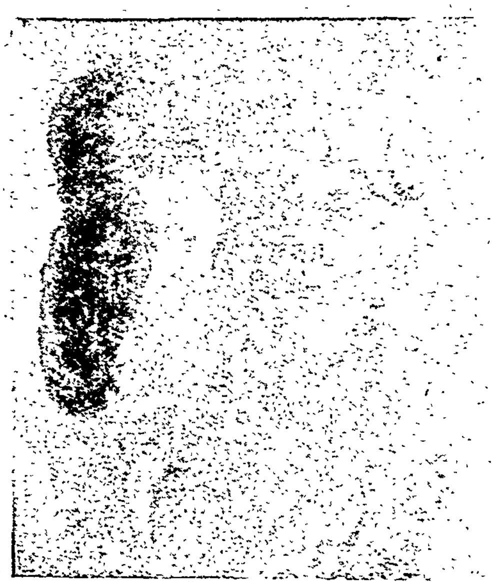

Fig. 2—Day after fig. 1. Ileus not so severe. Appearance suggests that barium is caking in ascending colon. Clinically there was evidence of mechanical obstruction.

The ætiological relation between the barium-meal examination and the perforation is not easy to assess. Very likely the barium meal has very little to do with it; the perforations would have taken place anyhow. This is borne out by the fact that in all the cases published there had been a recent exacerbation of symptoms, as in the present case. The most that can be said is that the barium meal accelerates the perforation. Eckman (1928), reporting 5 ulcers which perforated from a few to thirty-six hours after radiography, stated that patients with a recently active ulcer should be warned, after barium-meal examination, to remain within convenient distance of medical attention till the danger of perforation had passed. Singer (1934b), on the other hand, emphasises that in such cases barium-meal examination should be postponed until medical treatment has caused a retrogression of symptoms. The radiographic demonstration of an ulcer in the acute phase does not in any way alter the treatment, and only exposes the patient to additional hazards.

SUMMARY

A case is recorded where a duodenal ulcer perforated immediately after a barium-meal examination.

After an operation to close the perforation the convalescence was stormy and complicated by intestinal obstruction caused by the ingested barium.

The importance of postponing barium-meal examinations during the exacerbation of ulcer symptoms is emphasised.

I wish to thank Mr. Eric Greenwood, under whose care this case was admitted, for permission to operate and advice on the management; Dr. Angus Campbell, the house-surgeon, for his keen coöperation; and Dr. J. M. Corall for help in interpreting the radiographs.

THE VASOMOTOR DISTURBANCE IN PINK DISEASE*

D. G. VULLIAMY
M.D. Camb., M.R.C.P., D.C.H.
SENIOR REGISTRAR, THE CHILDREN'S DEPARTMENT,
GUY'S HOSPITAL

COLDNESS of the hands and feet is characteristic of pink disease and was mentioned by Selter (1903) in what is possibly the earliest account of this condition. It is, in part, a peripheral vascular disorder, but investigations of the kind used in the study of Raynaud's disease and acrocyanosis have not been published.

The skin-temperature of normal hands and feet varies over a wide range, depending on the need for retention or dissipation of heat in the regulation of body-temperature. Even under the same environmental conditions there may be fairly wide individual differences. By a long series of careful observations on normal children, Talbot (1931) has established that, except in premature babies, the behaviour of the surface temperature in children does not differ widely from that in adults. With variation in room-temperature the temperature of the extremities alters most, while the temperature of the trunk remains relatively constant.

The skin-temperature of the hands and feet is a useful indicator of changes in blood-flow, especially in the lower range, although it is not a precise measure of the flow. In the upper range big variations in flow cause small variations in temperature (Cooper et al. 1949).

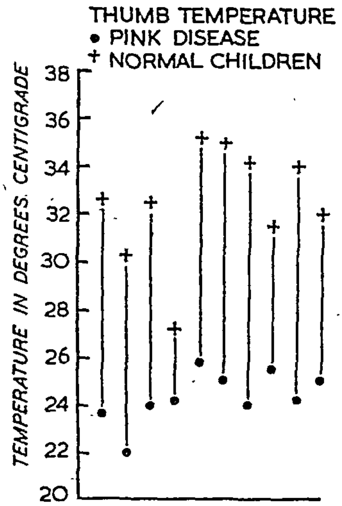

Fig. 1—Comparison between the skin-temperature of the thumb in 10 children with pink disease and in 10 convalescent children of similar age chosen at random from the ward.

Ordinary clinical observation of children with pink disease, and assessment of their hand and foot temperature by touch at short intervals, show that their extremities are generally colder than those of other patients of the same age in the same ward. According to Lewis (1936) such coldness signifies a decreased flow of blood through the skin arterioles or the small arteriolo-venous anastomoses. However, contact of the child's hand with a warm object, such as its own body, raises the temperature of the hand more rapidly than would be expected from simple thermal conduction, and this is presumably due to dilatation of the same vessels in response to direct heat.

In pink disease the colour of the hands and feet is always more intense than normal, but the tint varies from red to bluish-red according to their temperature. Even when they are quite warm the increased intensity remains. Clearly, the capillaries or the subpapillary venous plexuses are dilated, as in other conditions with habitually cold extremities—e.g., acrocyanosis (Lewis and Landis 1930).

The hands and feet are also moist from increased sweating, which is part of a generalised hyperhidrosis and is increased by warming the body.

INVESTIGATIONS

A direct-reading copper-constantan thermocouple of the type designed by Lewis and modified by Grant (1935) was used; this proved accurate within 0·3°C. The leads were fixed to the skin with small strips of zinc-oxide strapping and the infant was restrained as little as possible. For each experiment the infant was dressed in two short-sleeved upper garments (one of wool and the other of cotton) and a napkin. The recordings were made in cubicles kept at a temperature that was constant within about 1°C during the experiment; all the infants remained under these conditions for at least half an hour before the temperatures were taken.

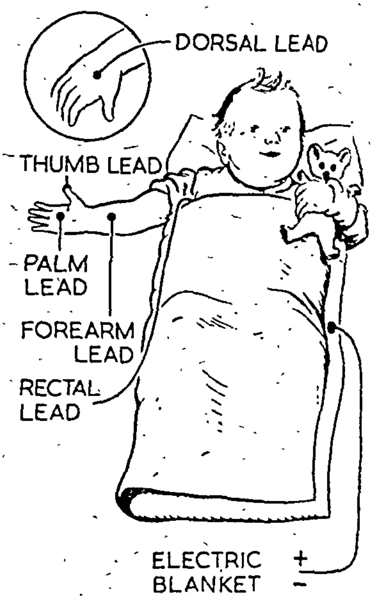

Fig. 2—Points from which skin-temperatures were taken, and method used for warming trunk and legs with electric blanket.

Under these conditions the clinical observation mentioned above was confirmed—the infants with pink disease had colder extremities than normal, especially the hands. Fig. 1 shows the skin-temperature of the thumb in 10 patients with pink disease as compared with 10 other convalescent patients of the same age chosen at random from the ward. For each pair the room-temperature did not differ by more than 1·5°C. The temperature of the trunk, forehead, and proximal parts of the limbs did not differ significantly from normal. The rectal temperatures were usually in the upper range of normal or slightly higher.

Reflex Dilatation

The next step was to determine, by attempting to obtain reflex vasodilatation, whether the coldness was due simply to excessive vasoconstriction of the skin arterioles.

Reflex vasodilatation in response to warming the body occurs readily in normal children. Fig. 2 shows the

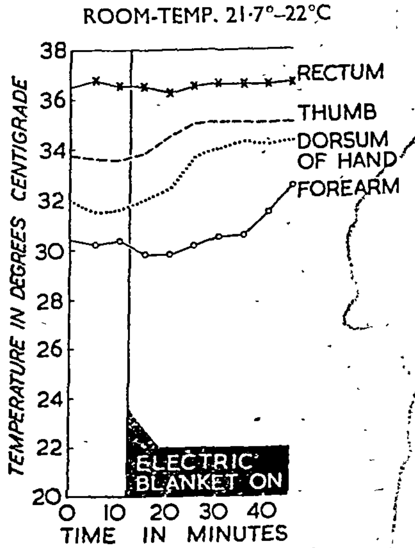

Fig. 3—Reflex vasodilatation in hand on warming trunk and legs, in normal child, aged 11 months, after stabilisation at fairly constant room-temperature.

method of heating with an electric blanket (45°–50°C), and the points from which the readings were taken (to avoid confusion on the charts not all of these are recorded). The temperature of the palm approximately followed that of the dorsum of the hand but was usually a degree or so higher. The electric blanket was covered with an ordinary blanket to insulate it as much as possible and thus to prevent warming of the hand by radiation.

Fig. 3 is an example of the temperature of the hand and arm in a normal baby after remaining for 1/2–3/4 hour under the conditions stated, and shows the immediate warming due to reflex vasodilatation when the trunk and legs were heated. The initial temperatures recorded on this and all the following charts were the first readings after reasonable stability had been reached. In every case the electric blanket remained on until the last skin-temperature measurement had been made.

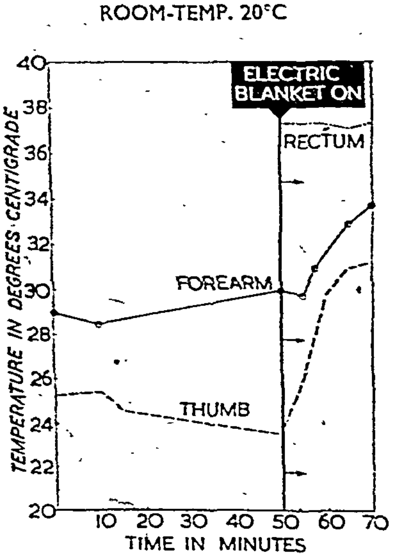

Fig. 4—Immediate reflex vasodilatation in hand on warming trunk and legs in unusual child, aged 2 years, with habitually cold extremities.

Fig. 4 (also from a control) represents the response in a constitutionally cold-handed child. The initial temperatures were much lower, but reflex vasodilatation occurred readily.

In pink disease, however, the response was strikingly different (figs. 5*a* and 6*a*). After keeping on the electric blanket for 40–70 minutes, and in most cases raising the rectal temperature by 1°–3°C, the hand did not become warmer. Eleven infants with pink disease were tested in this way, ten of whom yielded similar results, most of them on more than one occasion (see table). The exceptional infant showed a slow and delayed reflex dilatation after 35 minutes' heating, but in this case clinical recovery was already beginning.

On repeating the investigation when clinical recovery had taken place (six cases), heating was followed by the normal response of reflex vasodilatation (figs. 5*b* and 6*b*).

Warming these infants with pink disease induced excessive sweating, and it was at first considered possible that the evaporation of this sweat from the hand might have prevented the reflex rise in temperature. The same test was therefore made on a child with hyperhidrosis of the hands (fig. 7): in spite of a degree of sweating greater than that seen in pink disease the normal reflex vasodilatation took place.

Calibre of Vessels

The next thing to determine was whether there was structural narrowing of the small arteries or arterioles.

In two infants with pink disease ulnar-nerve block at the elbow with 2% 'Xylocaine' produced a full rise in temperature of the fifth finger, and the thumb remained cold (fig. 8), this being the result of functional interruption of the vasoconstrictor fibres which follow the distribution of the sensory nerves.

Blocking the transmission through the sympathetic ganglia by intramuscular injection of 100 mg. of tetraethylammonium bromide (T.E.A.B.) was followed in another case of pink disease by a similar release of vasomotor tone (fig. 9): the blood-pressure fell from 120/90 to 85/60 mm. Hg.

Intramuscular 'Priscol' (2-benzyl-2-imidazoline) produced rapid vasodilatation (fig. 10) in the four cases where it was used, but no constant change in blood-pressure. The mode of action of priscol is complex:

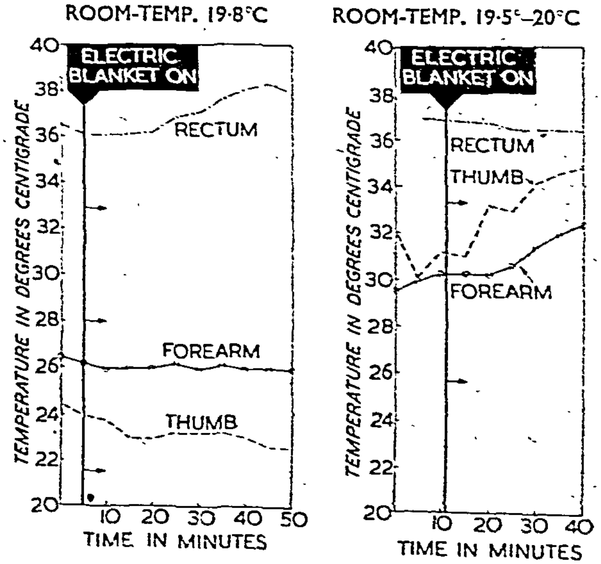

Fig. 5—Results of warming trunk and legs: *a*, in infant, aged 11 months, with pink disease, showing coldness of hand and absence of reflex vasodilatation in spite of significant rise in rectal temperature; *b*, in same infant after clinical recovery, showing further reflex vasodilatation in already warm hand.

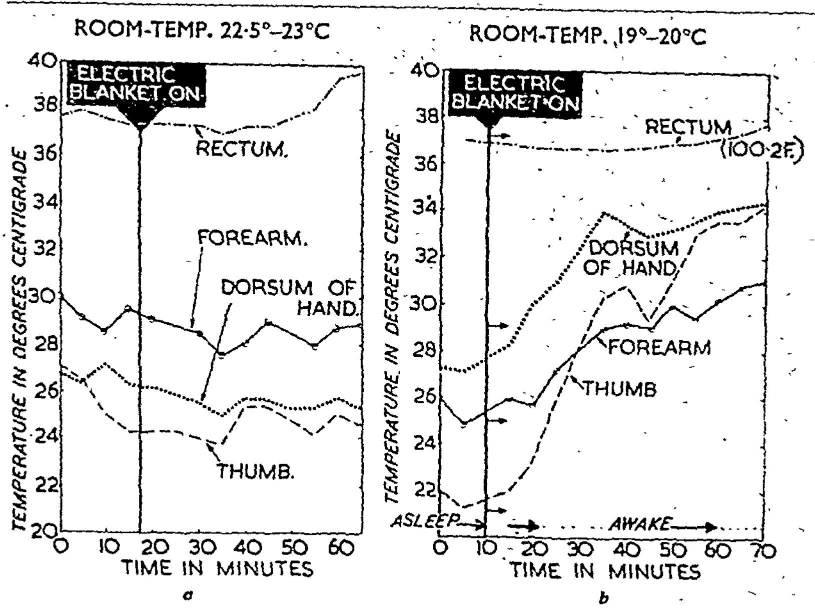

a *b*

Fig. 6—Results of warming trunk and legs : *a*, **in infant, aged 10 months, with pink disease, showing absence of reflex vasodilatation in spite of 2°C rise in rectal temperature ;** *b*, **in same infant when clinical recovery was almost complete, tested at lower room-temperature but now showing immediate reflex vasodilatation.**

predominantly, it annuls the excitatory effects of circulating adrenaline (or noradrenaline) and prevents the transmission of excitatory sympathetic nerve impulses from the postganglionic neurones to the effector cells in the blood-vessel wall, but it also increases the cardiac output, which probably explains why the blood-pressure did not fall. Priscol is now being tried in the treatment of pink disease.

In three cases of pink disease the temperature of the hand did not rise during sleep, although clinically it had been noted that at night, during long and deep sleep, the hand did become warmer. The accompanying table summarises the findings.

DISCUSSION

The presence of hypertension, tachycardia, and excessive sweating as prominent clinical features of pink disease led to the conception of it as a disease of the autonomic nervous system, with predominance of sympathetic activity. Feer (1925), who was the first to study it extensively, attributed the whole clinical picture, including the muscular hypotonia, to a "vegetative nervous disorder." His idea gained much support, and other workers elaborated it. Blackfan and McKhann (1933), for instance, after studying 40 cases, concluded that sympathetic overactivity was responsible for most of the symptoms and signs, but that the parasympathetic side was also involved—in the production of the increased salivation and lacrimation.

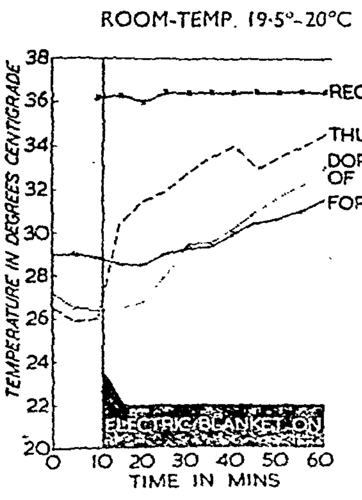

Fig. 7—Reflex vasodilatation in child with severe hyperhidrosis, showing that warming was not prevented by evaporation of sweat.

The notion of sympathicotonia as an explanation for the production of symptoms and signs is, however, insufficiently specific (Darrow 1943). *Pink disease* is likely to be better understood by investigating each separate neurophysiological mechanism concerned. Few attempts have been made to test the function of the autonomic system in pink disease. Day et al. (1939) set out to do so and showed that in three cases the tachycardia could not be significantly increased by emotion, from which they concluded that sympathetic tone was already at a maximum. They also demonstrated a further increase in the pulse-rate after giving atropine and inferred that the vagi were functioning. Hypersecretion of the adrenal medulla has been suggested as a possible explanation of the clinical features (Kühl 1928), and the resemblance of pink disease to the hypertensive paroxysm caused by a phæochromocytoma, with its tachycardia, sweating, and cold extremities, has been noticed (Hubble 1951). I have seen one patient who was confidently diagnosed as pink disease by a reputable pædiatrician until a phæochromocytoma was discovered. Check (1951), however, using a method which he admits is liable to an error of ± 10%, has found no increase in the adrenaline content of the blood in pink disease.

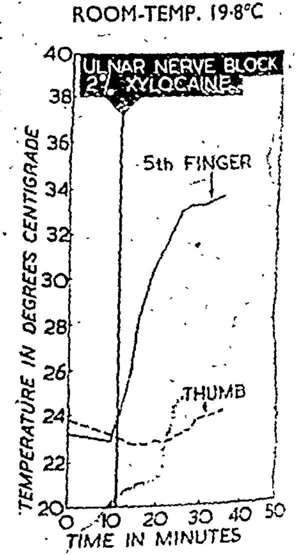

Fig. 8—Vasodilatation in little finger of infant, aged 11 months, with pink disease, after ulnar nerve has been blocked with 2% xylocaine.

Evidence from morbid histology is insufficiently conclusive to be of much help in supporting the hypothesis that pink disease is a disease of the autonomic system. Many of the reported necropsy changes in the nervous system have probably been due to the intercurrent disease which caused death. Péhu et al. (1936), in a critical review of the published findings, concluded that there were probably true widespread non-destructive lesions (chromatolysis, &c.) particularly in the sympathetic nervous system, including the hypothalamus. Lubin and Faber (1938), however, believed *that* such lesions were too inconstant to explain the physical signs, and found in their own case no changes in the hypothalamic region. Woringer (1926) reported hypertrophy of the suprarenal medulla in one case, and there have been other accounts of slight modifications of the histology which are too vague to be convincing.

The present investigation of the skin-temperature shows that in pink disease the blood-flow through the skin of the hands is decreased owing *not to structural* changes in the blood-vessels but to excessive vasoconstriction. This effect is abolished when the nerve-supply of the arterioles is interrupted, whether at the sympathetic ganglia (T.E.A.B.), in the peripheral nerve carrying the sympathetic fibres to *the blood-vessels* (ulnar-nerve block), or at the nerve-ending in the vessel

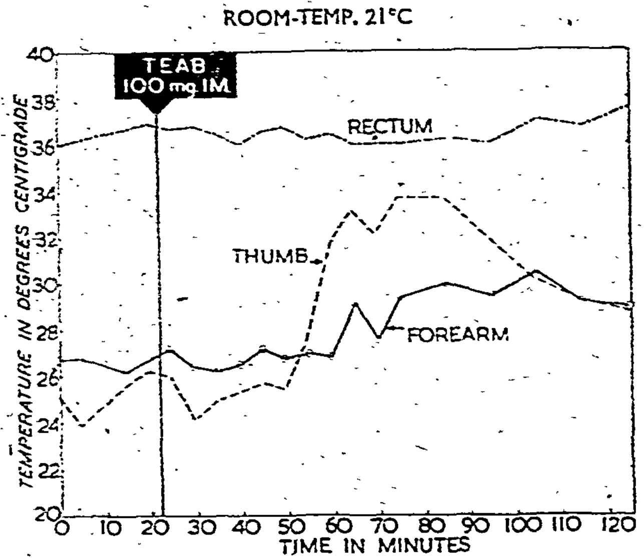

Fig. 9—Vasodilatation in thumb and forearm of infant, aged 16 months, with pink disease, after intramuscular injection of tetraethylammonium bromide 100 mg.

wall (priscol). The absence of reflex vasodilatation when warmed blood reaches the hypothalamus is probably due to the strength of the vasoconstriction, but a possible alternative explanation is that there is a specific disorder of function in the hypothalamus.

Tone in the small blood-vessels of the skin normally depends partly on impulses reaching them through their sympathetic nerve-supply and partly on humoral control. A dominant part is played by adrenergic vasoconstrictor nerves; and though cholinergic vasodilator nerves probably exist (Lewis and Pickering 1931) they are almost certainly much less important. The sympathetic system is influenced by cells in the hypothalamus, and these in turn receive from the cerebral cortex impulses which are probably inhibitory (Kuntz 1946).

The excessive vascular tone in pink disease may thus be due to stimulation of nerve-cells somewhere at or above the sympathetic ganglia, leading to an increased flow of impulses to the periphery. Lesions causing release of the sympathetic centres in the hypothalamus from the inhibitory influence of the cerebral cortex could theoretically produce the same effect. Although the experimental findings are therefore compatible with overactivity of the sympathetic nerves supplying at least the blood-vessels of the skin, the alternative possibility of a circulating vasoconstrictor substance acting directly on the blood-vessel walls is not disproved. It is reasonable to suppose that, if the excessive vasoconstriction were due to such a circulating substance, removal of the normal nervous impulses to the blood-vessels would allow vasodilatation to take place. An alternative possibility is that this substance might exert its action by potentiating the transmission of impulses through synapses or nerve-endings in the sympathetic pathways. Small doses of adrenaline, for example, augment the transmission of impulses through the sympathetic ganglia (Burn 1945). By analogy with a phæochromocytoma of the suprarenal gland, which has already been discussed, the supposed circulating substance might well be a mixture of adrenaline and noradrenaline (Engel and von Euler 1950). Since noradrenaline predominates in the suprarenal gland of early childhood (West et al. 1951), investigations to show whether it is present in excess in pink disease are being undertaken. So far it can only be said that a study of the peripheral vascular responses lends some support to the conception of this disease as a disturbance of the sympathetic-adrenal system.

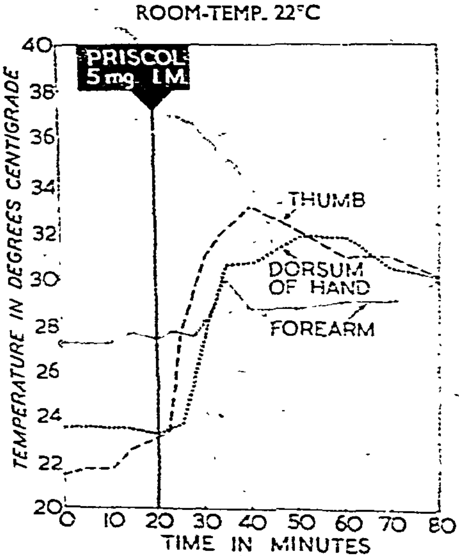

Fig. 10—Immediate vasodilatation in hand after intramuscular injection of priscol 5 mg. in infant, aged 10 months, with pink disease.

SUMMARY

The well-recognised clinical observation of coldness of the hands and feet in pink disease is confirmed by accurate temperature measurements under standard conditions.

Reflex vasodilatation in the hands, which normally follows heating of the trunk and legs, is absent in ten out of eleven cases of pink disease.

The capacity to produce reflex vasodilatation is, however, regained when clinical recovery takes place.

Ulnar-nerve block by local anæsthetic, intramuscular injection of tetraethylammonium bromide, and intramuscular injection of priscol, however, all lead to vasodilatation in the hands.

It is concluded that the coldness is caused not by structural occlusion of the vessels but by excessive vasoconstriction in the arterioles, with capillary dilatation. Certain hypothetical explanations of these findings are discussed.

I wish to thank Dr. P. R. Evans for his great help and encouragement; Dr. H. E. Holling and Dr. E. M. Glaser for advice and helpful criticism; Prof. A. A. Moncrieff and Dr. Wilfrid Sheldon for permission to carry out some of the investigation at the Hospital for Sick Children, Great Ormond Street; and Dr. Eleanor Coll and the sisters, nurses, and medical students who assisted at different times. The figures reproduced in this paper were prepared by Miss M. J. Waldron in the department of medical illustration, Guy's Hospital.

ACUTE ETHYLENE GLYCOL POISONING TREATED WITH CALCIUM SALTS

ALAN P. GRANT
M.D. Belf., M.R.C.P. Lond., M.R.C.P.I.
ASSISTANT PHYSICIAN, BELFAST CITY HOSPITAL

ETHYLENE glycol ('Antifreeze') has an effect like that of alcohol; it has a sweet pleasant taste, and gives a warm sensation when ingested. In the body it is oxidised to oxalic acid, and calcium oxalate is deposited in crystalline form in the kidney and brain.

The toxicity of the glycols first came to public notice by deaths which followed the administration of a solution of sulphanilamide dissolved in diethylene glycol. In 1930 two cases were reported in which the patients died of respiratory failure and convulsions after drinking ethylene glycol (*Journal of the American Medical Association* 1930). The pharmacology of the glycols is now better understood. Ethylene glycol is about twice as toxic as propylene glycol, which is oxidised in the body to lactic or pyruvic acid and combined with glycuronic acid. Ethylene glycol is only half as toxic as diethylene glycol. With these other two glycols, crystals of calcium oxalate are not found; and most of the main symptoms of acute ethylene glycol poisoning seem to be connected with oxalic acid. Smith (1951) described two subacute cases of such poisoning in which the patients died after 11 and 12 days from renal failure. Necropsy showed focal hæmorrhagic necrosis of the renal cortex and hydropic changes in the liver and renal tubules—changes which also occur in poisoning with diethylene glycol.

CASE-HISTORY

The patient, a slightly built male, aged 54, was admitted in deep coma with a vague history of having been exposed to fumes at work on the afternoon shift. He worked in an aircraft factory, and had that day been cleaning out the petrol tanks of an aeroplane; he had apparently entered the tank against regulations. He had left work early, staggering on his way out and falling on his back. Arriving home at 10.30 P.M. apparently drunk, he vomited his meal and staggered up to bed. His wife was not unduly perturbed, but she noticed that he was becoming very confused; and at 2 A.M. he was deeply comatose.

He was admitted to hospital at 7.30 A.M., deeply cyanosed. The respirations were stertorous—30 per minute—the temperature 98·4°F, and the pulse regular at 96 beats per minute. He was deeply comatose; there was no response to any stimulation, all deep and superficial reflexes were absent, and he was incontinent of urine and fæces. Frothy saliva was dribbling from his mouth, and his blood-pressure was 120/80 mm. Hg. The fundi showed no abnormality. His urine showed a trace of albumin, but no other abnormality. The stomach was aspirated as a routine measure, but the contents—20 oz. of foul-smelling fluid—were unfortunately discarded. Lumbar puncture yielded clear cerebrospinal fluid under normal pressure, containing 13 cells per c.mm., protein 120 mg. per 100 ml., and chlorides 840 mg. per 100 ml. He was given oxygen by inhalation, penicillin intramuscularly, and calcium gluconate intravenously. Milk was given by stomach-tube, because acute lead poisoning was suspected. Glucose-saline was given by intravenous drip to remedy dehydration.

The patient remained in deep coma for the next two days, during which administration of calcium gluconate was continued. Inquiry as to the cause was instituted at the works without success. Lead encephalopathy due to tetraethyl lead, which might have been present in the tank of the aircraft, was eliminated by urinary-lead estimation. Methyl bromide poisoning was considered, as on the day of onset he had also been shifting fire-extinguishers. It was not until the fourth day, when he was recovering consciousness, that we learnt that the patient had drunk about three-quarters of a tumbler of antifreeze. (This was confirmed by the patient on recovery.) On that day his urine contained a fair amount of albumin, he had pronounced tremor of the limbs, and he was incoördinated and rowdy. Distinct convergent strabismus was present. On the fifth day he was mentally much clearer, but tremor and squint did not disappear until the eighth day. During this period he felt extremely ill; he vomited bile-stained material, and the urine contained albumin but no bile. Fluids with glucose were given copiously and calcium lactate was administered by mouth. Recovery was gradual; and the patient was discharged, apparently cured although still shaky, after three weeks. A blood-count a this time showed no notable abnormality: red cells 4,400,0 per c.mm., hæmoglobin 82%, film normal. A van den Berg test was negative.

The patient was seen again two and a half years late complaining of general weakness, loss of weight and appetit and peculiar sensations in his abdomen. Complete clinic examination showed no abnormality other than a peculi yellow pigmentation of the face and arms, pronounce tremor, some loss of postural sense in the legs, and accentu tion of the deep reflexes. He was still shaky, lacked co centration, could not stand noises, and was very sensiti to cold. Sensibility to posture and deep pain was impaire in the lower limbs; and he was generally weak; the dee reflexes were increased. Previously a cheerful person all h life, he was now severely depressed. Investigations at th admission were as follows: alkaline phosphatase, 5·2 units thymol turbidity, 1 unit; van den Bergh, no increase albumin, 4·8 g. per 100 ml., globulin, 2·2 g. per 100 ml. barium meal, normal; glucose-tolerance test (fasting and half-hourly intervals after 50 g. glucose), 69, 83, 90, 66, 3 and 66 mg. per 100 ml.

COMMENT

The nervous manifestations presented appeared t fall into three stages:

1. Depression of the higher centres with ataxia and apparen stimulation similar to acute alcoholism, lasting three to fiv hours.
2. Deep coma due to gross depression of the nervous system with pronounced cyanosis and loss of deep and superficia reflexes, lasted four days.
3. Recovery with distinct tremor, incoördination of cortica type, and strabismus, lasting four days—although some evidenc of cortical deterioration was still present after three weeks.

The coma was probably due to a combination o cerebral depression and pulmonary œdema. The patient seems to have suffered permanent cerebral damage there was no evidence of permanent renal damage. The yellowish pigmentation after two and a half years is unexplained.

DISCUSSION

Few cases have been reported in which patients survived such severe ethylene glycol poisoning. The minimal lethal dose has been estimated as 100 ml., although Kahn and Brotchner (1950) report a case o a young man who survived after ingesting 240 ml. It was estimated that the patient described here drank 120-150 ml. He was a chronic drinker and *not* robust. Calcium, given under the initial impression that he was suffering from lead encephalopathy, combined with oxygen, may have enabled him to recover.

In cases coming to necropsy generalised congestion with degenerative fatty changes in the liver cells has been found; but the most pronounced changes seem to be as follows:

1. Well-marked pulmonary œdema, sometimes with early bronchopneumonia.
2. Tubular nephritis with deposition of calcium oxalate crystals, swelling of the lining endothelium, and granularity of the cytoplasm. Despite this there does not seem to be gross epithelial desquamation.
3. Congestion of the brain and meninges with œdema; in severe cases exudative meningo-encephalitis is the most important feature. In the brain and leptomeninges calcium oxalate crystals are found, lying mainly around the blood-vessels. Those present in the brain-substance proper evoke no reaction around them. Damaged cells are found in the motor cortex, brain-stem, and cerebellum. Pons and Custer (1946) suggest that ethylene glycol, like alcohol, becomes slowly concentrated in the cerebrospinal fluid, and that the concentration there is maintained for some time.

The pathology suggests that calcium oxalate crystals themselves are inert. The inflammatory changes are around the blood-vessels in contact with the cerebrospinal fluid, and may perhaps be due to oxalic acid. In the case described here the calcium given in large doses intravenously may have changed this oxalic acid to the relatively inert calcium salt. Milles (1946) suggested calcium or a parathyroid preparation as a possible therapy, although he did not try these substances.

SUMMARY

A case of ethylene glycol poisoning with recovery is described. In this case large doses of calcium given intravenously may have changed oxalic acid to calcium oxalate, thus preventing the destructive action of oxalic acid on the brain.

Re-examination after two years suggested permanent cerebral damage. There was no real evidence of renal or hepatic failure; but a peculiar yellowish pigmentation was observed on the neck and arms.

I am indebted to Dr. James A. Smiley, medical officer of Messrs. Short Bros. & Harland Ltd., for his coöperation.

PELLAGRA ASSOCIATED WITH CROHN'S DISEASE

J. R. Armstrong
M.D. Camb.

PHYSICIAN, STRACATHRO HOSPITAL, BRECHIN, ANGUS

Pellagra secondary to disease of the small intestine and nutritional disturbances depending on malabsorption has often been recorded; but as a complication of Crohn's disease it does not seem to have been described in the last twenty years.

CASE-RECORD

A trained nurse, aged 24, was a patient in a mental hospital where she had symptoms suggestive of catatonic schizophrenia, together with diarrhœa and loss of weight. No cause being found for the diarrhœa, she was transferred to a medical ward at Stracathro Hospital on June 10, 1949.

Condition on Admission

The patient was emaciated, apathetic, and mentally confused, and had a striking pink and white complexion with a malar flush. She was afebrile, her appetite was poor, and she passed fluid stools several times a day. The diarrhœa had started two years previously, after an attack of erythema nodosum. No evidence of any infection was discovered in the mouth, nasal sinuses, skull, or respiratory and cardiovascular systems. Radiography of the chest was negative and a barium meal and barium enema did not reveal any abnormality in the gastro-intestinal tract. The urine and cerebrospinal fluid were normal. There was no evidence of any gastro-intestinal infection, and the Wassermann reaction was negative.

Progress

During the first three weeks in hospital the patient developed spastic paraplegia and ataxia, and her mental condition deteriorated. Her stools became more frequent, and she began to show signs of dehydration. Steatorrhœa was present, but fat-splitting was normal. Her serum-calcium level was only 7·8 g. per 100 ml.; her plasma-proteins were 5·25 g. per 100 ml. (albumin 3·4 g., globulin 1·8 g.). Her blood-sugar was 90 mg. per 100 ml.

On July 9, 1949, a rash appeared on her face, neck, and backs of the hands, and she became completely disoriented and incontinent. Pellagra was diagnosed and treated. Immediate response was noted, and the patient improved so rapidly and gained so much weight that she returned home on Aug. 20, 1949. Her mental condition was then normal, and there was little ataxia or difficulty in walking, but her plantar reflexes, which had throughout been extensor, did not show any change. During the next nine months she was seen at intervals and steadily gained weight and improved in health.

In May, 1950, she complained of abdominal pain, attacks of vomiting, and slight diarrhœa, and developed a left-sided ischiorectal abscess, for which she was readmitted to hospital. The abscess was drained, and coliform organisms were cultured from the pus.

In July, 1950, the patient developed acute appendicitis, and at operation for appendicectomy the lower 18 in. of the ileum were found to be the seat of second-stage Crohn's disease. No further treatment was thought justifiable, and the abdomen was closed.

The patient again came under medical care on Aug. 30, 1950, with vomiting, flatulence, and hot flushes. There was no diarrhœa and no weakness of the limbs; the fingers and toes showed clubbing; and the blood-pressure was 90/50 mm. Hg. The abdomen was rather full; there was slight œdema of the ankles; the plantar responses were extensor on both sides, but there was little ataxia. Considerable anæmia was present, a blood-count showing red cells 3,900,000 per c.mm., white cells 6000 per c.mm. (polymorphs 86%, lymphocytes 8%, monocytes 5%, eosinophils 1%), and Hb 9·2 g. per 100 ml. The reds cells were normocytic and underfilled; and the plasma-proteins were 5 g. per 100 ml. An ischiorectal fistula was present, and this was excised on Nov. 9, 1950. The patient left hospital on Dec. 16, and was asked to return in January, 1951. It was thought that she was still suffering from a deficiency of vitamins as a result of malabsorption due to Crohn's disease.

Resection of Ileum.—On March 12, 1951, about 3 ft. of diseased ileum was removed together with its mesentery, and a primary anastomosis of the small bowel was made. Uninterrupted recovery followed the operation, and on March 28 the patient returned home. On histological examination the two wedges of intestine and omentum showed chronic granulomatous changes with much fibrosis and a few small follicles suggesting tuberculosis.

Follow-up.—The patient was last seen on April 1, 1952, when she weighed 9 st. 8½ lb., and examination of her blood showed red cells 3,700,000 per c.mm., white cells 7000 per c.mm., Hb 88%, colour-index 1·2, mean corpuscular Hb concentration 33%, mean corpuscular volume 105 c.μ., packed-cell volume 39 c.cm., and erythrocyte-sedimentation rate 32 mm. in 1 hr. (Wintrobe). Her plasma-protein level was 6 g. per 100 ml. (albumin-globulin ratio 2 : 1). A blood film showed red cells a little larger than normal and well filled with hæmoglobin; platelets present in adequate numbers. The patient was well nourished, her tongue was clean, her abdomen was well covered, there was no tenderness anywhere, and her liver and spleen were not enlarged. There was slight œdema of her shins, her deep reflexes were all brisk, her blood-pressure was 130/80, and both plantar reflexes were extensor. A fractional test-meal disclosed achylia gastrica, and no starch was noticed in any of the specimens. The only complaint which the patient had was that her bowels tended to be somewhat irritable and she usually passed two or sometimes three stools a day, but they were well formed and there was no diarrhœa. There was obviously no serious interference with nutrition, since she was well nourished and of normal weight.

DISCUSSION

Pellagra has been reported in association with extensive jejuno-ileitis (Killian and Ingelfinger 1944), gastro-enterostomy (Ferguson 1943), chronic amœbic dysentery (Blanc and Siguier), and annular carcinoma of the ileum (Nuzum 1925). Simpson (1934) stated that pellagra may follow a lesion almost anywhere in the gastro-intestinal tract, from the stomach to the rectum. Bean et al. (1944) stated that diseases such as pulmonary tuberculosis and malaria, as well as conditions such as pregnancy and lactation, may be responsible for its appearance in places where malnutrition is endemic.

Nutritional disturbances caused by diminished food intake, lack of absorption due to alteration of the intestinal mucosa, restricted areas for absorption of vital materials after short-circuiting operations, severe and prolonged diarrhœa, loss of protein through a chronic suppurating focus, and loss of body-fluids as after burns or from protracted diarrhœa, have all been cited as causing pellagra.

Mackie et al. (1940) found that in the early stages of vitamin deficiencies there is a disturbance of function, which precedes the structural changes which are found when the deficiency becomes more intense or has lasted a long time. Thus patients with signs of hypovitaminosis may have either reversible or irreversible lesions in the gut. In the present case it was tempting to think that the initial symptoms of hypovitaminosis were due to reversible changes, because the improvement after intense vitamin therapy was so pronounced, and that the relapse was in part due to the ischiorectal fistula. It is impossible, however, to reconcile this idea with the subsequent discovery of Crohn's disease—a condition which can only be regarded as irreversible.

The fact that the patient still has looseness of the bowels and macrocytic anæmia suggests that, though there is no reason to believe that a progressive lesion is still present, she cannot be regarded as cured.

SUMMARY

A case of pellagra in a patient with Crohn's disease is described. Resection of the diseased part of the small bowel was followed by improvement.

I am indebted to Mr. R. V. Liddell for the surgical treatment of this patient, to Dr. A. V. Hendry for his advice, and to Prof. A. C. Lendrum, of the University of St. Andrews, for a histological report on the tissue removed.

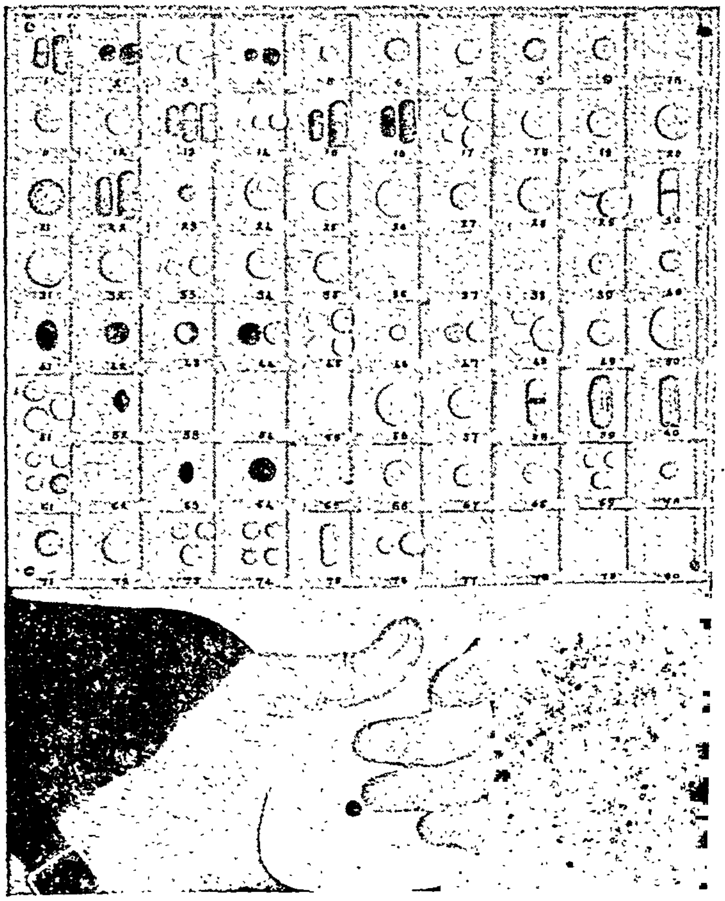
New Inventions

A TABLET-IDENTIFICATION BOX

In the last few years there has been a steady increase in the number of new drugs in common use. To name only the chief groups, there are hypnotics, antihistaminics, analgesics, antibiotics, aperients, and vitamins: their colours are spectral and their shapes and covering diverse; tablets may be smooth or grooved, coloured or white, coated or plain; and pills and capsules come in many sizes and shapes. Some of these are used in the treatment of skin diseases; and others at times cause drug eruptions.



When questioning patients attending a skin department, it is often difficult to discover what drugs they have been taking, and their doctors do not always give this information in the accompanying letters. If a patient is suspected to be suffering from a drug eruption, the elucidation of this point is most important, and only a few outpatients bring their medicaments with them. The need was therefore felt for a compact tablet-identification box which could be kept in the consulting-room, and from which patients could identify the drugs they have taken.

Dr. F. F. Hellier showed one of us such a box used in the skin department at Leeds Royal Infirmary. The box illustrated here is more elaborate and designed for long-continued use. Its chief features are strength and portability, and good visibility and easy recognition of the drugs inside. It can be taken to pieces if necessary for alterations or additions to the contents. A box of this sort is also useful for teaching purposes.

The box (see accompanying figure) is made of $^1/_8$ in. sheet 'Perspex,' and weighs 2 lb. The over-all measurements of the box are $10^1/_4 \times 8^1/_4 \times {}^7/_8$ in., with a handle projecting for $4^1/_2$ in. from one of the longer sides, the grip being $2^1/_4$ in. wide. The box is built around a central sheet of white opaque perspex which is extended to form the handle. The edges of the box itself are $^1/_2$ in. deep, and it is subdivided into 80 compartments, each $^7/_8$ in. square. Both the edges and the internal divisions are fixed to the opaque sheet by perspex cement. The handle is strengthened by cementing to it a piece of $^3/_{16}$ in. perspex of similar shape. When not in use the box may be hung on the wall by a hole through the handle. The front and back are formed by two further sheets of perspex which are held in place at the corners by four brass nuts and bolts.

Both tablets and capsules can be attached to the opaque sheet with 'Dyrofix' or a similar glue. They can easily be removed to change the contents if need be. The squares are numbered in rows of ten, while the key, giving particulars of the dosage and nature of the drugs, is typed on quarto-size paper and inserted between the opaque and the back perspex sheets.

We wish to thank Mr. J. T. Edwards, of the London Hospital Medical College, who kindly constructed the box to our design.

Reviews of Books

Antibiotics

A Survey of Their Properties and Uses. 2nd ed. Contributors: S. J. EDWARDS, D.SC., A. KEKWICK, F.R.C.P., F. A. ROBINSON, M.SC., G. SYKES, M.SC., B. J. THOMAS, M.P.S. Published by direction of the Council of the Pharmaceutical Society of Great Britain. London: Pharmaceutical Press. 1952. Pp. 274. 25*s.*

THE number and uses of antibiotics have been increasing so rapidly that it has been virtually impossible for anyone to keep himself fully conversant with the latest developments. This book is therefore welcome, since it provides a relatively short and concise, yet remarkably complete, account of the uses and abuses of these drugs. The book is intended primarily for general practitioners, veterinary surgeons, and pharmacists, whose requirements are admirably met. It is perhaps rather overloaded with laboratory details; some of those relating to chemical analysis and biological assay methods might well have been omitted.

Genes and Mutations

Cold Spring Harbor Symposia on Quantitative Biology. Vol. 16. Cold Spring Harbor, New York: Long Island Biological Association. 1952. Pp. 521. $9.

THE science of genetics seems forbiddingly formalistic to many who are not in any way enemies of Mendelism, like the followers of Lysenko. The subject is sometimes thought to be less a branch of experimental biology than a playground for mathematical statisticians. There could hardly be a better corrective to this belief than the contributions to a recent symposium on genes and mutations, organised, like its predecessors, by Professor Demerec and held at Cold Spring Harbor.

In his introductory paper Goldschmidt points out that the idea of correlating one enzyme with each gene, though logical, may require revision. Mutations in neurospora and *Bacterium coli* have repeatedly been shown to produce metabolic alterations or defects which are attributable, according to the work of Horowitz and Leupold, to changes in single enzymes. On the other hand, the "position effect" phenomenon, investigated profoundly by McClintock, especially in maize, points to genes having actions which vary according to the nature of their genic neighbours.

The causes of gene mutation are multiple; and, as Auerbach shows, radiation produces immediate effects whereas those of nitrogen mustards and formalin are often delayed. There is still no known common factor among mutagens. Westergaard and others point out that it is difficult to prove that any substance is not mutagenic, because changes produced may be very slight. A criterion of the difference between true gene mutation and chromosome damage might be the ability to produce back-mutation—a return to the original state. Stadler takes the matter even further, and, on the basis of his experiments, doubts whether there is any way of distinguishing absolutely between gene mutations and other processes, such as crossing-over at very closely adjacent loci.

Thus the ground is prepared for the reception of the idea of "pseudoallelism" as propounded by Lewis. Pseudoalleles are complex genes, of which the rhesus types in man are probably examples, and they are thought to arise in the first place by duplication of one gene, followed by divergent functioning of one of the pair as a result of a "position" effect. Justification for Goldschmidt's assertion that there is no fundamental distinction between chromosome breakages, rearrangements, and point mutations thus becomes evident.

The facts about the genetics of bacteria, as set out by the Lederbergs, may seem incredible enough; but the reader may be pardoned if he gasps with astonishment when Luria describes experiments on mutant genes in the phage infecting *Bact. coli*, and when Hershey and Chase demonstrate recombination, proving that the genes in phage T2H are arranged in linear order. Then again, there is the follow-up, by Hotchkiss, of the work of Avery and McCarty in which he transformed pneumococci into a penicillin-resistant type by adding a desoxyribonucleate prepared from resistant strains.

Of more direct interest to human genetics by analogy is the exact measurement of mutation-rate at specified loci in the mouse. This was found by Russell to average 25×10^{-8} per röntgen—a higher rate than that formerly established for drosophila. Aspects of the influence of cytoplasm on heredity are discussed by Ephrussi and by L'Heritier, and the interaction of cytoplasm and nuclear components in chlamydomonas and paramœcium is explained by Sonneborn.

Altogether there are over thirty papers, every one of which is of first-rate interest. An attractive feature throughout is absence of complacency; ideas are changing, and a vast field of investigation into fundamental biological processes is being rapidly developed. It is becoming clear that, as a small sacrifice to facilitate these advances, many current concepts of the gene and its functions will have to be modified considerably.

Injury of the Xiphoid

MICHAEL BURMAN, M.D., SAMUEL E. SINBERG, M.D. New York: Columbia University Press. London: Oxford University Press. 1952. Pp. 92. 22*s.* 6*d.*

IT seems hard to believe that the xiphoid should be sufficiently important to justify a monograph, but the authors' experience of nearly 100 cases of serious injury shows that it deserves attention. Direct injury, leading to dislocation of the cartilage from its normal site, results from sudden blows in the solar plexus, or when the driver of a car is thrown forward against the lower edge of the steering-wheel in an accident. The surgeon cannot be exonerated from being the cause of a xiphoid fracture when an enthusiastic assistant during a laparotomy exerts unduly vigorous retraction at the upper end of the abdomen. Like the coccyx, the xiphoid may become hypersensitive as a result of injury, and in many such cases the authors recommend its excision. Though the main concentration is on the xiphoid itself, this monograph touches on a slightly wider field than its title would suggest.

Primer on Alcoholism

MARTY MANN, chairman and executive director, National Committee on Alcoholism in America. London: Gollancz. 1952. Pp. 160. 8*s.* 6*d.*

ALL doctors should be adequately informed about alcoholism; and this book, though written by an American expert primarily for her fellow-countrymen, contains much that the British doctor should know. Mrs. Mann was herself an alcoholic, and has been cured. She has become a recognised expert on alcoholism, and has held her present post for seven years, so she is well qualified to speak on the subject. Throughout her book she emphasises that alcoholism is a disease, and therefore should be treated as objectively as pneumonia or diabetes. If this were more generally recognised a great deal of the guilt and shame from which the alcoholic invariably suffers, and in which his family and friends share, might be alleviated and treatment might be more readily accepted.

Mrs. Mann gives a good general description of the course of alcoholism and its effects both on the patient and his family; and she discusses in practical detail what can be done about it. Medical and psychiatric treatment, both at home and in institutions, is outlined and the work of Alcoholics Anonymous is particularly well described. This valuable organisation is already well established in Great Britain, with twenty groups in London, Liverpool, and other cities (headquarters address BM/AAL, London, W.C.1). The work of the Society for the Study of Addiction and the recently formed Advisory Council on Alcoholism is also sympathetically mentioned. There are two brief appendices by British doctors describing the treatment of alcoholism by apomorphine and 'Antabuse.'

Adrenal Cortex

Transactions of the Third Conference, Nov. 15–16, 1951. Editor: ELAINE P. RALLI, department of medicine, College of Medicine, New York. New York: Josiah Macy, Jr., Foundation. 1952. Pp. 204. $3.25.

WHEN such workers as Astwood, Ingle, Kendall, and Pincus (to mention only 4 out of 25) are brought together a verbatim report of their discussion, quickly published, is really up to date. Much of the material in this volume has not yet appeared elsewhere: some of it indeed is still in the stage of pure speculation. This conference dealt with the effects of adrenal cortical hormones on renal function, the rôle of the hypothalamus in regulating A.C.T.H. secretion, the estimation of blood steroids, the biogenesis of the adrenal cortical steroids, and the clinical use of adrenal cortical hormones and A.C.T.H. The discussion has been illustrated with graphs, tables, and photographs.

Anæsthesia for Thoracic Surgery

HENRY K. BEECHER, M.D., professor of research in anesthesia, Harvard University. Springfield, Ill.: Charles C. Thomas. Oxford: Blackwell Scientific Publications. 1952. Pp. 65. 18*s*.

THE methods advocated here are those of the author, and the book is therefore neither a review of present-day techniques nor in any way a critical analysis of them. A valuable account is nevertheless presented of thoracic anæsthesia as practised at the Massachusetts General Hospital.

Professor Beecher is a strong exponent of ether for thoracic anæsthesia. His advocacy of assisted respiration rather than controlled respiration may well be associated with his use of ether, the difficulty of controlling respiration with this anæsthetic being well known. Many of the ideas and practices described are clearly more in accord with surgical conditions in the United States than in this country. One example indicative of the gulf between Beecher's methods and those used here is the brief mention and somewhat offhand dismissal of the use of curare or other relaxants in thoracic anæsthesia.

Anæsthetists will read the book with interest.

Monographs on Surgery 1952

Editor: B. NOLAND CARTER, M.D., PH.D., professor of surgery, University of Cincinnati. 1952. Pp. 430. 95*s*.

THE policy of publishing annual volumes of monographs on surgery seems to be amply justified by this volume, the third in the series. Among the subjects reviewed are the radical surgery of pancreatico-duodenal cancer, stress incontinence in the female, arthroplasty, and current views about the internal fixation of fractures. All the articles are detailed and written by authorities on their subjects. The reader is thus spared the labour of wading through irrelevant and useless papers: the selection has already been made for him by reliable people. Monographs of this kind are of real help to busy surgeons.

Normal Blood-Pressure and Hypertension

New definitions. ARTHUR M. MASTER, M.D., cardiologist, Mount Sinai Hospital, New York, and associate clinical professor of medicine, Columbia University, New York; CHARLES I. GARFIELD, M.D., research assistant in cardiology, Mount Sinai Hospital, New York; MAX B. WALTERS, M.D., F.R.C.P. Can., member, heart station, Vancouver General Hospital, Canada, formerly research assistant in cardiology, Mount Sinai Hospital, New York. London: Henry Kimpton. 1952. Pp. 144. 30*s*.

THE correct interpretation of blood-pressure readings is earnestly to be desired; but opinions vary widely about the range of normal.

During the last thirty years there has been a tendency to accept 140–150 mm. systolic and 90–95 mm. diastolic as the upper limit of the normal, irrespective of age and sex. These authors contend that such limits are too rigid, and set too low; moreover, they are largely based on life-insurance statistics, which are in any case unsound because the material is highly selected, and relates to more men than women; moreover, most of the subjects are young, and the analysis is based on group-mortality. Dr. Master and his colleagues discuss the influence of age, sex, emotion, and other factors, and criticise the value of "basal" readings, concluding that it is more important to find the range of "casual" readings, since these reflect the subject's ordinary life.

They also consider local factors. Thus the relationship between the size of the arm and the width of the cuff greatly influences the accuracy of the pressure reading. It is noteworthy that arterial disease does not affect the reading; but spasm does, producing a false elevation of pressure which can be eliminated by repeated inflation of the cuff. Recommendations for cuff-size, design, and technique are given in detail.

Race, country, altitude, pregnancy, exercise, meals, and starvation do not exert an appreciable effect on the blood-pressure. Height has no influence; but weight is important, and reduction in weight is followed by a lowering of blood-pressure. The blood-pressure normally increases significantly with age, and this rise is more rapid and greater in females than in males after the age of 40.

The authors studied 74,000 unselected subjects representing the average working population between the ages of 16 and 65, and have tabulated their results in detail; and they have summarised their conclusions about normal and hypertensive limits in a final table. They discuss the interpretation and clinical application of the new blood-pressure limits, pointing out that the precise level of the blood-pressure is not so important as the presence or absence of underlying cardiovascular disease. There is no correlation between the height of the blood-pressure and symptoms, rate of progress, or development of complications; and the most important factors in prognosis are cardiac enlargement, albuminuria, changes in the retina, and the electrocardiographic findings.

There is a wide field of application of this new range of pressures in the practice of medicine and in clinical research; and the final table, a spare copy of which can be removed for mounting, should be on every doctor's desk.

Anglo-Saxon Magic and Medicine

J. H. G. GRATTAN and CHARLES SINGER. London: Oxford University Press. 1952. Pp. 234. 28*s*.

THE essential part of this important work is an edition of the definitive text of *Lacnunga*, an Anglo-Saxon book of prescriptions, incantations, and methods of treatment in various diseases. The text was last published in 1866 by Cockayne and is now very rare.

The present edition, which has been issued by the Wellcome Historical Medical Museum, is preceded by a detailed introduction by Professor Singer dealing with the whole subject of Anglo-Saxon medicine and enlivened by a choice and unusual collection of reproductions of contemporary illustrations. The second part of the book consists of the text, some of it in facsimile, of *Lacnunga*, and Professor Grattan's translation, notes, and commentaries.

Barbarian man had no mechanism for recording experience. His views on the nature of disease remained disjointed; but—since he knew well that he could sustain injury at his own hands or those of others—he commonly conceived that his symptoms were due to injuries inflicted by beings like himself, and that his sufferings were produced by weapons or agents identical with those that he himself employed. Elves were often regarded as the cause of disease, but as Christianity penetrated into the country God became pictured as the avenger in their place. The Anglo-Saxon leechdoms are a mass of folly and credulity. This is hardly surprising when it is remembered that there was no proper theory of disease and in consequence no rational remedies could be applied. The writer of *Lacnunga* dwells in the barbarian world of magic and hardly ever emerges. Here is an example of his text:

> "If there be a pock in the eye take marrow soap and hind's milk; mix and beat together; let stand until it be clear. Then take the clear fluid; put into the eyes. With God's help the pock shall away. . . . If a man be swollen within so that he cannot swallow the liquid, sing into his mouth."

This book will be welcomed as a treasure by students of Anglo-Saxon and medical historians interested in that period. The authors have garnished their scholarship with charm and humour.

Progress in Neurology and Psychiatry (Vol. 7. New York: Grune & Stratton. 1952. Pp. 604. $10).—Swelling year by year, this review, edited by Prof. E. A. Spiegel, seems to be approaching the awkward stage at which it must choose between blowziness and austere self-discipline. The book cannot cover everything written within its wide range, and a severely selective policy will save those who use it from the exasperation of looking up articles which turn out worthless. On the whole the neurological section remains the more satisfactory, as well as the more detailed: with the sections on neurosurgery and on the anatomy, physiology, and pharmacology of the nervous system, it takes up nearly two-thirds of the book. In the section on psychiatry the contributors seem unduly numerous, an extreme instance being the chapter of six and a half pages on the neuroses, prepared by no less than twelve doctors and a librarian. The value of the review would be increased by the inclusion of an index of names.

THE LANCET

LONDON: SATURDAY, DEC. 27, 1952

Deficiency of Potassium

Our understanding of the manifestations of sodium deficiency is derived from the classical studies of experimental depletion of sodium in man.[1] There have been no similar accounts of experimental depletion of potassium, because diets lacking this element are difficult to devise; and so our knowledge of potassium depletion is based mainly on clinical studies.

Deficiency of potassium may result from inadequate intake, excessive loss, or increased need. The intake may be inadequate in patients maintained with parenteral fluids. Excessive loss may take place from the alimentary tract[2] by vomiting, diarrhœa, aspiration of gastro-intestinal contents, or drainage from fistulæ; and from the kidney,[3] where acidosis, "osmotic diuresis," and adrenocortical hormone may in different ways lead to increased excretion. The need for potassium is enhanced by the deposition of protein tissue[4] or glycogen,[5] which are laid down with the normal constituents of intracellular fluid. These mechanisms are exemplified in the deficiency of potassium that may be found during the treatment of diabetic coma.[6] While the coma develops the patient loses potassium by vomiting; and he loses it from the kidney because, firstly with the acidosis there is an increased demand for the excretion of base, secondly with the glycosuria there is osmotic diuresis, and lastly there is increase in adrenocortical activity as part of the non-specific reaction to injury. The patient is treated with parenteral fluids which are unlikely to contain potassium; and there is an increased demand for potassium and other constituents of intracellular fluid as glycogen is laid down after administration of insulin. It is understandable, then, that these patients may show a potassium deficit; and this may amount to some 30 g., which is more than one-quarter of the normal content of the body. Yet it is only in recent years that such deficits have been recognised in patients with diabetes and other diseases.[7] This is partly because deficiency of potassium may not be easily demonstrated. Nearly all the body's store of potassium is in intracellular fluid, and serum levels may fail to reflect a deficiency. Though the serum-potassium can fall quite quickly with moderate deficits, it may not fall if there is renal failure or oliguria; and in untreated diabetic coma the serum-potassium level may be raised. Furthermore, the acid-base balance appears to affect the level of serum-potassium.[8] Potassium deficiency itself leads to alkalosis, and conversely alkalosis leads to loss of potassium; but with acidosis the serum-potassium level may be maintained despite a deficit of this ion.

The clinical picture is vague. It is usually described as one of apathy leading to mental confusion and disorientation, with anorexia, vomiting, and intestinal atony or sometimes paralytic ileus.[9] There may be muscular weakness and even flaccid paralysis; but this, though characteristic enough if present, is rare. By an unexplained paradox tetany occurs in other patients.[10] When present, the electrocardiographic changes of potassium deficiency, with depression of the ST segment, prolongation of the QT interval, and appearance of U waves,[11] are very helpful in diagnosis. Since potassium deficiency gives rise to such an indefinite clinical picture its importance may be doubted, except in those few patients who become paralysed or in whom myocardial necrosis is found post mortem.[12]

Two groups of workers in this country have sought to produce potassium deficiency experimentally in man, by giving either a diet from which potassium was removed by an exchange resin or else a normal diet with the resin. By the first method Black and Milne[13] in Manchester produced a deficiency of some 280 m.eq. of potassium. Symptoms were slight. Nevertheless the deficiency was accompanied by a fall in the level of serum-potassium; retention of sodium, mainly in extracellular fluid; and mild alkalosis. As the alkalosis developed, the urine became more alkaline; the alkalosis was not therefore the result of compensation originating in the kidney. Cooke et al.[14] have suggested that the alkalosis is extracellular and a result of the transfer of H ions from extracellular fluid to intracellular fluid to replace potassium there. Fourman and Ainley-Walker,[15] working at Oxford, produced a more severe depletion of potassium, amounting to 600–800 m.eq., by giving resin by mouth; but in their experiments the depletion of potassium was at first complicated by acidosis—presumably a side-effect of giving resin. In their two volunteers symptoms became pronounced, though the level of potassium in the serum fell only moderately in one and not at all in the other. The symptoms—apathy and mental confusion, anorexia and nausea—were in keeping with clinical reports, but may have been aggravated by the complicating acidosis. These experiments showed indirectly that potassium may be lost from the body without corresponding amounts of intracellular water; and, though there may be some intracellular dehydration,[13] loss of potassium leads mainly to a change in the composition of intracellular fluid through loss of the main cation without

an equivalent loss of the corresponding anion, phosphate.[15] This has long been suspected[16] and has been proved in work on animals.[17] The experiments on man also revealed an excessive increase in extracellular fluid, and one subject became œdematous.[15]

All these results suggest that moderate potassium deficiency does not in itself cause serious symptoms but may predispose to œdema; more severe depletion may have important effects, particularly in the presence of acidosis when potassium apparently continues to provide base for the excretion of acid even if the stores of potassium have been depleted. Clinical data suggest, too, that severe depletion—even without acidosis and with sodium available to replace potassium—is best avoided. In babies at least, the mortality from diarrhœa can be greatly reduced by administration of potassium.[18] Because moderate depletion does not produce striking symptoms, the diagnosis of potassium deficiency will often be a matter of conjecture based on the knowledge of the patient's probable intake and losses. When deficiency is suspected—for instance, in ulcerative colitis[19]—one is usually justified in administering potassium. So long as the urinary output is satisfactory this can be done simply and safely with potassium citrate mixture (*N.F.*), which contains about 50 m.eq. of potassium per ounce, or with other salts[7] by mouth. Without clear evidence of deficiency it is not justifiable to risk giving potassium parenterally so long as the patient can take it by mouth; but for many surgical patients, and particularly those with paralytic ileus where deficiency of potassium may be a contributory cause,[20] parenteral administration is necessary. Such patients may conveniently be given the solutions devised by COOKE and CROWLEY[2] to match fluid aspirated from the stomach or intestine; they are given in amounts equivalent to the aspirates, so that severe depletion is avoided from the start. Weaker solutions, such as Ringer's fluid, contain too little potassium to do any good. On the other hand stronger solutions are needed for the treatment of an established deficiency; but their dangers and limitations must be borne in mind.[7]

Searching for Better Anticoagulants

HEPARIN and dicoumarol have great value in the treatment of thrombo-embolic diseases; but both these substances have troublesome disadvantages. Heparin must be given intravenously—intramuscular preparations are still not entirely satisfactory—and the effect of each dose lasts only a few hours. Dicoumarol takes up to 72 hours to exert its maximum effect, and its action continues for at least as long after the last dose. This means that if rapid anticoagulant action is needed—and it often is—heparin must be given for the first 3 days; and if the dicoumarol reduces the prothrombin concentration too far, any hæmorrhage is difficult to control. The success of the anticoagulant treatment of coronary thrombosis has given an immense fillip to the search for better anticoagulant drugs, for coronary thrombosis is one of the most dramatic of modern scourges. As GILCHRIST[1] has put it: "Thirty years ago it was a rarity even in pathological experience. Today we count our cases in hundreds and pass on to the next." And, after much experience, he claims that by efficient use of anticoagulants the death-rate over the first 6 weeks can be halved and the danger of thrombo-embolic complications reduced to negligible proportions.

In 1948 VON REINIS and KUBIK[2] introduced a dicoumarol ester which was given the name 'Tromexan.' Tromexan has the advantage that in therapeutic doses it will effectively reduce the prothrombin level in 24 hours, and that its action ceases a few hours after administration is discontinued. BURT *et al.*[3] reported favourably on it in 1949; and since then there have been several accounts of its value, especially in coronary thrombosis. BRONSTEIN and WITKIND[4] studied a group of 50 patients, 22 of whom had myocardial infarction. To reduce the prothrombin concentration appropriately within 24 hours a "loading dose" of 1500–1800 mg. (five to six times that of dicoumarol) proved necessary. Then, in the first 7 days especially, they noticed that wide fluctuations of prothrombin level were liable to occur, and consequently daily control by prothrombin estimations was essential; even so, in some patients smooth control was possible only by giving the drug in divided instead of single daily doses. If the daily dose was entirely omitted because of low prothrombin the level was liable to rise sharply next day and be difficult to re-establish at a suitable level. Despite these difficulties, they concluded that tromexan was safer than dicoumarol, and no serious hæmorrhage occurred in their patients. ILLINGWORTH[5] aimed at keeping the prothrombin level of his patients at between 30% and 10% of normal. He found that the initial 24 hours, before the action of tromexan reached its maximum, could be covered by a single intravenous dose of 100 mg. of heparin. He also noted the difficulty of forecasting the daily dose; age and weight were no help, and the only method of control was to have the prothrombin estimated every day and not to give the day's dose until the result was known. He gave a table of doses for various levels—at 80% prothrombin concentration about 900 mg. is needed, and at 10% 150 mg. since even at this level the drug should not be entirely stopped. ILLINGWORTH observed that, even with these precautions, patients on tromexan treatment were liable to sudden "escapes" from anticoagulant control. Of 60 patients with cardiac infarction who were treated in this way, only 2 had bleeding episodes, although the prothrombin level was sometimes less than 10%; this compared well with 7 cases of hæmorrhage among 36 patients treated with dicoumarol. Similar results have been described by STIRLING and HUNTER,[6] who had rather a higher rate of hæmorrhage—13 (8·6%) in 151 patients treated.

The most ambitious comparison of dicoumarol and tromexan is that organised by the American Heart Association and embodied in a report by SCARRONE et al.[7] Seven hospitals in various parts of the U.S.A.

took part; and records were collected of experience with 514 patients, comprising 262 with myocardial infarction, 87 with thrombophlebitis or venous thrombosis, 41 with pulmonary infarction, 20 with other arterial thrombosis or embolism, and 104 to whom the drugs were given for coronary insufficiency or "for prophylactic purposes." The dosage of tromexan and the method of control were similar to those already described. These workers confirm fully the relatively rapid initial action of tromexan and the relatively rapid return of prothrombin levels to normal when the drug is stopped. They suggest that tromexan gives no more protection from thrombo-embolic complications than does dicoumarol; in fact they found that rather more complications were liable to occur when the prothrombin level was within the desirable range. In their series the total rate of gross hæmorrhage was slightly higher during tromexan therapy than during dicoumarol therapy; but they found that this difference was largely due to the difficulty of controlling prothrombin levels with single daily doses of tromexan; and they agree that control is easier with the daily dose divided into two or three portions. No difference in toxicity between the two drugs was found, nor did there seem to be any significant difference between their protective action in myocardial infarction. Clearly tromexan is far from the ideal anticoagulant. Its two advantages—rapid initial action and rapid control of possible hæmorrhage—are counterbalanced by the additional difficulty of determining the daily dose. This justifies MURRAY SCOTT's [8] contention that without a laboratory that can give rapid daily estimations of prothrombin concentration dicoumarol is the safer drug. Recent work with vitamin K_1 has suggested that control of hæmorrhage due to tromexan or dicoumarol may not be so difficult. DOUGLAS and BROWN [9] tested various vitamin-K preparations to see how they corrected the hypoprothrombinæmia induced by these two drugs; they found that only vitamin K_1 (2-methyl-3-phytyl-1:4-naphthaquinone) was effective; and it was consistently effective in doses of 200–340 mg. intravenously. TOOHEY [10] found that a single oral dose of 500 mg. of vitamin K_1 could restore to safe levels a prothrombin concentration depressed by these drugs; the action was perceptible in 4 hours and complete in 8 hours; a single dose was enough to counteract tromexan, but repeated doses were needed when dicoumarol had been administered.

The search for a better anticoagulant continues; and the latest substance to be introduced is phenylindanedione, which differs in its chemical structure from dicoumarol and tromexan. This substance, first used clinically by SOULIER and GUEGUEN [11] in France and by BLAUSTEIN et al.[12] in the U.S.A., has a hypoprothrombinæmic action roughly intermediate in rapidity between dicoumarol and tromexan. Its use in 74 cases (44 of coronary thrombosis) has recently been described by PRESTON and his co-workers [13] in Chicago. They found that as a rule blood-prothrombin levels between 10% and 30% of normal were reached in 18–36 hours with an initial dose of 150–200 mg., and these low levels were maintained by doses of 50 mg. twice daily; all their cases were controlled by daily prothrombin estimations. They had no trouble with "escapes" from control such as occur with tromexan, but 3 patients were somewhat refractory and probably needed larger doses. Minor hæmorrhages occurred in 5 cases. Among the 200 cases hitherto reported, there has been no instance of severe hæmorrhage due to phenylindanedione; but PRESTON and his colleagues reasonably attribute this partly to our growing experience in handling anticoagulants. The effect of this anticoagulant persists for 2–4 days after the final dose, but the hypoprothrombinæmia can be rapidly corrected by vitamin K_1. Phenylindanedione has still to be subjected to the searching trial that tromexan has had; we need to know especially whether control of its action is steadier and more easily achieved than with tromexan. Meanwhile the observation by DOUGLAS [14] that tromexan depresses "factor VII" rather than prothrombin suggests that we still too easily assume that a prolonged prothrombin-time exactly reflects pure hypoprothrombinæmia. These different substances may act on different coagulation factors; and more research into their pharmacology is likely to be needed before we find the ideal anticoagulant.

From Teaching to Learning

FOR years we have been telling one another what is wrong with the medical curriculum; and now some American medical schools, backed by the moral and financial support of the Commonwealth Fund,[15] are looking into the facts. In these schools the emphasis is shifting, so the annual report of the fund says, "from teaching to learning, from the department to the school, and from the specialty to the patient." The history of medical education is seen in three stages. The first, the age of scientific medicine, has already lasted forty years; but we are now at the opening, the report suggests, of the second or transitional stage "in which the concept of comprehensive medicine is beginning to modify the definition of scientific medicine"—a reaction, in fact, against extreme specialisation. The third stage, it is hoped, will be a reconciliation of scientific and general medicine, of the specialist and the general practitioner, and a new integration in both medical education and medical care. To achieve this end the medical curriculum will have to be reoriented; for it is in the nature of specialists to teach passionately their specialties, and they do not take easily to what the report calls "a whittling down of departmental prerogatives." Yet, to the credit of the profession, the demand for a broader approach comes primarily from physicians and surgeons; and these American experiments have been undertaken on the assumption (still to be verified, as the report justly notes) that "medical teaching organised around the student's need to learn and the patient's need for care will prepare students to meet the responsibilities of medicine as a social institution more effectively than medical teaching organised around the preoccupation of teachers with what they as specialists think they ought to teach."

One important enterprise has been maturing at Western Reserve School of Medicine since 1950, when the fund made a 5-year grant towards it; and the new teaching plan was put into effect for the class entering in September this year.

> The 4-year course covers our preclinical and clinical periods, and has been divided into three phases. Phase I "orients the student to medicine and to the patient and presents the fundamental principles of man's structure, *function, growth, behaviour, and relation to his* environment; phase II deals with disease, first in general principles and then by organ and site; phase III deals with the care of sick people."

The first two phases occupy together 2½ years, and teaching is to be done not by the departments separately but by inter-departmental teams. Moreover, to help the student to feel that he is studying medicine as a whole, all his laboratory work (except anatomical dissection) is done in his "home room"—an all-purposes laboratory where the instructors come to him. Some additional building has been necessary, but in the main the extra space has been found by rearranging existing laboratories. Under the departmental system many laboratories stand idle for much of the time: the new system has made them fully active throughout the day. The final result is that students have more room to work and also, it is believed, a far better opportunity for coherent learning. Those trained in the English tradition of bedside teaching may wonder whether phases II and III of this scheme can really be separated; and, if they can, whether they should. Detailed plans for these two phases have not yet been worked out.

If Western Reserve has approached its problem by way of the student and what he is to learn, Harvard approaches it by way of the teacher and how he is to teach. Twenty graduates working in the medical division of the Graduate School of Arts and Sciences (which is closely linked with the medical school of the university) are taking a PH.D. course in the fundamentals of medical science—including not only the functions and structure of cells, organs, and systems, but also techniques—with a view to becoming "integrated teachers" in the medical school. It is not easy to tell from the brief account in the report exactly what kind of rare birds will be fledged from this unique nest, but the fact that the fund has provided a substantial 3-year grant gives grounds for confidence in their value.

Experiments of another kind are in progress at Colorado, Cornell, and Tennessee Universities. At Colorado and Cornell the aim has been to bring students into closer touch with the lives of their patients, and also to measure accurately the effects of whatever changes this produces in the students. In each of these schools a young physician has been put in charge of a new kind of clinic which places "a premium on continuity and comprehensiveness in medical care." At Cornell a period of experience in the clinic is being given to senior students, while at Colorado undergraduates and house-officers are being exposed to "a reasonably general point of view" throughout their clinical years. Which will prove the more effective? To decide the question Cornell is investigating the student's attitudes, expectations, judgment, and scale of values by getting him to fill in, at the end of his last academic year, an adroitly worded 26-page questionary; while at Colorado a psychologist has collaborated with the educational testing service of Princeton in developing devices to study short-term changes in student behaviour. By using these and other methods on successive classes of students both schools hope to measure their success in teaching good medicine.

In Tennessee people have a preference, very natural as it seems to us, for family doctors; so in the autumn of 1951 the Tennessee medical school started, with the help of the fund, a "family general practice clinic," designed to resemble the practice of a good family doctor. All senior students spend a short time in it, under the continuous supervision of a staff of general practitioners. Every fifth patient who comes to the hospital outpatient department is assigned to this clinic, and four out of five of these are treated in the clinic without the direct help of specialists. Students are given plenty of responsibility and often take their own radiographs and do their own laboratory work. Again the effects of the experience on the developing doctor are to be studied. A more thoroughgoing effort to bring the student face to face with the patient and his family is being made at the University of Pennsylvania, where the freshman is assigned to a family as an "adviser"—not as an adviser on medical matters, for which he is not competent, but rather as an intermediary between the family and the hospital. He visits their home as "a doctor-in-training," is present when any of them comes to the hospital, is consulted by his seniors about the home situation, helps members of the family when they are anxious or puzzled by explaining hospital procedure to them, and in fact learns to maintain "a constructive relationship with the patient, which is half the doctor's job." And he thrives on the responsibility. Under a similar plan at Boston University, the student has a year of family study and a month of home calls on the district. It is noteworthy that teachers of social science and of nursing have begun to follow this lead, and are now giving their students similar experience.

The University of Florida has been given, by the State legislature, a most unusual opportunity to develop schools of medicine and nursing in a medical centre, and has begun a study of the existing university resources which can be woven into the pattern of medical education. These include a university college giving a 2-year course in general education built round the social sciences, an agricultural experiment station undertaking research into nutrition, a cancer research laboratory, a centre for clinical services with a special interest in psychology, and a student health service with a large medical staff. A research group have been appointed "to think out what a medical school ought to be and do, before a staff is hired and building plans are fixed," and they are to report in the spring of 1953. The fund has made a large grant towards the expenses of this study. Finally, at Columbia University the bureau of applied social research is making a pilot study, financed by the fund, of "the character of the social and psychological environment comprised by the medical school and the bearing of that environment upon the acquisition of knowledge and skills, attitudes, and values by medical students." If this proves informative, it may lead to a 4-year full-scale study of one or more medical schools.

The results of these varied types of study will be as instructive for us as for the Americans; and, as the report points out, many other American medical schools and universities besides those in which the fund is interested are now making experiments. Medical education can never be static or defined: its content changes constantly with our growing knowledge. This is well recognised; but we have been slow perhaps to admit that even the structural pattern of teaching should be pliable—a tent, easily pitched and struck, rather than a classic fane.

Annotations

A EUROPEAN HEALTH COMMUNITY?

THE latest proposals of the French government for a European Health Community were discussed at a meeting in Paris this month. The plan of M. Ribeyre, the minister of public health and population, is based, like the Schuman plan for coal and steel, on the assumption that certain supranational powers should be given to a new health organisation representing a Community of those European nations wishing to join. As in the case of the Schuman and similar plans, the British Government made it clear at the meeting that it was not prepared to join such a Community on those terms, though it would wish to be very closely associated with it. Further, if such a new health organisation was to be considered without supranational powers, the Government felt that careful examination was needed to see whether the existing intergovernmental organisations—the World Health Organisation with its Regional Organisation for Europe, the Brussels Treaty Organisation, and the Council of Europe—could not do the job themselves. It was therefore agreed that a committee of experts should examine the proposals and report back to the conference as early as possible next year.

The proposals themselves fall into two groups: (1) obligations or restrictions incumbent on all members of the Community, such as the abolition of customs dues on pharmaceutical products or medical appliances, and the abolition of unfair competitive practices in these fields; and (2) common tasks and objectives, such as the pooling of medical products and facilities and the results of research, as well as uniformity in social-security legislation. Such objectives might lead to the establishment of laboratories by the Community and of centres for research into such questions as silicosis or the treatment of burns or of cancer by high-voltage apparatus. The suggested organisation would perhaps consist of a high authority, a council of ministers, and an expert advisory committee; and the facilities set up under the Schuman plan might be used.

This is not the first proposal to give executive powers to an international health organisation. There were the old sanitary councils of Egypt, Constantinople, and Tangier. The fourth International Sanitary Conference in Vienna in 1874, discussing the function of an international commission on epidemics, rejected a suggestion to give the commission executive as well as advisory powers, because it seemed unlikely that many governments would agree and because the step might prejudice "the scientific nature of the commission." These arguments hold good today, particularly since a much greater variety of activities is now proposed. No doubt a careful examination of the proposals by experts is proper, but without supranational powers, which few countries seem disposed to give, there would have to be a very strong case indeed to warrant yet another international health organisation.

TREATMENT OF SHOCK IN CARDIAC INFARCTION

WHEN cardiac infarction is accompanied by shock, the precise mechanism by which the blood-pressure falls is not at all clear. On the one hand, a large part of a ventricle may be rendered suddenly ischæmic and consequently non-contractile, and the effective myocardium remaining may well be unequal to the circulatory burden; disturbances of rhythm may supervene; under such conditions the cardiac output falls,[1 2] and this alone may contribute largely to the hypotension. On the other hand, there is evidence of peripheral vascular collapse as well. To some extent, this may be compensatory, for a reduced load is then imposed upon the damaged heart. At all events, the prominent feature of traumatic shock—namely, a fall in volume of the circulating blood—is of no great significance in cardiac infarction, and there is no justification at all for intravenous infusions of blood or plasma. Nevertheless, persistent hypotension carries its own dangers—impaired coronary flow, aggravated myocardial depression, the risk of further coronary occlusions, and a deprivation of blood-supply to the brain, kidneys, and liver. No ingenious statistics are required to demonstrate convincingly that, when shock occurs with cardiac infarction, the prognosis is much more serious than when the blood-pressure is scarcely affected.

A direct therapeutic attack on the infarcted heart is clearly out of the question with the resources at present at our disposal. But it can be relieved as far as possible of all unnecessary loads, and the hypotension which often follows infarction certainly contributes in this way. If, however, the hypotension is so profound or prolonged that it becomes a danger in itself, then its correction by improving peripheral vascular tone may be justified in principle. Now orthodox teaching is against such a step: Wood[3] says that, because of the increased risk of ventricular fibrillation, "adrenaline, ephedrine and other adrenergic substances should be avoided . . . no matter how low the blood pressure." This, of course, underlines the real difficulty—namely, to find a drug that will bring about satisfactory peripheral vasoconstriction without, at the same time, stimulating the heart itself.

American workers, who remark that the use of "pressor amines" for the treatment of shock following cardiac infarction is a "relatively new concept," have lately subjected the idea to clinical trial. Kurland and Malach[4] have reported their results with 14 patients. Noradrenaline, given as an intravenous infusion, brought about a rise in blood-pressure in most cases; and, unlike the other sympathomimetic amines that have been tried, it had no effect on heart-rate, cardiac irritability, or the central nervous system. Disappointingly, however, the proportion of survivors was not convincingly higher than would have been expected with conventional treatment. In another series, Hellerstein et al.[5] used mephentermine, a synthetic pressor amine, giving it intravenously to 18 patients with acute cardiac infarction in whom there was unequivocal evidence of shock; and of these patients, 7 recovered sufficiently to leave hospital. As Hellerstein et al. consider that the usual mortality in patients of this kind is about 80%, they feel, perhaps a little optimistically, that their results show a significant improvement. Unfortunately, neither of these reports gives full details about the course of events in the individual patients, so it is impossible to make a direct comparison between what happens when shock is not treated and the developments when the blood-pressure is deliberately raised. Certainly, before we can agree with Hellerstein et al.

that the "more favourable results of pressor therapy in comparison to other methods justify further clinical application in the treatment of shock accompanying myocardial infarction," we should like to have more information about the way in which their patients responded and the precise mode of death in the fatal cases.

PERSISTENT HICCUPS

A MILD attack of hiccups may amuse or embarrass, according to temperament or circumstances. A severe and prolonged attack is a serious disorder calling for energetic treatment to save the patient from dangerous exhaustion. Nearly every year one or more papers are published on the subject—a fact which shows how little we know of the cause or treatment. Hiccups has been described as intermittent clonic spasm of the diaphragm, but the latest observations cast doubt on the accuracy of this definition. Samuels[1] has made repeated fluoroscopic examinations of patients suffering from severe hiccups, and he concludes that the type of diaphragmatic contraction differs from patient to patient, but that one pattern of contraction leads to the next if treatment is delayed or unsuccessful. The transition from the milder attack to the more severe is especially rapid in debilitated patients. In the mildest form the spasm is a unilateral pyramid-like contraction. After five to eight days of hiccuping the pyramid becomes flatter, and wavy contractions appear at the outer segment on the same side. Finally these contractions spread across the whole dome. Rarely the hiccups may be bilateral from the start. Samuels considers that complete flattening of the whole dome with wavy contractions at the outer segments is a grave sign indicating muscular exhaustion.

The muscular spasms are of reflex origin; and the efferent path is most commonly the phrenic nerve, at any rate in the early stages. But other nerves and muscles of respiration may be involved, for in a patient of Campbell's the hiccups persisted in spite of bilateral phrenicectomy.[2] Moreover, Samuels's observations on the innervation of the various parts of the diaphragm showed that the peripheral areas, which could be involved in the contractions, interdigitated with bundles from the transversus abdominis muscles and were supplied by the anterior branches of the lower three thoracic nerves, with few or no fibres from the phrenic. The crura, too, have a limited phrenic supply, and are innervated mainly from the last two thoracic and the first two lumbar nerves. The phrenic itself, on reaching the diaphragm, fans out from the central area into a plexus formed by its own subperitoneal branches and by sympathetic nerves arising mainly from the cœliac plexuses and travelling to the diaphragm along the inferior phrenic artery. Vagus fibres are said to join the plexus as well. The anatomy of the upper parts of the phrenic nerves is of considerable surgical importance. The phrenic originates from T3, 4, and 5 in 70–80% of cases, while in the remainder it may come from some or all of T2, 3, 4, 5, and 6. This would matter little to the surgeon were it not that the 5th thoracic root often forms a fine separate nerve which runs its own course until it joins the main trunk in the superior mediastinum. Occasionally the same is true of the 3rd thoracic root. In addition to its variable origin, the phrenic is a mixed nerve and may be joined by fibres from the superior and inferior cervical ganglia, the vagus, the spinal accessory, and the hypoglossal nerves. An interesting anatomical finding by Funaoka[3] is that communicating strands with the vagus are more common on the right side than the left. This may, or may not, have any connection with the fact that hiccup spasm occurs more often on the left side than the right.

The afferent side of the hiccup reflex can arise almost anywhere in the viscera, or where nerves containing fibres of the visceral sensory system are involved by disease process; and it can also originate in the central nervous system. The cause may be physical, such as pressure, or chemical, as in uræmia; alcohol, too, may be classed as a chemical irritant. Bailey[4] says that he has not seen a single case of persistent postoperative hiccup among over 1500 patients who had operations on the stomach or gall-bladder, including repair of perforated gastric ulcer. He is, therefore, convinced that irritation of the lower surface of the diaphragm is not an important cause of hiccups. By contrast, the condition often followed operation on the bladder or prostate, even in the absence of uræmia. He comments on the rarity with which severe hiccups developed in women. There are many possible peripheral causes, including acute dilatation of the stomach, irritation of the peritoneum and infections or tumours in the respiratory tract or the mediastinum. Hiccups may be initiated centrally by pressure changes due to tumours or hydrocephalus, or by bacterial or parasitic infections, including neurosyphilis and neuromalaria. It has been reported in the fœtus,[5-7] where it presumably results from passage of a chemical substance across the placental barrier. Samuels[1] stresses the importance of psychogenic disorders, whether overt or latent.

If there is no removable or evident cause, some of the many suggested remedies must be tried. Carminatives produce a sense of gastric comfort, and are sometimes of more than temporary benefit. Gigot and Flynn[8] found that occasionally so simple a manœuvre as slightly painful pressure on the eyeballs, maintained for at least a minute, was successful. Many sedatives have been tried, with about equal degrees of success and failure. General anæsthesia and psychiatric treatment are both said to be useless. Antispasmodics have their supporters. Carbon dioxide inhalation, used within the first few days, is often a success, either by the homely method of rebreathing into a paper bag, or by using more expensive apparatus. The important point is that inhalation must be continued to the stage of moderate discomfort. Barnard[9] had good results with the application of sinusoidal galvanic current. Another method, spraying of the posterior cervical triangle with ethyl chloride, is inadvisable, for it can too easily lead to necrosis of the skin and deeper tissues. If no simple method works, the phrenic nerve can be crushed; and this operation, performed under local anæsthesia, nearly always produces a complete and permanent cure.

The phrenic-circle test can be used to determine on which side the spasms occur or which is the pacemaker side. Firm pressure by the fingers is applied over the phrenic nerve just above the clavicle, and any spasms on that side usually stop within a minute. Hiccups is far more often left-sided than right, and unless there are indications to the contrary the left phrenic nerve should be dealt with first, because further measures may then be unnecessary. In the rare cases in which bilateral crushing fails, Samuels recommends that the sympathetic and the lower thoracic and upper lumbar nerves be interrupted. As a precaution in all operations, Gigot and Flynn[8] advise the use of antiparasympathetic drugs during anæsthesia.

But we are still in the dark about many questions. We do not know why severe hiccups is sometimes seen after operation, how or where uræmia facilitates the reflex arc, why persistent hiccups is uncommon in women, or whether the parasympathetic system bears a special responsibility.

AN OSSEOMUSCULAR CIRCULATION

THE histopathological foundations on which the clinical diagnosis of fibrositis rests are for the most part obscure. Stockman's definition[1] of fibrositis as "a condition of chronic inflammation of the white fibrous tissue . . . of muscles" (and other connective-tissue entities) is often refuted by biopsy of the nodules, which may show no characteristic changes.[2 3] Surgical exploration of a fibrositic trigger-point sometimes discloses herniation of a fat lobule through a gap in the fascia, but Copeman[4] pointed out that this explanation certainly does not account for all cases. When the clearly mechanical reasons for muscular pains of fibrositic type—prolapsed intervertebral disc, spondylitis, and trauma—and infective and parasitic causes have been excluded, a number of cases (perhaps the majority) are left without a satisfactory explanation, although Cyriax[5] does not think that such a group exists.

In these circumstances investigations of the anatomy of the muscles and the muscle attachments to bone are of particular interest; and Cecchi and Fiumicelli,[6] following up Heald's observations,[7] have turned their attention to the circulatory paths between bone and muscle. Heald's work showed that local injections of a mixture containing benzyl salicylate were most effective in relieving primary fibrositis when the injection was made near the bony origins of the affected muscles. Indeed, the best clinical results were obtained when the injection was made into the cortex of the metaphyses of the bones from which the painful muscles arose. The distribution of the injected material was traced by including a radio-opaque oil in the mixture. Injected into the cortex of the humeral metaphysis, the oil quickly left the bone as a fine spray, apparently within the deltoid muscle.

Cecchi and Fiumicelli have now confirmed these findings. They used a similar technique and they obtained radiographs which show fasciculated strands of oil running in the direction of the muscle-fibres like the warp on a loom. On the other hand, oil injected directly into the muscle belly gave a localised fusiform opacity of quite different appearance; and an injection into a region of the metaphysis devoid of muscular attachments gave no indication of any communications between the bone and the adjacent muscle. From these results they suggest that there is a humoral osseomuscular circulation, related to the sites of muscular attachments, and they think that it may be of physiological importance. In support of this view they quote Cretin's finding[8] that an area of bone stripped of its muscular insertions shows an underlying osteoporosis, and they point out that fractures involving a bare region of bone heal more slowly than those involving the regions of muscular attachments. They imply, therefore, that the nutrition of both bone and muscle depends in part on this circulation between them. Wood-Jones, quoted by Heald, thought that a dye injected into a fresh femur post mortem left the cortex by multiple fine openings alongside Sharpey's fibres; and histological findings in similar experimental injections of bone support the view that these communications between bone and extra-osseous tissues are vascular.

These two sets of observations are convincing evidence for the existence of these osseomuscular channels. It is conceivable that they are of physiological significance, but at present this is far from certain. It would be attractive to postulate that primary fibrositis is due to a disturbance of muscle nutrition associated with a derangement of function of these vascular channels. The periostial thickening which Stockman described in fibrositis has been found by Heald and his colleagues in about half the cases submitted to biopsy, but there is nothing yet to suggest that this thickening has anything to do with the vascular channels. Until more is known of the function of these vessels, their importance will remain in doubt.

ALMONERS

HOSPITALS took a long time to grasp the value and proper uses of almoners, but once they had accepted the idea they took to almoners warmly—and now literally cannot get enough of them. There are always well over 100 vacancies going. The Secretary of the Institute of Almoners, the *Manchester Guardian* of Dec. 5 reports, puts the numbers now working in England and Wales at about 1000, but estimates the numbers needed for a full service at double or treble that figure. In Scotland[1] the situation is considerably worse; only 75 almoners are employed, whereas a full service is estimated at 500. Moreover, since they are mainly concentrated in the general hospitals, there are many hospitals in rural areas with no almoners at all; indeed, of the 346 hospitals in Scotland, only 35 have an almoner on the staff, and though there are 25,202 beds with almoner service there are still 12,323 without; and the scarcity is particularly noticeable in the tuberculosis hospitals.

The haphazard distribution is partly the outcome of the way the almoner service has developed. Voluntary hospitals first employed almoners to assess the capacity of the patient to contribute to his maintenance in hospital. The development, by almoners themselves, of the medicosocial side of their work has led to a complete reorientation of their position, and a special type of training. But there are still hospitals where the medical staff, never having worked with almoners, have not realised the value of their work. Even now recruitment to the profession is very small: the numbers coming forward are barely sufficient to make good the annual wastage, let alone to provide for extension of the service. A fresh blow to recruitment has been the withdrawal, by the Ministry of Health this year, of its grant towards training; which has meant that the institute has had to raise its fees from 30 to 85 guineas. Grants from local authorities vary widely in amount, and are not easy to get; moreover there are often delays in payment and uncertainty about the amount, even when grants are promised. Again, Home Office grants towards training in other branches of social work, such as child care, divert candidates who might otherwise enter almoning. The Scottish subcommittee regard the withdrawal of the Government grant as a retrograde step, and suggest that the attention of local education authorities should be drawn to the fact that they may make grants to students wishing to train for this profession.

Meanwhile they propose that the best possible use should be made of the almoners already in the service, by staffing hospitals serving industrial areas, especially teaching hospitals (which have to train medical students in social medicine), other general hospitals and chronic sick hospitals in these areas, and tuberculosis hospitals and sanatoria. Hospitals in country districts, where the sense of community is usually well developed, can afford more easily to wait for better times. To ease the shortage they also propose that the service should be diluted by a second grade of "almoners' assistants," or "almoners' apprentices," analogous to enrolled assistant nurses; and they recommend the Institute of Almoners to consider a scheme of recruitment and training of such a grade. This question of dilution is always very difficult. It is serving well in nursing because that is a profession

which offers scope for widely different talents. Almoning, however, demands, as well as humanity and a gift for making good relationships with people and with public and voluntary bodies, a special kind of shrewdness, ability, and judgment; and it is doubtful whether those training for a second grade would bring quite these qualities to the task. It would surely be better, as a first step, to consider the factors which are hindering recruitment of almoners of our present high standard.

CHEMOTHERAPY OF TUBERCULOSIS

Sir Howard Florey, F.R.S., opening a symposium held by the Royal Society of Medicine on Dec. 10, suggested that in the attack on tuberculosis we must study not only the parasite and the host but the influence of each of these on the other. In developing chemotherapy both in-vivo and in-vitro techniques could be of great value. A striking feature of subsequent papers was the close agreement between the assessment of antituberculous drugs by these two techniques.

Dr. A. G. Sanders and Dr. L. F. Dodson have used a specially prepared chamber in the rabbit's ear for studying the development of tuberculous lesions and the effect of drugs on them; while Dr. G. B. Mackaness has studied the survival of tubercle bacilli both in laboratory media and inside macrophages by an elegant and useful technique. Prof. J. M. Robson gave an account of results obtained by the intracorneal inoculation of tubercle bacilli in mice and rabbits; and Prof. Robert Knox described in-vitro studies of sensitivity and resistance to isoniazid, including an agar-plate culture technique using *Mycobacterium smegmatis* as a test organism. Dr. D. A. Mitchison discussed the value of different techniques used in the laboratory for determining sensitivity and resistance of tubercle bacilli to drugs such as isoniazid.

The general conclusions from this group of papers were remarkably harmonious—that isoniazid has an undoubted inhibitory effect on the growth of tubercle bacilli, which in some ways is greater than the effect of streptomycin; that the initial effect is short-lived; that drug resistance rapidly develops; that isoniazid and streptomycin combined are much more effective than either alone; and that drug resistance can be greatly delayed by this combination. Dr. Mackaness suggested that in any long-standing tuberculous lesion there may be large numbers of "dormant" organisms which are relatively insusceptible to the action of drugs. This concept recalls the views of the late Prof. J. W. Bigger on the part played by "persisters" in the development of penicillin resistance by staphylococci, and is well supported by the observations of other workers that many antibiotics are especially effective against actively dividing organisms. Professor Knox and his colleagues observed that the action of isoniazid was profoundly modified by quite small changes in the temperature of incubation, and suggested that perhaps increase in temperature of incubation or combination of isoniazid with other drugs make it more powerfully bactericidal. This observation may perhaps help to explain Professor Robson's finding that isoniazid alone is much more effective in the treatment of corneal tuberculosis in the rabbit than in the mouse, whose mean corneal temperature is several degrees lower than the rabbit's. It may also partly explain the dramatic response to isoniazid by patients with high temperatures. Dr. Mitchison, who has handled the large amount of reference work in the bacteriology of the Medical Research Council tuberculosis trials, suggested that an in-vitro resistance of about 1 µg. per ml. was likely to indicat clinically significant resistance.

This rather satisfactory correlation between in-vitro and in-vivo results was somewhat disturbed by Dr. P. D'Arcy Hart and Dr. R. J. W. Rees, who have found a baffling but extremely interesting group of surface-active agents most of which show powerful antituberculous activity in vivo, but none in vitro. As Sir Howard Florey suggested, these observations, though puzzling at present, may lead to new ideas on chemotherapy.

In the second part of the symposium Dr. Wallace Fox gave an interim account, prepared in collaboration with Dr. Marc Daniels, of the M.R.C. trial of isoniazid alone and in various combinations, in the treatment of pulmonary tuberculosis. The present [illegible] (1) a comparison of isoniazid with [illegible] (P.A.S.) plus streptomycin; (2) a comparison between isoniazid, P.A.S. plus streptomycin, and isoniazid plus streptomycin; and (3) a comparison between isoniazid plus different doses of streptomycin, and isoniazid plus P.A.S. Preliminary results for the first two groups, up to the end of three months' treatment, suggest that on the whole isoniazid plus streptomycin will prove the most valuable combination; it has shown itself strikingly superior to streptomycin plus P.A.S. or to isoniazid alone in the type of case where chemotherapy is expected to give little benefit.

Other aspects were discussed by Prof. John Crofton Sir Clement Price Thomas, and Dr. Honor Smith. In conclusion Sir Geoffrey Marshall suggested that isoniazid should clearly not be used alone; but a combination of isoniazid with other drugs might prove superior to any other known combination.

SCREENING FOR DISEASE

"SCREENING" is a military term that was borrowed some years ago to describe the process by which people in danger of infection are sifted for the earliest signs of such diseases as tuberculosis and syphilis, and the source of infection is traced. Public-health measures devised with this aim have been very successful. Such measures are now termed "monophasic" because they deal with one aspect of illness. Lately American workers have been testing "multiphasic" screening, which has included a questionary completed by the patient, blood-pressure reading, radiograph of the chest, electrocardiogram, urine-analysis, Wassermann reaction, and hæmoglobin and blood-sugar estimations.

The advantages and deficiencies of multiphasic screening have lately been discussed by the Medical Society of New York.[1] The conditions for which screening is carried out, it was argued, should be remediable; and they should not be so common that screening is inappropriate, nor so rare that the return is disproportionate to the cost and labour. The accuracy of methods also needs careful scrutiny; for whereas a false positive result may be corrected by the patient's physician who receives the technical report, missed diagnoses can lead to a false sense of security. Two different types of multiphasic screening have been tried. In one a large number of presumably healthy adults was submitted to clinical test; the results were compiled and reviewed by a physician, who did not interview the patients, and those with possibly abnormal findings were urged to see their family doctor. Dr. V. A. Getting described his experience of this method at two pilot health-protection clinics in Massachusetts. Dr. M. L. Levin, of the New York State department of health, described a rather different plan, by which the health department provided a series of diagnostic aids to help practising physicians. This is akin to the help offered by public-health laboratories in this country, though the American tests were directed towards early detection of degenerative disorders no less than of infectious diseases.

In this country multiphasic screening might eventually be undertaken at health centres. With the present restriction on expenditure, however, there is little hope of an extensive trial of this technique in the National Health Service.

Dr. GIBBON FITZGIBBON, who was Master of the Rotunda Hospital from 1919 to 1926, died in Dublin on Dec. 1, at the age 75.

Points of View

THE SIEGE ECONOMY AND THE WELFARE STATE OF MIND *

Sir Geoffrey Vickers
V.C., M.A. Oxfd
MEMBER OF THE NATIONAL COAL BOARD AND OF THE MEDICAL RESEARCH COUNCIL

During our lifetime the economic stability of this country has declined to a startling degree. For some decades of the 19th century we enjoyed a pre-eminence, in some fields almost a monopoly, in the arts of turning raw materials into manufactured goods. Raw materials were abundant, the accumulations of capital and skill needed for manufacture were scarce, and, as pioneers in the field, we reaped the benefit of their scarcity. We multiplied our population five times in 150 years; raised our standard of living for the few and took it as our target for the many; and became dependent on the rest of the world for half our food.

Meantime, the monopoly passed and some of the natural advantages on which the pre-eminence was based —the early importance of coal, for example, in the world's carrying trade—dwindled in importance. Other manufacturing nations arose, their later start being in some ways an advantage rather than a handicap; and each addition to the world's manufacturing power increased still further the power to expand manufactures both there and elsewhere. For many years this power has been rising far more rapidly than the power to increase the production of natural resources, even if we include the power to bring new raw materials into use. The pressure of rising populations tilts the balance still further in favour of primary and against secondary production. We share with other manufacturing nations the loss of a differential advantage, in addition to losing our particular advantages over them. The terms of trade move on the whole against us—we have to export today nearly twice the value in manufactures which would have sufficed in 1938 to secure the same return in raw materials—and we are warned on all hands that this deterioration is bound to go on. We shall be stemming the tide for the rest of our lives and perhaps our children's also; and if we are to hold our own with those whom that tide now favours, or even to avoid being carried backwards on to the rocks, it can only be by virtue of some differential in our favour created by our own energy and skill.

Yet collectively we are not, I think, fully aware of what has come to us, still less of what is coming.

THE SIEGE ECONOMY

One result of our economic decline is the increase in planning and in policy-making and in control. This is inevitable in a siege economy. Whenever anything becomes so scarce that its distribution cannot be left to the market, someone is saddled with an inescapable responsibility for settling priorities. Who shall buy what with our limited foreign exchange? Who shall make what with our limited timber and steel? Deliberate policy must decide the answers; deliberate control must enforce them.

This tendency affects relations not only between industry and Government but also throughout industry itself. A siege economy makes policy more dominant, control more anxious and pervasive; and the effect is much the same whether an industry is organised as a single corporation, like the coal industry, or whether many units, still formally independent, coördinate their policies through an association. Standardisation, to take a simple example, can bring savings in money and labour and material; and it claims much attention in the nationalised coal industry; but I gather that it claims even more in the non-nationalised motor-car industry.

Even when the advantages of "coördination" are obvious, we all view the process itself with a suspicious eye, alert to attack bureaucracy, centralisation, and other [illegible]h sinister growths; and it is right that we should. But, on the other hand, we should not deceive ourselves about the result. If nothing were ever decided one single level higher than the lowest which would do; if no "return" ever called for a single piece of information which was not really wanted; if no committee ever sat unfruitfully, or reported unnecessarily, or advised ineffectively; above all, if no-one were ever asked to conform with anyone else about anything without good and sufficient cause—even in that perfect world, we should still find ourselves being "coördinated" much more than we ever were before.

A siege economy demands more solidarity, makes more demands on undeveloped loyalties, assumes a common understanding and a common will which only the demand can create. It thus provokes conflicting responses and breeds the frustration which is their inescapable (though, let us hope, temporary) result.

Frustration is a sign of the times, and a sign which is easy to misread. You have probably noticed the curious fact that many Englishmen will accept a much worse deal from Providence than they will from their fellow men, or at least from any of their fellow men with whom they stand in any sort of relationship. If they are ruined because the bottom falls out of a free market, they may possibly blame themselves but they will at least blame no-one else. But if they are even mildly mulcted by the award of some price-fixing body, they are likely to feel much deeper indignation. They can accept stoically the uncertainties and unfairnesses of an uncontrolled world, but they cannot accept without fury the shortcomings and vagaries of a controller, even though in sum his results are more good than bad. This seems to me both odd and important; and if it were a permanent shortcoming of human nature, the outlook would be sombre.

Happily we can most of us call to mind "combined operations," whether in peace or in war, in which groups of men, dispersed, exhausted, ill informed, have none the less managed to carry out a common plan. I recall an offensive in France in 1915, carefully planned, elaboratel[illegible] rehearsed—it failed. I recall other operations three yea[illegible] later, more difficult, far less prepared, which succeed[illegible] The men engaged were not better or better trai[illegible] Things went wrong just as often—but the organism [illegible]d developed the power to put them right. Som[illegible]ing subtle and unexplained had happened. There ha[illegible]ome into being among all levels of command a mutua[illegible]der-standing not wholly dependent on the telephon[illegible]

I think this illustrates the general truth th[illegible] men are to accept common direction without har[illegible]o their springs of energy and initiative, there must ex[illegible] between them a particular kind of mutual rapport. [illegible]ustration is the sign of its absence and it is a dange[illegible]gnal. [illegible] remedy is either to relax the intensity o[illegible] the direction or to increase the sensitiveness of the r[illegible]port. [illegible] siege economy prohibits the first, the [illegible]ond becom[illegible] the more important.

Reflecting then on the effect of t[illegible] siege economy I am led to conclude that it is bou[illegible] to lead [illegible] situation which will make great dema[illegible]s on our [illegible]tions and our morals, as well as on [illegible]ur brains [illegible]

* From an address, entitled Background to Management, which was delivered in opening the autumn conference of the British Institute of Management on Nov. 13, 1952, and which has appeared in full in the December issue of the institute's journal, *The Manager*.

the task of adapting ourselves to new relations with people is an imaginative and a moral test, not merely an intellectual exercise. I conclude, too, that this is *the aspect of organisation which is likely to try us most highly.*

I would not, however, attribute this demand for closer rapport exclusively to the siege economy. It stems in part from the sheer growth in size of industrial units, which has been a feature of the whole industrial age and which would of itself have set us the same problem in the end, though more slowly. I agree also that our collectivism did not begin as an effort to close the dollar gap. Dicey, writing in 1905, dated the beginning of collectivist legislation at 1856, on the occasion when the House of Commons for the first time threw out a Bill for enclosing a common and thereby registered the opinion—rank heresy at that date—that at least that bit of our English heritage was better left in common ownership. In 1902 the present Lord Samuel wrote a book to explain why the Liberal Party had abandoned unqualified laissez-faire in favour of such collective projects as accessible higher education and publicly provided housing. Neither Dicey the old-fashioned Whig nor Samuel the new-fangled Liberal based their views on the country's impending bankruptcy. Nothing was further from the thoughts of either. To Samuel in 1902, and to many like him, the perplexing portent of their time was that in the richest country in the world a fifth of the population were too poor to keep themselves in health. The Welfare State can trace its lineage further back than 1902, and its developments had begun to quicken the pace of national integration, with all its strains and rewards, long before the economic blizzard brought its chilly emphasis.

The fact remains that the economic controls which today coördinate British industry and set so many of its problems are products of the siege economy, and that the policies which are affected through those controls are policies aimed primarily at economic defence and economic survival.

THE WELFARE STATE OF MIND

I am concerned here not with the substance of the Welfare State but with the state of mind which it connotes.

The Welfare State connotes a demand by the citizen for security; for status; and to a less extent for opportunity. The character and emphasis of these demands were generated over the last hundred years by way of reaction to the experiences of that time, and they crystallised in the depression of the early '30s; but they may well persist long after the circumstances of their birth have passed away. Any Government in this country must do its best to satisfy this complex of aspirations and expectations; and the management of any industry must do likewise. For the same citizens who press these demands on Governments make the same demands as workers on their employers. Indeed, they are more concerned with the life of the workplace than with the life outside. It is in the workplace that these demands matter most today, and it is there that they are hardest to meet. Industry needs efficiency and mobility of labour; men need status and security; and both demands have somehow to be satisfied.

Thus in facing nationally an unfamiliar and dangerous situation, we bring to it a national state of mind formed in a situation which was very different. Our aspirations, our expectations, and our fears are a response not to the situation we are in now, still less to the situation to which we can look forward, but to a situation which we have left. Our economic situation calls for a great increase in productivity and hence for quick adaptation and a rapid increase of effective energy, both mental and physical. At the same time it calls for more coördination of policy, with greater attention to ends and closer economy of means—two demands which in themselves are hard to reconcile. Our psychological situation, on the other hand, calls for a more assured status for each producer, more attention to the impact on him of each new decision, more consultation with him, more security for him, more leisure, and a greater individual return for effort.

At first sight this would seem to be a mental inheritance perfectly unsuited to our needs. Yet I believe that it is at least a stage along the road to becoming the sort of community which we need to be—a community which is informed throughout by so great a capacity for sensitive response that it can meet without confusion or disruption the sort of challenges which are coming to us. Whether we shall achieve such a community in time only time itself can show. But if we are still unprepared for the next ten years, we are at least better prepared than we were fifty years ago.

The great coal strike of 1893 was settled by the Foreign Secretary at a conference held at the Foreign Office. Seen from the 1950s it seems a strange choice of mediators. Was it prompted perhaps by the sense that here the two nations of which Disraeli spoke were at issue and that mediation between nations was a Foreign Office job? Little more than fifty years later the Foreign Secretary was himself a great trade-union leader. We should not suppose on that account that the two nations have completely fused. They have not. But they are immeasurably nearer to fusion. Our attitude of mind is itself partly the product and partly the cause of that mutual penetration of two once separate worlds, and as such it is precious past telling. For the task ahead is a task for one nation, not two. As two nations we should be doomed from the outset. As one we have a chance.

The chief difficulty about the welfare state of mind today is that collective security cushions the effect of national insecurity in the mind of the individual citizen and makes it harder for him to recognise or to respond to it. In a simpler economy the peasant knows whether his efforts are winning him a livelihood. He knows how much it is. He knows that it is not necessarily as much as his efforts "deserve." He knows that whatever it is he cannot both have his cake and eat it. All these homely truths are still true of our national economy, but they are not wholly true of any individual one of us. How are we to produce a national response to a national situation, if what is wanted is something different from the sum of our individual responses to our individual situations?

Fifty years ago it seemed a paradox that there should be so much individual insecurity within a situation which was nationally so secure. Today the paradox is reversed. How can we reconcile collective security with national insecurity? Fundamentally, the paradox is, I think, unreal. The harder the times, the more important it is that the load shall be fairly shared, that such security as there is shall be spread as it may best be borne, that everyone shall count and that nobody shall be wasted. So we can say with truth that fundamentally a siege economy calls for a Welfare State. The danger lies not in the Welfare State but in some aspects of the welfare state of mind. In a real siege, every citizen can see the besetting dangers, and every private life is altered by it. In our situation it might be that the individual first felt the impact on his own life after the walls had been breached. Unless we can respond individually to a group situation, collective security will damp down our responses until they are too late.

THE BURDEN OF BEING SOCIALLY MINDED

Well, there are my two facts—the siege economy on the one hand, the welfare state of mind on the other. The roads from them have converged on a single problem.

Both demand that we shall learn individually to respond to a situation much wider than the one which we can directly know. This is a most difficult [illegible] indeed unnatural thing to do.

Much has been talked and written about the passing of the old many-skilled craftsman and his replacement by the specialist or the semi-skilled man on the assembly line. The old craftsman, they say, was better placed, partly because he had more scope to plan, execute, and finish a complete job, and partly because he was more independent of other people. I have watched a Scottish quarryman working alone in the section of face which was allotted to him—his "motion" in local parlance. He had his tools and unlimited stone, periodically blown down for him; and every week they came and took away the sets and kerbs and borders which he had made and paid him for them. He kept his own hours, worked at his own pace, waited for no man, hurried for no man, neither received nor gave an order. . . . He was a perfect example of the type with whom we are accustomed to contrast the man on the assembly belt.

What is the essential difference which we instinctively feel and deplore? To appreciate the answer, we need to think of action as response to a situation. The satisfaction which we get from acting depends very much on how free we are to respond to the situation as we see it; and the effectiveness of our response depends on how adequate our appreciation is. My quarryman was completely free to respond as he pleased to every situation which arose; and he was aware intuitively of almost everything which he needed to know in order to respond effectively. He scarcely needed conscious thought. The same may be true of men working in a small team. But the man on the assembly line and the specialist whose work is part of a still wider synthesis tends to be pulled back, pushed on, or pushed about by events to which he cannot effectively respond—the stoppage of the conveyor belt, for instance—or by decisions with which he cannot identify himself; and he needs a profound change of mind if he is to be happy and effective.

Like my quarryman, the proprietor of the one-man business had the world for his oyster and was free to respond to it as he pleased. The manager of today is making part of a collective response to a situation wider than he can know and much wider than he can feel; and in so far as he does know the new features in this situation they are often the harder to accept, because they seem irrelevant to his job. Most of them stem either from the siege economy or from the welfare state of mind; and neither of them shows the slightest tendency to abate.

Clearly both managing and being managed are getting more difficult, and in at least three ways. First, it is difficult to assemble all the relevant facts for the broad decisions. Next, it is more difficult still to make the decisions acceptable to those who are to act on them—I do not mean difficult to exact their obedience but difficult to get them to put it into effect with the same lively initiative which they would put behind a response of their own. These are difficulties of communication. Finally, there are difficulties inherent in the act of decision itself.

THE ART OF DECIDING

My quarryman's decisions were barely conscious; he seldom needed to weigh the pro and con, for the whole situation was present to him and his response was almost instinctive. So were mine when I practised as a lawyer; so are most of the responses of an independent manager so long as the scale of his operations is not too big for him to apprehend his situations directly. But in industry today decisions have to be taken over a field too wide to be within the intuitive grasp of anyone. Even in policy-making, therefore, we are up against the difficulties which specialisation always involves. No-one enjoys either the satisfaction or the certainty of responding directly to the situation. The processes of rational decision have to be dragged up into the light of day. Intuitive assurance of what to do—which is the best sort of assurance—plays an ever smaller part in major decisions and the part it does play becomes ever less helpful, for it tends only to exaggerate the importance of those parts of the situation which are intuitively known.

There is a point at which the scale of management changes its problems not only in degree but in kind. Men successful and experienced in what would have been called large-scale management thirty years ago have to learn new and irksome tasks when they come to what is large-scale management today. They have to learn to accept the limitations of remoteness, to learn the infinitely difficult art of helping to make up a collective mind instead of merely making up their own.

THE ART OF BEING INFORMED

They have today some remarkable technical aids. The mechanical means now at our disposal for collecting, classifying, and handling facts—especially facts which can be expressed as figures—already far exceeds our human abilities for using them. Calculating machines and card-punching machines occupy even more of our offices; within a generation we shall all have an electronic brain in the basement. All these devices will give us the right answers if we feed them with the right facts and ask them the right questions; but they do not help us with those two "ifs"; and they make it harder for us to proceed by trial and error, because they give a certain rigidity to the questions which they are set to answer. No doubt in the future we shall have to know more about the methods, the possibilities, and the limitations of statistical science; but this in itself will not help us in deciding what questions to ask or, if you like, what indices to watch.

Here again times change. In a private undertaking the primary criterion of efficiency is whether it pays; and of this its accounts provide a clear and reliable index. In an undertaking with statutory duties, like the National Coal Board, the proper criterion of efficiency is to inquire how well it is doing the job which it was set up to do, having regard to all the circumstances. In judging this, how are we to weigh the indices of output, of productivity, of cost, and of price, and with what standards are we to compare them? Under these new and exacting conditions, how are we to measure and to audit efficiency?

THE ART OF COMMUNICATING

In the art of communicating there is much more than merely passing information, and communications is itself a wider term than is always recognised, even by its exponents.

Human communication has nearly always a double effect and usually a double object. When A and B talk, they may or may not learn something from each other but they certainly create or modify a mutual relationship. "Did you meet A?" I say to B.—"Yes," says B. "What did he say?"—"He agreed that the weather was warm." "Did you like him?"—"No." How are we to explain "communications" of this kind? B has apparently received some information but it was not about the weather and it was not what A meant to convey. Is it not clear that the technique of speech is being used not to exchange information but to establish a rapport?

A man who spent part of the war in Fighter Control told me that the tone of voice was as essential to success as the speed and accuracy and relevance of the information passed. The fighter pilot, you may say, wanted information and nothing else; but it could only travel along a bond of human confidence.

What happens in the course of industrial consultation? Is its value measured by the information which is imparted? If so, we must widen the meaning which we give to information. In the coal industry since Vesting Day we have closed 137 pits, for various technical reasons: and each closure has meant the breakup of a social group, often with a long history. In 5 cases the closure was not agreed by all concerned without reference to headquarters, and on each of these 5 occasions the process of consultation was repeated at national level. Everyone came, and the whole decision was reviewed. So far as I know, nothing new was said and nothing previously overlooked emerged. Every fact and every argument had already been used at other levels. No information passed which had not passed before. I am not even sure that anyone changed his opinion. In all but one of these cases the final decision was the same as the original proposal. Yet something happened in those cases, no less than in the one where a change was made. A decision, previously unacceptable, was accepted. There was a change, not in opinion, but in relationship and hence in attitude.

THE LIMITATIONS OF HUMAN NATURE

I have invited you to agree that both the siege economy and the welfare state of mind call for a very high degree of coördination in our actions and consequently in our understanding and our sympathy. I have pointed out that this requires us to share individually in forming a common view of the situation and in responding to it, in making up our collective mind and in carrying out its decisions as if they were our own. The logic of all this seems to me to be disagreeably cogent; but the still unasked question is—have we any reason at all to suppose that human beings are capable of a relationship of this sort?

The answer is emphatically "No." We are committed to a social exploration far ahead of the bounds mapped by any previous group of adventurers. We should not on that account despair; but it is only common prudence to make a realistic assessment of our resources. We have no assurance at all that human nature is capable of the sort of collective response for which the situation calls.

I sometimes think that we are in danger of inventing a Social Man capable of doing almost as much damage in our day as the Economic Man did in the days of our grandfathers. It is important, certainly, not to think of men as things or as cogs in a machine; but it is equally important not to think of them as gods or as cells in an organism. We still tend to start from the assumption of man with all the rational character that the 19th century gave him and then let the psychologists and the sociologists explain why he is neither so rational nor so individualistic as on that showing he ought to be. I think we should do better to start with the zoologists and speculate how it is that we humans are on the whole so much more socially adaptable than our fellow creatures and how we can best respond to this new and sterner challenge to adaptation.

If we look at behaviour throughout the animal world, we see the same picture constantly repeated. We see creatures producing beautifully apt and quick responses to the kinds of situation which they normally meet, yet thrown into utter confusion if the situation is unfamiliar or if it awakens two different responses at the same time. We see, too, that situations are recognised by one or two conspicuous features rather than by their essentials. The young of the mallard, I understand, will accept as "mother" any creature whatever which makes the right quack at the right moment—even if it be a zoologist! We see the power of habits which have survived their usefulness to imprison the creature which they once served and often to bring it to destruction, by confining it to a definite sequence of responses. Well, this nature is part of our human heritage also. Men also tend to recognise situations by superficial labels and to respond to them by stock reactions. Men also are often ready to follow the wrong leaders in the wrong directions, so long as they make the same old quack. And is not the history of industrial relations littered with unhappy memorials to men who become imprisoned in "a definite sequence of responses" by habits of mind forged how many years before?

Yet we have far outstripped the rest of the animate world in adaptability. How we do this is by no means clear; but it seems to include at least three processes. We come to understand our situation; we realise it imaginatively in our heads; and we respond to it perhaps with as much liveliness as if it was before our eyes. This is magic indeed. It enables us sometimes, though rarely and with great difficulty, to break our own habits before they break us. We do not know how far this faculty can be developed; so we do not know for certain that the adventure on which we are embarked is impossible.

What we have somehow to do is to build up in our imaginations a picture of our common situation so lively and so accurate that we can respond to it willingly and effectively. We have to recondition ourselves to respond differently to new situations, even though their conspicuous features do not change; and thus to change our habits, without losing them. We have to establish by these means a sufficient common element in our inner worlds to ensure that our responses will be coherent in themselves and consistent with those of others; and on this basis we have to build within industry and to the measure of its expanding needs a social relationship equally remote from the law of the jungle and from the law of the hive.

Public Health

The National Diet

THE original purpose of the National Food Survey, which has been keeping an eye on the country's diet since 1940, was to examine food consumption and expenditure in war-time, and so to measure the effectiveness of the Government's food policy. But the Ministry of Food's worries certainly did not end with the war, and the survey has continued its work. Last year it reported on the changes in the diets of urban working-class households between 1940 and 1949[1]; and now the first of a series of annual reports has been published.[2] An important change in method has been introduced: by choosing a representative sample of the country's households the survey has extended its scope, which has hitherto been confined to urban working-class families; and it is now possible to look at a much more comprehensive picture of our menus and food bills.

The report says that as a nation we now show a much greater uniformity in what we eat and in what we spend on eating than we did before the late war. During the winter of 1950 the average expenditure on food was 14*s.* 6½*d.* per head, per week; and the better-off households (those whose principal wage-earner received £13 a week or more) spent 4*s.* 1*d.* a week more per head than families living on £4 10*s.* a week or less. The most closely comparable pre-war figures (for 1936–37) gave an average of 8*s.* 11½*d.* per head per week and a class range of 10*s.* 10*d.* In those days the top social class spent three times as much on eggs, butter, and fresh meat as the lowest income group; in 1950 there was little difference. This change, however, was not confined to rationed foods; expenditure on fresh milk, vegetables, and fruit showed the same trend.

---

[1] See *Lancet*, 1951, ii, 1032.

[2] Domestic Food Consumption and Expenditure, 1950. Annual Report of the National Food Survey Committee. H.M. Stationery Office. 1952. Pp. 131. 4*s.* 6*d.*

More bacon, butter, fresh rationed meat, and eggs went into our larders in 1950 than in 1949, but the increased consumption of meat only took us back to the 1946 level. Analysing the constituents of the national diet, the report finds that it contained more fat and protein than before, though its energy value remained much the same. The average value, for all households, of a day's diet in 1950 was 2474 calories per head; and energy needs seem to have been met by more bacon, meat, eggs, milk, cheese, and fats, offset by less bread and other cereals, potatoes and other vegetables, sugar, and jam.

Care of Old People

In his report for 1951, Dr. George Nisbet, county medical officer for the Soke of Peterborough, mentions the county's plans for a hostel for old people. His chief aim, however, has been to help the elderly folk to stay in their own homes; and he has been surprised how often his department has had to arrange for district nurses, home helps, and voluntary workers to help these people because the relatives have made little effort to do anything themselves. The relatives' attitude is partly explained, Dr. Nisbet says, by the fact that nowadays fewer children settle down in houses close to their parents' homes; many of them move out to new estates on the outskirts of the town. But, in Dr. Nisbet's experience, complete disinterest, and even blatant coldheartedness, often mean that old people have to depend on assistance from the local health authority; and this assistance, though of considerable value to them, can never be a complete answer to their difficulties.

The Third Quarter in Scotland

In Scotland during the September quarter of this year[1] the infant-mortality rate was the lowest ever recorded in any quarter—30 per 1000 registered births. The birth-rate was 17·3 per 1000 population; this was 0·3 more than in the same quarter of 1951, but 1·0 less than the average for the past five years. The still-birth-rate was 24 per 1000 total births; and the neonatal death-rate was 21 per 1000 live births, which was the same as in the corresponding quarter of 1951. The death-rate of 10 per 1000 population was below recent and pre-war averages.

Public-health Administration

The first report of the W.H.O. expert committee on public-health administration has now been published.[2] The report pays particular attention to the personnel of health services. The committee thinks that the needs of the public-health services are at present insufficiently considered both by the authorities who plan undergraduate and postgraduate courses in medicine and other subjects connected with health work, and by the graduates themselves. More stress should be laid in curricula on the preventive and social aspects of medicine. If more doctors are to be persuaded to take up this work, better pay and prospects of promotion must be provided.

Traffic in Dangerous Drugs

The Government's report to the United Nations on the traffic in opium and other dangerous drugs in 1951 shows that seizures of hemp in this country increased over previous years, while the quantity of opium seized continued to diminish. The majority of hemp users were between 20 and 30 years of age, and were men of West African and West Indian origin; and nearly all the persons prosecuted for the illegal possession of opium or opium-smoking utensils were Chinese. Of the known drug addicts in this country in 1951, 67% took morphine either alone or in combination with other drugs. Pethidine was used by 18%, as compared with 12% in 1950. The report says that there is no evidence to suggest organised trafficking in this country, and that drug addiction is not a serious problem, though very strict supervision continues to be exercised.

Special Articles

THE WORLD'S FOOD-SUPPLY

THE difficulties of maintaining the food-supply of the world and ways of solving them were discussed at a meeting of the food group (nutrition panel) of the Society of Chemical Industry on Dec. 10. Mr. J. I. M. JONES, M.SC., chairman of the nutrition panel, presided. This was the first of four discussions to be held by the group on this subject during the present session.

Mr. F. LE GROS CLARK said that a revolution in farming methods was necessary. There had been agrarian transformations before—the enclosure movement in this country and the coöperative movement in Denmark. The process of starting and carrying through such a revolution should have begun at least fifty years ago, when the pressure of population was not so great. If we did not make up for the delay, we should be condemned by future generations; for today we knew the facts. Discussing population increase, Mr. Le Gros Clark said that we could not expect Asians and Africans to take kindly to advice on birth control. "Is it not obvious," they would say, "that you preach to us only when you grow tired of your own fecundity?" But this did not mean that in time the world population would not reach some measure of stability. From a demographic point of view the world's history fell into three phases. In the first, the population of the world, after its primary growth, was held almost stable by high death-rates. There was then a period of accelerating increase, followed by a gradual control of the infectious diseases. If the birth-rate slowly declined, there must come a stage beyond which this growth could advance no further; and if by that time methods of birth control had been widely adopted, we might at last be in a position to suit our numbers to our own convenience. Referring to the need for more research in plant pathology, meteorology, hydrology, and plant genetics, Mr. Le Gros Clark said that most nations were not giving the agricultural scientist and the food chemist half the chance they should have. As to the human factor, turn the peasant into an alert modern farmer, and there was some prospect of getting him and his family to think in terms of scientific family control. But the order could not be reversed. Clearly, the transformation of a largely illiterate peasantry could not be completed for a century or so, but it was high time to plan our grand strategy.

Mr. E. W. RUSSELL, of the department of agriculture in the University of Oxford, discussed the factors limiting food production in this country. It was no answer just to say: "Get rid of all the less good farmers." Who was to take their place? Farmers were a cross-section of the community and, like every other cross-section, included good, mediocre, and bad; and we could only achieve uniform excellence in farming by taking good men from other occupations. The intractable difficulty in the way of increasing productivity in the hills was to get more men with new farming skills into these areas, and to improve the skills of those already there. Yet these were the very areas where the more enterprising and intelligent men were unwilling to live; and therefore the amenities would have to be vastly improved. In the world at large, food production was limited by three sets of conditions—those due to site, those due to disease, and those due to the characteristics of the people living in a particular area. The plant-breeder was helping to reduce the effect of a short growing-season; irrigation could sometimes make good a lack of water; and manuring and a suitable system of crop rotation could alleviate soil poverty. Animal production was limited mainly by the lack of land available for growing animal food; but disease, and particularly insect-

1. Quarterly Return of the Registrar-General, Scotland: Births, Deaths and Marriages Registered in the Quarter ended Sept. 30, 1952. H.M. Stationery Office. Pp. 30. 2s. 6d.
2. *World Hlth Org. techn. Rep. Ser.* 1952, no. 55. Obtainable from H.M. Stationery Office, P.O. Box 569, London, S.E.1. Pp. 41. 2s. 3d.

borne and mite-borne disease, could be very important. The scientist, the agriculturalist, and the social worker or anthropologist should combine to persuade the farmers to adopt new methods. Another important limitation, particularly in the subtropics and tropics, was the hindrance caused by debilitating diseases, such as malaria and those due to intestinal parasites, which sapped the desire and ability to do much work in a day.

Mr. **Norman Wright**, d.sc., chief scientific adviser to the Ministry of Food, asked whether greater production was to be expected by increasing the cultivatable area or by increasing the production of the existing cultivatable area. He had understood that the general pattern of food habits was related to economic conditions—for example, meat consumption was high where meat production was plentiful. What would be the increase in food available if people lived on the crops which could be most suitably cultivated in the area where they lived?

Mr. **Russell** replied that many acres were certainly not being cultivated, but it was not known how to cultivate them. He considered that increase would come from raising the yield per acre. As to food habits, the Scotsman used to eat oatmeal—now he ate bread and just a dash of oatmeal to show his nationality.

Mr. **Le Gros Clark** commented on the suggestion that if we eradicated malaria and other mass diseases, the population would grow more rapidly than ever. But he thought that there was no alternative. More human beings might lead to a famine. Very well, he said, there would have to be a famine.

Mr. F. **Wokes**, ph.d., had hopes that young green leaves, whose protein content was greater than that of older leaves, could make a significant contribution to diet in some parts of the world. The plants that grew in profusion in the tropics were a possible source; and he thought that the date palm should be grown more widely.

Mr. R. **Braude**, ph.d., said that the potential food-producing areas of America could support 500 million people; and some parts of the Middle East could also feed a far greater population than they did at present. Mr. **Russell** pointed out that American irrigation schemes in Arizona had often failed because they tried to irrigate too much land with the available water.

Prof. J. **Yudkin** remarked on the number of subjects involved in the study of nutrition: two of these were psychology and politics. Glass and other psychologists and sociologists had emphasised the fact that much intellectual ability was being cramped by inadequate education and poor social conditions. With a radical change in methods of education, it should be possible to raise the standards of the worst farmers. Professor Yudkin pointed out that there were countries where the question was not how to increase food production but how to limit it—Canada, for instance, would produce more wheat if she could only sell it.

Mr. D. M. **Freeland** spoke of the difficulty of young people who were unable to get farms when they left an agricultural college. Would it not be possible, with all the lands in the possession of the National Trust, to hire out some farms to these men? But Mr. **Russell** did not want young men straight from college to be given charge of farms. The farms of the "surtax farmers" were on the whole in the best class; and these farmers employed keen young men as managers. He thought that it was better for a man from college to spend a few years as manager or assistant manager.

Mr. A. E. **Bender** said that scientists could no longer sit down and say they had done all they could, and that now it was up to the politicians; for chemists were also citizens. Technically the problem had been solved; but success could not be achieved by scientists acting as scientists, but only by scientists acting as politicians.

Mr. A. L. **Bacharach** wondered whether the drive for self-sufficiency in agriculture in this country was economically and socially sound. There was little alternative during the present state of international tension, but a vast amount of time and money was wasted by some countries in producing things which could be much more efficiently produced elsewhere. It was nice for scientists to congratulate themselves and say, "we have solved all the problems, if only the politicians would get on with it." But that was not quite true. Fundamental research was essential, but during the past fifty years there had been a revolution in the attitude towards training in chemistry and possibly also in physics—a realisation that most students would enter the applied branches—and other sciences could with advantage follow the example. Mr. Bacharach found hope in the expectation that the birth-rate would drop as standards of living rose and the value of the child as a labourer decreased.

BIOLOGICAL WARFARE

In a statement on biological warfare the executive committee of the Medical Association for Prevention of War declares that the effect of other weapons cannot be concealed or simulated and the fact of their use is bound in the long run to become public; bacteriological warfare is exceptional in that its use or non-use in a particular theatre of war can be open to dispute.

> "It must now be evident how serious a psychological effect the knowledge that an insidious and inconspicuous weapon of this kind is being stock-piled, must exert on international tension. It seems plain to us that, so long as the development of bacteriological weapons continues unchecked, no official protestations about their defensive character will prevent the dangers which they involve. Accusations that they have been used will recur; these may be true, false or based on genuine error. Such accusations carry a continual risk of reprisal in kind. They can rarely be verified or disproved to the satisfaction of everyone and, in an atmosphere of international tension, the knowledge that such weapons exist, and that their exact nature is secret, will contribute to public anxiety, damage still further the repute of science, and might provide the spark to kindle a new world war."

The association points out that an instrument for international agreement for the prohibition of bacteriological weapons already exists in the Geneva protocol of 1925, which has been ratified by all the major states except the U.S.A. and Japan. The 1952 International Conference of Red Cross Societies appealed to all nations to adhere to the protocol. The association welcomes this appeal, but does not believe that an international agreement not to use a weapon is, in itself, an adequate guarantee that the weapon will not be used. The association does, however, believe that such an agreement would be a significant step towards attaining international confidence, would facilitate future agreement on methods of ensuring that the undertaking is honoured, and would bring nearer the eventual renunciation of all forms of war.

The association urges the governments concerned to view the issue as a problem of fundamental human importance, and not as an opportunity for propaganda; and it proposes the following measures:

1. That all governments publicly state that they will not in any circumstances resort to this form of warfare.

2. That those governments which are not signatories to the existing undertakings on this subject should sign them.

3. That secrecy in the field of bacteriological research should be replaced by full publication, and that all research stations engaged in such research should be opened to international inspection by an agreed authority.

4. That pending the realisation of these requirements medical and scientific workers should decline to participate in any secret research which appears to them to be directed toward the further development of these weapons.

unning Commentary by Peripatetic Correspondents

HAVE always been impressed by the extent and ety of my colleagues' fan mail. From all quarters he free and occupied globe the letters pour in, and the cards requesting reprints are neatly stacked in r rooms according to the country of origin. A brisk e in stamps is done, and their children are well up ne latest Peruvian and Senegalese issues. No sooner s [illegible] my acquaintances express himself in print [illegible] obsequious missives begin. "Illustrious and o [illegible] Professor," they write cringingly to our new or research assistant, "the world is richer for your k. Will you please have the gratitude to send me ten ies. Accept, I pray, my compliments the most inguished. I remain, illustrious Professor, Scribble-atch. Over-Chief of Clinic."

y own publications arouse minimal enthusiasm, and ever have any stamps to swap. Occasionally at the of a long and scurrilous letter on other subjects there urs some such phrase as "Your last effort wasn't h tripe as usual—send us along a reprint, will you ?"; there is no emotion, no soul, in such requests. It is that I once received an undecipherable postcard n Hungary, and on one glorious morning a letter ved for me from Guam; I let it lie for a day to sink my colleagues' subconscious. Alas, it proved to be a uest for an article written by a namesake of mine in a l establishment.

f this were all it would not be so bad. But the other uests that arrive are equally humiliating. My friends nd their time attending conferences in Rio or congresses Brno—always by invitation, and usually to open the ceedings—and keep their hands in during the close son by dropping into the Royal Society to read one or papers. In the winter evenings they are asked to on the Third Programme or they dash off a book the humble request of the publishers.

y own life is very different. My books are always t to cynical readers who return them with such nments as "Style pedestrian; content uncritical: ited public only." If I attend a congress it is always Birmingham, and my paper is always taken as read ause the time-table has fallen into desuetude. But I e had my moment. The other day a colleague velled sixty miles on the British Railways accom-ied by the decapitated head of a ferret in a paper to ask me what in my opinion were the names of the scles in its neck.

* * *

squeal of brakes, then "Crash!" the motor-cycle s the wall. The passenger is flung clear; the rider beneath his machine. Spectators rush to the scene, l four St. John Ambulance men hurry through the r. Another team competition begins.

he ambulance men swing into action.

What happened ?" the leader asks the spectators.

They were turning into the side road. Took the corner fast, and hit yon brick wall," they tell him.

Right, men," he gives his orders. "Stop the bike engine. ntrol traffic. Telephone an ambulance and the police. examine the casualties."

ne casualty is on his back, his leg under the machine. ckly the cycle is lifted away, and a rapid examination made.

Oh, my leg, my leg!" he moans, entering into the spirit the game. "Do something, quickly!"

All right, chum. We're first-aiders. We'll soon put it t. Lie still, now."

ey pull up his trouser leg ("really we should slit Doctor, but then he would have nowt to go home in") l gasp at what appears. From a red, gaping wound trudes a jagged broken bone. Blood covers the leg. looks a nasty compound fracture of the tibia. And done with putty, red paint, and a small piece of bone, hioned on a length of inner tube. The pillion-rider quietly on his face, as he fell. His face is naturally e. He looks the perfect case of shock. An abrasion nted on his cheek provides a further complication.

Steady and support the injured limb," orders the leader, en he gets his breath back. "Any dressings available, tor ?"

"Yes, there are."

"Can I ask where ?" looking hopefully round the hall.

"No, you cannot," I answer, giving nothing away. The competition is to test powers of observation. "There is a package of dressings, but you have to find it."

Now begins the most entertaining part of the test. Frantic searches under forms, into cupboards, behind the curtains, in the pockets of the "casualties," everywhere but the right place. It reminds me of hunt the thimble. In varying times, all the teams find the package. The winners, four calm, efficient police constables, find it quickly, though they eye it doubtfully for a second, suspecting a trap. Others see it, handle it, even push it further from sight without recognising its significance. Where was it ? In a first-aid satchel marked with a plain red cross, attached to the seat of the motor-cycle in place of a toolbag. Who said the best place to hide a letter is in a letter-rack ?

The dressings, when found, are limited. The loud groans of the fractured tibia, with the life-like appearance of his wound, tempt some teams to cover it with all they have. Then they have nothing left to dress the abrased pillion-rider. One team, to overcome this difficulty, did not hesitate to remove lint, bloodstained, from leg to face. The ambulance, a table carried by the driver and his mate, arrives five minutes after being called. Four blankets, two stretchers, and some triangular bandages are available. Most teams distribute these fairly between the two casualties, but one gives all the blankets to the fractured tibia. They lose marks for inadequate treatment of his friend.

We all have a very good evening. The marks are totted up, the results announced. I give a little homily on observation and the best use of insufficient material. All is over five minutes before closing-time.

* * *

Dear Mrs. Agony,—On 47 occasions during 1952 you summoned me to visit you, often late in the day, sometimes at night. On no single occasion was there any need for my professional services.

In view of my improved financial position I am now able to offer a substantial No-Claims Bonus for 1953—say fifteen bob. What about it ?

Yours sincerely,
G.P.

P.S.—I might even go so far as £1, and you could come to the surgery without forfeiting your bonus provided that you came during surgery hours.

* * *

Since we started fixing a deadline by which each viva in the dissecting-room had to be taken we have had many excuses for non-appearance at the appointed time. They range from the ingenious "frightful toothache, sir, my impacted molar," "my cousin is selling his house, sir, and I have to be there to show people round," to the ingenuous "lost my book, sir," "can't find my partner," or merely frank "awfully sorry, sir, I was playing hockey." The best one, however, came the other day. A student arrived breathless at the appointed time and asked: "Please sir, may I postpone my viva till this afternoon ? My partner is still unconscious in the physiology department."

* * *

My wife and I are going on a trip abroad from which she must return before I do, and we have had our single passport converted into two. This was done by extending its availability and deleting my wife, who was given a brand-new shiny passport of her own. We now find, on inspecting the newly arrived documents, that my wife can go to the Canary Islands, Iceland, Madeira, or the Azores, and I cannot follow her. It is little consolation to know that we may visit Algeria or the United States in company, and that neither of us can go to Peru; nor does it soften the blow that I have a Foreign Secretary's autograph while she has none. Since the passports came I have noticed my wife thinking, and there is a gleam in her eye I do not like.

Letters to the Editor

RESECTION FOR PULMONARY TUBERCULOSIS

SIR,—Your leading article of Dec. 6 indicates a startling revolutionary change in medical and surgical practice which calls for the strictest examination.

The logic of the argument, that patients, who have made a good recovery and have been proved to have consistently negative sputum are the fitter and more likely to tolerate surgery well, must be conceded as correct; but to subject such patients to the risks and the mutilation of resection of the lung and thoracoplasty would appear to be as indefensible as, and to a degree the same as, to remove healthy lungs or other structures to prevent disease developing in them at a subsequent date.

Pathologists have taught us for a century or more that unknowingly the majority of us have had tuberculous foci in some part of the body, and for the past fifty years radiologists have demonstrated the very common occurrence of old tuberculous foci in the chest and abdomen. Prior to the introduction of mass radiography these calcified masses were merely recorded by the radiologist and were ignored by the clinician, since they were unassociated with any clinical signs or symptoms. Even with the introduction of mass radiography in this country the directors were advised to ignore them.[1] But in view of these developments it is as well to note the original instructions to the directors of these units, which I criticised[2]: "It is important to avoid creating the impression that Mass Radiography (1) is intended for those already ill, or (2) there is danger in his work or life."

In support of the removal of these calcified lesions from healthy people it is stated that some showed a lamellated structure; and liquefaction of the focus with discharge of its contents, teeming with bacilli, is a common cause of relapse. But the former is a characteristic protective feature of the chronic inflammatory process which prevents the latter. I have seen the massive gumma and the chronic abscess and its sequestra in bone disappear with effective medication.

One might conclude that tuberculosis was a localised lesion which could readily be eradicated by resection, and that we had no means to combat it; but this is not true. One has seen resection of one lesion when many others were present, and resection followed by dissemination of the disease; but today with the aid of chemotherapy widespread lesions are healed and the lung cleared entirely—occasionally localised calcified foci have been left, but even these have been resected. I have watched calcified lesions for many years and seen no change. If the condition of the patient suggests a possible reactivity and radiography confirms it, surely chemotherapy, and not surgery, is indicated. I am not overlooking the fact that the coroner has inquired into the death of a young man who died of extensive pulmonary tuberculosis without any signs or symptoms.

If the patient can overcome the generalised disease of tuberculosis with the mutilations of surgery he can overcome it more readily without. Not all patients who were living useful lives survive the operation; and, as your leader indicates, not all cease to spit up tubercle bacilli, [illegible] not all fail to develop progressive fatal disease.

Formerly the argument for resection and thoracoplasty was that it was a preventive measure, but now the patient must not have the lung resected until he has ceased to be infective and is happy and well; the fitter he is the better he will stand the operation. These operative measures are opposed to the teaching of established medicine: Never remove the normal, for in attempting to remove the localised [illegible] tissue is removed and other structures are [illegible] no little risk to the patient.

As far as the radiography is concerned, I [illegible] at the satisfaction with work, producing gr and extensive changes in the chest, whi undertaken because of lesions such as one shrink and cease to mar the course of a long life.

We now see the admittance of failure measures of all degrees of severity—artific thorax, pneumoperitoneum, phrenic avulsion, crush—thoracoplasty, and more recently resection. To think of it: "30 wedge or s resections, with bilateral resections in 3 patien had 9 wedges removed)." If mass radiogra used to detect the unknown healed lesions people—i.e. "surgeons' radar"—the sooner it the better.

With the advent of beneficial chemotherap claim for improved housing and standards o the reinstatement of the patient into the h general practitioner would appear to be the for the patient and the eradication of the dis

CURE OF TOBACCO-SMOKING

SIR,—I can assure your readers in ge *Dr. Joullié (Nov. 1) in particular, that* t mention in the *Koran* of the tobacco plant o The tobacco plant was introduced into E Arabia after the discovery of America—abou after the death of Mohammed.

Bagdad, Iraq. BAHJAT AL

BOVINE TUBERCULOSIS AND HU TUBERCULOSIS

SIR,—There are several statistical points wh be made with regard to Mr. Pitcher's lette in which he shows that in certain Scottish where the proportion of attested herds is gre 50%, the annual number of pulmonary tu notifications per 100,000 population has in m increased, *and that other counties where attes* number less than 16½% show on the whole tuberculosis notifications.

If the counties for which Mr. Pitcher gives f classified according to whether the popul increased or decreased between the 1931 a censuses, it is found that the division is almost with that made by Mr. Pitcher on the basis o centage of attested herds. The counties with 50% attested herds all show an increased except Zetland (where incidentally tuberculos tions have decreased). Moreover the counties Perth for which only old figures are given by M with less than 16½% attested herds have populations, with the exception of Kincardine, and Inverness (the increase being small in th counties).

Therefore, without some additional eviden Mr. Pitcher does not supply), it is as reasonab bute the changes in tuberculosis notifications population density as to reduction in bovine This statement must not be interpreted as a increased population density "causes" increa culosis notifications; it merely shows that at alternative hypothesis fits Mr. Pitcher's facts could be suggested. The point I wish to ma something more than an apparent statistical r is required before any such hypothesis can *be* as true.

It seems very doubtful that the proportion o herds in each county today is a suitable meas ich has taken place, over the past 20 or 30 the proportion of tuberculous cattle in that hich is what Mr. Pitcher wants to measure. ole, in his original letter[1] he stated that when of Zetland were tuberculin-tested in 1945 there ly any reactors. Thus the introduction of the attle scheme can have made little difference to but what [illegible] the position 20 years earlier? ss the percentage of attested herds represents of an examination of all the cattle in the gives only a doubtful indication of the prevaovine tuberculosis; and this applies particularly percentages.

cher gives figures for only 20 of the 33 Scottish How do the others fit in with his theory?

Ir. Pitcher's arguments unconvincing, but this is tant matter and it seems to me that some or medical evidence is required before any ns can be drawn. The national statistics are by too many extraneous influences to provide more than indications for further research.

Middlesex. R. H. DAW.

ESTHESIA FOR TONSILLECTOMY IN CHILDREN

rightened children, as seen in hospital outinics, often fall into one of two classes:

toddler whose only contact with a doctor in a at has been in the diphtheria prophylaxis clinic d of a needle, with other children crying round. Results might be happier, though less hygienic, if its were abandoned in such clinics.

post-tonsillectomy "smash and grab" child who has hyxiated into unconsciousness beneath the glare of light or the beam of the throat raider's headlight.

e visited hospitals and departments where the ed child is placed on the operating-table "so o start the anæsthetic outside." Induction takes the ever-increasing roar of running water and the f stainless-steel buckets.

ll who operate upon the young make it their l business to see that no conscious child ever he anæsthetic room. Light premedication is not ; for it merely makes the child unable to accept urances (so freely given) of the nurse "that the is not going to hurt."

ds, sights, and smells of surgery must not be to enter the child's absorptive memory. In such ve anæsthesia there is only one danger— ence.

1, W.1. D. F. ELLISON NASH.

HÆMORRHAGIC FEVER IN KOREA

I was interested to read Captain Rowe's review s on this subject (Nov. 15). All the cases among Commonwealth troops in 1951 and the onths of 1952 were seen in the 29th British Hospital, now known as the British Commoneneral Hospital, in Kure, Japan, where I lately

sease, which first appeared among troops in Korea 1951, is now known both there and in Japan rrhagic fever, for there is no certain evidence isease is epidemic. In our experience the age occurred nearer the tenth day than the it was often heralded, and sometimes manily, by epistaxis. It is generally agreed that he early signs of the "bleeding tendency" seen t four or five days of the disease are attributable ontinuous and violent vomiting and retching. more emphasis should be laid on the albumich is a characteristic feature—so much so that me it was only in exceptional circumstances that a diagnosis of hæmorrhagic fever was mad absence, and even then some doubted the valid such a diagnosis.

Of the other points one in particular is both important and interesting. Patients with hæmorrhagic fever travel extremely badly, and quite often the journey from the forward medical units in the field to the base hospital in Japan was a major factor in the severity of their illness. Since the introduction of helicopters by the U.S. medical services to evacuate patients with hæmorrhagic fever from forward to rear medical units, there has been a reduction in the mortality of the disease and in the severity of the individual case.

Finally, I would like to mention the excellent work performed by the regimental medical officers of forward units in diagnosing the disease in its early stages.

London, N.W.1. C. BERNSTEIN.

ESTIMATION OF BLOOD-DEXTROSE

SIR,—I have read with great interest Mr. Sheridan's comments (Dec. 13) on the theory of my method for rapid blood-sugar estimation. While I respect his views, I am unable to agree with him for the following reasons:

(1) A consideration of the formula concerned will show that for the usual concentrations of dextrose in the blood and for a vessel of the length of the eye the optical rotation produced would be extremely minute—a fraction of a degree.

(2) Light which has been rotated on entering the eye would be rotated back again to an equal and opposite extent on reflection.

(3) We have been able to reproduce the results using a series of stops to measure light intensity without polarising the light.

The London Hospital,
Whitechapel, E.1. D. W. VERE.

DEATH AFTER ANÆSTHETIC WITH HYPOTENSION

SIR,—Dr. Bodman (Nov. 29) draws attention to the slower recovery following the use of the methonium compounds. I agree that such is quite often the case. I feel, however, that the cause lies in the lowered metabolic rate and, therefore, the slower elimination of the drugs used, rather than in stagnant anoxia. If anoxia were present it would surely have shown itself by now by an increase in postoperative morbidity.

It is unfortunate when an able anæsthetist has such an experience in a short series of cases using a particular technique. I would cross swords at once with Dr. Belfrage for his uncomprehending letter (Dec. 13) condemning Dr. Bodman for his choice of drugs and technique.

Rather let us congratulate Dr. Bodman on his courage in reporting a death which he believes was associated with hypotension. I suggest that his technique may, in fact, have been responsible, not only for a bloodless field, but for getting the patient off the operating-table alive. It could be argued that hexamethonium bromide may well have dilated, and temporarily relieved, the diseased arterial circulation. Blood-loss with an ordinary anæsthetic could easily have caused compensatory vasoconstriction and thrombosis during the operation in such a case.

Queen Victoria Hospital,
East Grinstead, Sussex. JOHN F. PELMOR[illegible]

SIR,—I was glad to read the spirited protest by [illegible] Belfrage (Dec. 13) against the indiscriminate use of hypotensive techniques in anæsthesia. There is no doubt that these techniques, especially when associated with the head-up position, carry a serious risk, and can only be justifiable in those few cases in which the *possible benefit* to the surgeon outweighs the *certain risk* to the patient.

In the first article on the use of methonium compounds in anæsthesia,[1] I uttered a caution which I repeated plified on several occasions, particularly at a ng of the section of anæsthetics of the Royal ety of Medicine in March, 1951,[2] but with small port from the body of anæsthetists. No new techie should be introduced into anæsthetic practice ss it brings with it greater safety for the patient: ppears from the reported fatalities that the methonium pounds, used to produce hypotension, fail by this, and their use should be abandoned, save in very and carefully selected cases.

DEALING WITH DISASTER

IR,—I should like to make some points arising from r editorial (Dec. 6) on the organisation and treatit *of casualties in a major accident.*

he so-called "general surgeon" no longer exists. is a specialist in abdominal surgery and surgery of the k and of a few other areas, and is as much a specialist for example, an orthopædic surgeon. It is therefore gical to suggest that a surgeon with such specialised erience should lead a team to deal with accidents re 90% of the casualties are orthopædic.

esuscitation in the form of blood-transfusion should vailable on the spot in an accident of this kind, where re is delay in extricating people who are trapped.

f, however, the injured can be readily transported hospital then this is the best course to take. But in the sorting and decision as to the immediate tment would be best made by an accident or orthodic surgeon who is constantly meeting this problem is daily routine work.

indsor. G. P. ARDEN.

HE WHOLE-TIME OFFICER AND MILEAGE ALLOWANCES FOR HOSPITAL STAFFS

IR,—In the Supplement of the *British Medical Journal* Dec. 6 (p. 220) we are given the impression that at concessions have been secured for whole-time cers by the agreement reached on mileage allowances the General Whitley Council. Let us examine these oncessions" more closely.

irst, the new mileage allowances will be introduced only the employing authority by resolution so decide." They not national awards, but depend on the charity or whim he employing authority. They may vary from region to on and be terminated at a moment's notice. Unforately *the matter does not end* with the sacrifice of a vital iciple. When the Staff Side of Whitley "B," in their ecent haste to secure better *terms for their part-time* eagues, agreed to the imposition on whole-time consultants egulations that had hitherto been applied only to *clerical* manual workers, they opened the door to the application nore of these regulations and the further degradation of status of whole-time consultants. Our chances of getting Spens report implemented have been gravely impaired reby.

econdly, the "concessions" are so restricted in their lication that they do not "benefit" more than 1–5% of ole-time medical staff. How many whole-time consultants e a *definite commitment* to visit a second hospital or ic every day? Does this include Saturdays and Sundays? *st consultants* with these *commitments* have, where the ional boards would allow it, gone part-time, as they then a *higher net income* for possibly less work and they are e of their travelling allowances.

he other alternative, where the *liability of being called* to make emergency visits is "so extensive and the journeys practice so frequent," depends for its application on the erpretation of "extensive" and "frequent." They can given such a restricted application that they apply *only* hypothetical cases; and, of course, the employing authority s the last word.

The average whole-time consultant who does a few ergency visits or makes some other official journeys each week, and who must run a car (for which he c claim no income-tax allowances), is still worse off un *the new regulations* than he was under the old if he u his car routinely to travel from home to hospital sol in the interests of the employing authority.

These facts prove conclusively that the negotiat committee, and those who "b[illegible]f" them, are competent to speak for whole-time medical staff. ask once more for adequate representation of who time consultants and specialists on the Staff Side Whitley "B."

THE PROSPECT OF GENERAL PRACTICE

SIR,—Having spent forty-one years in general practic I read with interest the comments on this subject i your columns.

The general practitioner's work is attractive becaus of his privileged position as the family doctor wh advises and befriends all the members of the family I reject outright your correspondent's reproach (Aug. 16 of "*low professional standard* and lack of opportunit for good work." In my practice I had at hand a electrocardiograph, X-ray apparatus, *polarimeters*, microscope, and so on; and I could investigate ever case thoroughly. Certainly such investigation require *time and patience*; and one regrets that the genera introduction of health insurance has lowered the standar of care, for the doctor now has simply not enoug time, and the fountain-pen has become the most impor tant instrument in the consulting-room.

The general practitioner deals with the whole ma and therein lies his gratification.

TH. OLBERT.

Düsseldorf, Germany.

VITAMIN B_{12} IN PRACTICE

SIR,—With reference to your leading *article on* th subject (Dec. 13), we would draw your attention to th fact that we have been misquoted in two respec *Firstly*, we did not say that signs of reversion in th bone-marrow could be detected after *40–50 days*, that signs of reversion in the bone-*marrow* could detected 40–50 days *before* signs were evid in peripheral blood. Secondly, we did not conclude t the technique of massive *single dosage* was not pr ticable; we said[1] that, "while of theoretical a practical interest, these findings do *not* justify, witho further trials, the routine treatment of pernicious anæn by 1 mg. doses of vitamin B_{12} at long intervals."

ROBERT B. HUNTER
W. WALKER.

Department of Pharmacology
and Therapeutics,
Medical School, Dundee.

SIR,—In addition to the investigations mentioned your article, several others have been made into t effect of vitamin B_{12} as a growth *factor* in childr Though some reports describe a failure to improve t growth of premature infants,[2–4] attempts with ol children have proved *more* successful.[5 6] We are parti larly impressed with the results just published by Wetzel and his colleagues[7]; *for great* care was taken assess their statistical significance. We believe that reason for his success lies in the choice *of* children th whom he worked." Another colleague tells of od judgment as a surgeon and of his amiable and l nature; and a third writes: "Without being ically brilliant he possessed a good intellect; self-discipline he rose above trials and frustrations might have weighed down a lesser man."

JOHN HENDERSON SMITH

B.A. Oxfd, M.B. Edin.

Henderson Smith, who died at his home at nden on Nov. 26, had a distinguished career. a bacteriology and later in plant pathology.

n Henderson Smith was born in Edinburgh in He was educated at Fettes and went on to ol College, Oxford, where he read classics. After ating with first-class honours in Greats in 1898, ook up medicine and qualified at Edinburgh in . Thereafter he returned to Oxford, where he held ilip Walker studentship in pathology.

t this time pathology was developing very rapidly, its scope was being enlarged beyond the study of bid anatomy. The advances in physiology and the discoveries in bacteriology were creating almost a discipline in pathology; and one of the most active res of this work was in Oxford, where J. S. Haldane James Ritchie were training a rising group of ologists.

enderson Smith was chiefly attracted by bacterio- and immunology, and at the end of his studentship went abroad and spent some time in Germany and mark. In Denmark he worked with Professor lsen, and was much influenced by the attempts there find a physicochemical basis for the principles of unity which were being gradually uncovered by eriments along biological lines.

n 1907 he was appointed assistant bacteriologist he Lister Institute, then under the directorship of Charles Martin. Here he worked chiefly on the hoid-coli group of bacteria; on complement devia-, as it was then called; and on the Wassermann tion. In the early months of 1913 he was appointed etary to the Government Advisory Commission on gue in India. Late in that same year, however, his lth deteriorated; and from then onwards his life e a struggle with ill health.

fter his first illness he returned to work and gave llent service as head of the bacteriological depart-nt at the Lister Institute in 1915. Early in 1916, ver, he was again seriously ill, and he resigned from nstitute.

a pathologist he carried out his work with excellent ique, and expressed his findings in clear, logical age. He was always highly critical of his own oc.

1919, after he had made a more solid recovery of h, he was appointed assistant mycologist at amsted Experimental Station. Thus at the age of began a new scientific career; and it says much f is intellectual capacity and his courage that he e a distinguished reputation in this new field.

is first work at Rothamsted was an excellent research he death-rate of spores of moulds killed by heat and henol. He then took up the study of virus diseases, icularly the mosaic diseases of tomatoes. He ved that the streak mosaic of tomatoes could be oduced in plants grown aseptically and was not, d been believed, a bacterial disease.

a result of his successful work in this field a research was appointed in 1929 to work on these diseases r his leadership. In 1933 he was appointed head e department, which was re-named the department ant pathology. He was one of the first to recognise alue of the chemical work on plant viruses carried during the 1930s. In his presidential addresses to Association of Applied Biologists in 1938, and to the section of the International Congress of Micro-gy in New York in 1939, he accepted the view that of the viruses at least were proteins. He retired his post at Rothamsted in 1940.

took pleasure in outdoor things and played games particularly golf and tennis. Apart from his work, his main interest was his collection of the heraldry associated with them.

M. R., to whom we are indebted for th writes: "Henderson Smith brought to his work scholarly appreciation of the logic of facts. W fine capacity for exposition he was an admirable te and it was a pity that he never held a chair. He ha kind, friendly disposition and was always willing to give any point of view a hearing."

Dr. Henderson Smith married Miss Alice Robinson, who survives him.

Births, Marriages, and Deaths

BIRTHS

Betts.—On Dec. 9, at the London Hospital, to Mary, wife of Dr. Anthony Betts—a daughter.

Chalmers.—On Dec. 10, to Doreen (née Boorman), wife of Dr. Theodore Chalmers, of St. Mellons, near Cardiff—a son.

Lewis.—On Dec. 13, at the Barratt Maternity Home, Northampton, to Kathleen (née Seely), wife of Dr. M. Peebles Lewis—a daughter.

Lockyer.—On Dec. 9, to Cicely (née Nelson), wife of Dr. J. C. G. Lockyer, Colonial Medical Service, Tanganyika—a daughter.

Nicholl.—On Dec. 12, at The Castle Lodge, Lewes, to Margaret (née Pippett), wife of Dr. Patrick Nicholl—a son.

Richards.—On Nov. 16, in Birmingham, the wife of Dr. D. G. Richards—a son.

MARRIAGES

Taylor—Sanderson.—On Dec. 13, Joseph Taylor, M.B., of Chislehurst, to Joan Agnes Sanderson, of East Grinstead.

DEATHS

Craig Mooney.—On Dec. 6, at Yelverton, South Devon, A Craig Mooney, M.B. Lpool, D.M.R.E., F.F.R., aged 62.

Evans.—On Dec. 13, Alfred Ernest Evans, M.B. Glasg. of Kingston Hill, Surrey, aged 82.

Evans.—On Dec. 11, at Edmonton, London, Charles Evans, L.R.C.P.E., aged 85.

FitzGibbon.—On Dec. 1, at Clonskeagh, Dublin, Gibbon, M.D. Dubl., F.R.C.P.I., late Master of the Hospital, aged 75.

Hessey.—On Dec. 13, James Dodson Hessey, M.R.C.P., of ton, and late of St. Leonards-on-Sea.

Hunt.—On Dec. 15, Edmund Henderson Hunt, M F.R.C.S., of Farnham, Surrey, formerly of Secunderabad aged 78.

Johnson.—On Dec. 12, at Bassingham, Lincs, Osborne L.R.C.P.E., aged 91.

Kay-Mouat.—On Dec. 11, John Richard Kay-Mou D.P.H., late professor Singapore Medical Colleg New South Wales, aged 71.

Keates.—On Dec. 13, in London, Henry Crewe Kea lieut.-colonel, I.M.S. retd, aged 73.

Kellaway.—On Dec. 13, in London, Charles Ha M.C., F.R.C.P., F.R.S.

Knowles.—On Dec. 9, at Crieff, Kate Knowles,

Porter.—On Dec. 15, in London, Charles Porter, M.R.C.P.E., D.P.H., barrister-at-law, of Clift N.W.8.

Wostenholm.—On Dec. 12, Maurice Humph F.R.C.S., aged 37, of Harpenden, Herts.

PUBLISHED by the PROPRIETORS, THE LANCET LIMITED, 7, Adam Street, Adelphi, in the County of London.
Printed by HAZELL, WATSON & VINEY, LTD., London and Aylesbury.—Saturday, March 7, 1953.
PRINTED IN GREAT BRITAIN—Entered as Second Class at the New York, U.S.A., Office.

We know that we can remove the disorganised tissue in some of the less active and more localised growth disorders so that the patient lives his normal span of life without recurrence, but we also know that he may harbour a tumour focus for twenty or thirty years without knowing it, only for it to wake to activity at last to cause his death. The wonder is not that disorganisation of the normal processes of growth and repair occur, or that their manifestations are so varied, but that we maintain so long as we do our wonderful steady state despite our extraordinary internal turmoil. We had to wait for radioactive isotopes to tell us just how extraordinary that ordered turmoil is.

The wide variety of degree of incoördination of growth which we cover by the vague word cancer is one of the universal ways in which living things decay and die. As accidents and infections are warded off and life is prolonged, death depends more and more on the degenerative diseases for its necessary toll. The more we understand about the particular relaxations, stresses, strains, and irritations which chiefly predispose to the disorganisation of growth control in various tissues, the better shall we be able to postpone the day when restraint breaks down. The more we learn about the earliest manifestations of such disorganisations, the more quickly shall we be able to deal with the situation before it has got out of hand. The more we know of the natural history of growth disorders at different sites and can assess the degree of disorder and extent of spread reached, the more efficiently shall we be able to choose and apply our treatment methods.

PRESCRIBING TREATMENT

In a general discussion of this kind a detailed account of a treatment plan for patients with cancer of the breast would be out of place. Such an account needs setting in a framework of general principles, the reasons for accepting which are given, together with the evidence on which each one is based. These principles must be interpreted in the light of the needs of each individual patient. Patients vary as much in personality and circumstances as they do in the type of tumour and degree of advancement of the disease with which they present themselves. There is as much difference from one to another in the confidence with which we can rely upon our clinical assessment of the extent of the disease as in the reliance we can place on the history that they give. These things may have an important bearing on the treatment we prescribe. I propose merely to make a few short statements here as illustrations of the kind which I think should colour our view of this treatment problem. They seem to me at the present time to fit in well with the evidence available and to provide a guide to help us make the best use of all the proved treatment methods available. Since several hospitals employing only one or other of these methods as their main treatment plan produce survival-rates of the same order, when allowance is made for differences in material treated, we must either conclude that all these methods have some merit, chiefly exercised in different groups, or that the treatment method used makes little difference to survival, which we know to be untrue for the later cases and which we have good reason to believe to be untrue for the earlier cases also. Patients in the same clinical stage of advancement may still be clearly distinguishable as having a different prognosis and in needing different treatment plans. Radical mastectomy (with postoperative irradiation where indicated), local mastectomy with irradiation of the regional lymph-node regions, and radiotherapy alone or preoperatively, may all have their place within one clinical stage.

The few short statements about the treatment of patients with breast cancer which I would put forward at present to illustrate an approach to the problem are as follows:

1. The outcome of any treatment for patients with breast cancer depends more on the degree of advancement of the disease, which is largely dependent on the nature of the tumours they develop, than on any other factor.
2. Only surgery, radiotherapy, and occasionally hormones, have been shown to modify the course of the disease.
3. Surgery is generally more effective than radiotherapy in eradicating breast cancer, both in the primary site and in the axilla; but unsuccessful surgery usually makes matters worse, whereas radiotherapy normally provides at least some degree of improvement and may lead to complete clinical tumour regression lasting many years.
4. The first consideration in treatment is what chance there is that surgery will be successful. When the chance of complete removal of the tumour by surgery does not seem to be good, or the assessment of that chance is difficult, radiotherapy is to be preferred. The breast and the axilla should be considered separately in making this decision. In some of the doubtful cases operation is best performed after radiotherapy.
5. A worth-while estimate of the nature of the tumour, on which the chance of success with treatment so much depends, can usually be made by considering the length of history, good sense of the patient, size of the tumour, and clinical evidence of spread in relation to the ease of making the examination.
6. A sensible patient with a small hard tumour in the outer half of the breast which has been noticed for some months, who is reasonably thin and easy to feel, and has no more than one or two hard mobile nodes low down on the medial wall of the axilla (stage II), *is usually best treated by radical mastectomy.* Postoperative irradiation should be reserved for those patients in whom detailed pathological examination of the specimen removed suggests that local recurrence is likely, and that the clinical judgment was at fault.
7. A patient with a small hard mobile primary tumour who is either too fat for adequate palpation of th axilla, or who on palpation has several sma nodes extending high up into the apex (stage II is usually best treated by local mastectomy an radiotherapy to the lymph-node regions, especiall if the history is short.
8. A patient with a short history and a large tumou in the inner half of the breast with several har nodes palpable in the axilla (stage II) has a ba prognosis, may never be suitable for operation, an is usually best treated by radiotherapy alone.
9. The more differentiated, slow growing, and localise the tumour, the more reason for primary surgic treatment. The more undifferentiated, rapidl growing, and disseminating, the more reason fo primary radiotherapy. In the middle group, whe in doubt, it is wise to use radiotherapy first wit a view to using surgery later; but if the conditio is still doubtful after irradiation, surgery is stil to be avoided and reliance placed on radiotherap and hormones.
10. *Careful management* and energetic treatment o patients with more advanced disease, avoiding surgery in regions where it is likely that all th abnormal tissue cannot be removed, is often wel worth while.
11. In elderly patients with slowly progressive ulcerating breast tumours, œstrogen therapy may be completely successful—i.e., enable them to live their normal span of *life* without discomfort. Premenopausal women with metastases may be helped, sometimes *dramatically*, by *surgical* or *X-ray castration*. Androgens may sometimes be of value when the castration effect has worn off, or for debilitated patients of any age with widespread deposits especially in bone. In general,

hormone response is infrequent and uncertain and the treatment is at present best reserved for patients with symptoms due to multiple metastases no longer controlled by irradiation. Its combination with X-ray therapy holds out a real prospect of improvement in results as we learn more about their joint action on both the tumour cells and their environment.

12. The most successful palliative treatment may take as much time and care as that designed with a more ambitious aim. At the mere mention of the word palliation the extremes of either giving some easy, quick, ineffectual treatment and then sending the patient home to die under someone else's care, or of pushing treatment till it adds to the patient's discomfort while merely prolonging the act of dying, are still far too often adopted.

Envoy

We can now at times eradicate, we can often delay progress, and usually we can relieve suffering for a time at least; but it seems that more is expected of us not only in the quality of the work we do, which is reasonable, but in its very purpose. The purpose of medicine is surely not to change the whole face of Nature. It is good to set ambition high but not to let our thoughts get out of hand.

> "Couldst thou make men to live eternally
> Or, being dead, raise them to life again,
> Then this profession were to be esteemed."

It was thoughts like this which led Dr. Faustus straight to the devil saying "Physic farewell." Is not the pursuit of a "universal cancer cure" dangerously near to the desire to be "a sound magician" and "a mighty god"? This is for the quacks, a few of whom are no less earnest and well-meaning than we are, but who nevertheless impose on the pitiful anxiety of the public, supported by an ill-advised press at times and quite often sustained by doctors who see and know little of the fine variability of growth disorders, and who, by endorsing their spurious remedies, monotonously expose their own inexperience as one after another they announce that they have never seen anything like it happen before. Credulity, in many fields other than medicine, is due less to lack of brains than to lack of knowledge; it is often easier to fool the intellectual when he is out of his depth than it is to take in the illiterate.

The necessity for cancer treatment is an indication of our failure to prevent, or marks the limit of our ability to postpone; and treatment itself is designed to keep a man healthy for his normal span of life if that be possible and to relieve his suffering if it be not. This seems to me to be the very stuff and heart of medicine, just as universal cures are the stock-in-trade of magicians. Sir William Jenner said that the three essential qualities of a doctor were that he must be honest, that he must be dogmatic, and that he must be kind; he did not say that he must work miracles. Familiarity with the advances that have been made in the knowledge of cancer, and of the effects produced by the treatment methods that are used, will help us to offer our patients the best advice and treatment that is procurable for them at the time. A close study of each individual, to assess both the activity and degree of advancement of the disease and the particular suffering, mental and physical, which that patient is experiencing, will help us to decide what we want to achieve. The difficult things that sound so simple, like a clear idea both of what we want to do and what is possible, are more likely to lead to progress in the treatment of breast cancer than the easy things that sound so grand, like either sitting waiting for someone else to find "a cure" or reassuring ourselves that what we have always done is still the best.

SURVIVAL OF TRANSFUSED RED CELLS

PREVIOUSLY STORED FOR LONG PERIODS IN THE FROZEN STATE

RED cells in 15% glycerol can be frozen and thawed with the production of only slight hæmolysis (Smith 1950). The glycerol can be removed from such cells by dialysis, and the recovered red cells can then be used for transfusion (Sloviter 1951). Human red cells, recovered in this way after having been kept at −79°C for two hours, survive normally in the recipient after transfusion (Mollison and Sloviter 1951). Red cells stored at −79°C for up to eight months appear normal (Sloviter 1952a), and it is shown here that such red cells survive normally after transfusion.

In a study of the behaviour of red cells at temperatures between 0°C and −79°C it was found that a considerable proportion of the red cells could be recovered after storage in 15% glycerol at −15°C for several weeks (Sloviter 1952b). The percentage of red cells which can be recovered after storage at −15°C is much lower than after storage at −79°C. Nevertheless transfusion experiments were made to determine whether −15°C is a sufficiently low storage temperature to prevent those changes (presumably due to metabolic activity) which shorten the survival of the red cell after transfusion. The results show that red cells recovered after storage at −15°C for eighty days have an approximately normal survival in vivo.

METHODS

Storage of Blood

Pilot tubes obtained at a routine blood collection of the National Blood Transfusion Service were tested and bottles of group-A type-N blood selected. The bottles of blood had been stored for three or four days at + 4°C by the time they were selected. Before mixing with the glycerol solution, about 150 ml. of plasma was removed to prepare a concentrated suspension of red cells. The procedure for freezing and recovery of the red cells was exactly the same as that described by Mollison and Sloviter (1951), except that the red cells were stored at −79°C (solid carbon dioxide-alcohol) for periods up to eight months. As before, the red cells were transfused seven or eight days after thawing; this delay was due mainly to making sterility tests on the red-cell suspensions before transfusion.

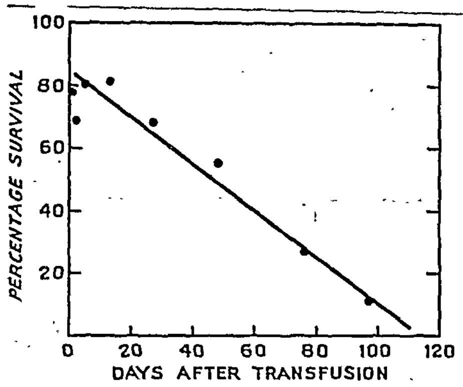

Fig. 1—Survival after transfusion of red cells stored at −79°C for three months and at +4°C for eleven days (case 1).

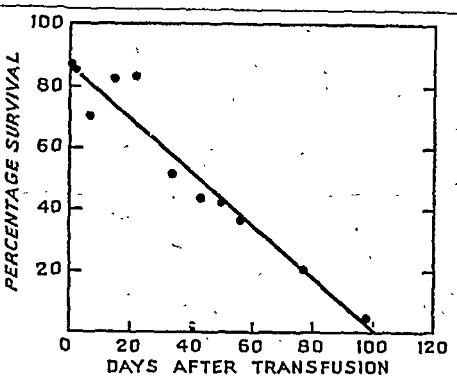

Fig. 2—Survival after transfusion of red cells stored at −79°C for six months and at +4°C for eleven days (case 2).

In further experiments blood was stored at −15°C. In these experiments the procedure was similar, except that the blood-glycerol mixture was simply placed in an ordinary deep freezing cabinet and in some instances solidified quite slowly (many hours). Thawing was carried out by placing the bottles in a water-bath at +37°C. Thereafter the procedure was the same as for blood stored at −79°C.

In the present work the volume of red cells frozen was determined by measuring the volume and hæmatocrit of the original suspension; and this was compared with the final volume of red cells recovered after freezing, thawing, dialysis, and washing. Thus the estimations of the percentage recovery of red cells include losses during dialysis and washing.

Control Blood

On the day of transfusion a donor of group O, type M, was obtained and blood was drawn into acid-citrate-dextrose about an hour before the time arranged for transfusion. A and B substance (Sharp & Dohme) was added in the proportion of 1 ml. to every 50 ml. of blood to reduce the anti-A activity of the donor plasma.

Choice of Recipients

Ten patients were transfused, each receiving both stored (previously frozen) and fresh (control) red cells. All the patients belonged to group A (Rh-positive) and were M-positive. All but one of the patients were women, and most of them had iron-deficiency anæmia connected with pregnancy.

Measurement of Survival of Transfused Red Cells

The concentration of surviving cells was estimated by differential agglutination, Dacie and Mollison's (1943) modification of Ashby's method being used. The method was further modified because of the rather small quantities of red cells transfused in some experiments. The modification consisted simply in using a more concentrated suspension of red cells, so that the final concentration of blood in the tests (after adding the agglutinating serum) was 1 in 42. For counts of O cells highly potent anti-A sera produced in rabbits were used; for counts of N cells anti-M powdered globulin (Lederle) was used (Ebert and Emerson 1946).

"Blank" (pre-transfusion) counts with anti-A serum were 4000–11,000 cells per c.mm. in nine cases, and 21,000 in the remaining case; with anti-M sera the blank counts were all between 2000 and 7000 cells per c.mm. On the day after transfusion the counts of previously frozen cells were 128,000–254,000 per c.mm. in eight cases, and 67,000 and 478,000 per c.mm. in the remaining two. *Counts of control cells were higher; 126,000–280,000* per c.mm. in five cases, and 408,000–862,000 per c.mm. in the remaining three.

For each population of transfused cells, estimates on the day after transfusion were based on counts of 4000 cells; most other estimates were based on counts of 2000 cells; but, when very few cells were left, only 1000 cells were counted.

The volume of cell suspension transfused was measured by weighing the bottle with its contents before and after transfusion and determining the specific gravity of the blood mixture. Any cell suspension left in the giving set was returned to the bottle before the final weighing.

The red-cell count of a well-mixed sample from each bottle was determined by counting not less than 4000 red cells. From these data the "expected" ratio of test cells to control cells was calculated—i.e., the ratio expected if the previously frozen and the freshly drawn red cells survived equally well. For convenience the ratios actually found have in each case been expressed as percentages of the expected ratio (see table I).

These "percentage survivals" express simply the survival of the stored cells relative to the control cells; thus, "100% survival" implies that the stored cells are surviving exactly as well as the control cells, and not that all the stored cells are surviving.

The absolute percentage survival was estimated in the following way. First, the concentration of test cells expected on the day after transfusion, if the test cells survived just as well as the control cells, was:

$$\text{Observed count of control cells, Day}_1 \times \frac{\text{No. of test cells transfused}}{\text{No. of control cells transfused}}$$

This figure was considered as 100% survival of the test cells, and the observed count of test cells on any day

TABLE I—PROTOCOL OF CASE 2

(The method of obtaining the figures in columns 4–8 is described in the text)

(1) Days after transfusion	(2) Test (prev. frozen) red cells (×10³ per c.mm.)	(3) Control (fresh) red cells (×10³ per c.mm.)	(4) Observed ratio: test/control	(5) Ratio observed/Ratio expected (%)	(6) % Survival of test cells (uncorrected)	(7) "Expected" counts of control cells (×10³ per c.mm.)	(8) "Absolute" survival of test cells (%)

119	3	—	—	—	—	—	—

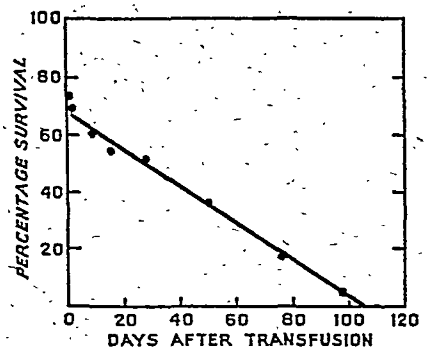

Fig. 3—Survival after transfusion of red cells stored at −79°C for six months and at +4°C for ten days (case 3).

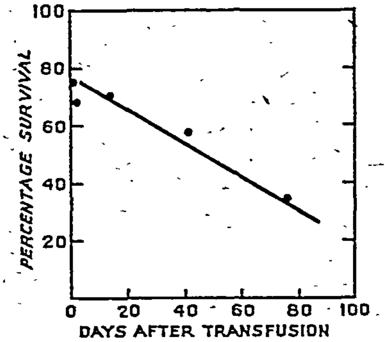

Fig. 4—Survival after transfusion of red cells stored at −79°C for six months and at +4°C for eleven days (case 4).

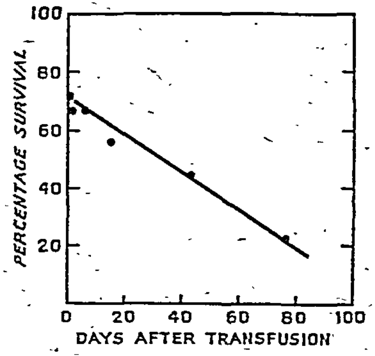

Fig. 5—Survival after transfusion of red cells stored at −79°C for six months and at +4°C for ten days (case 5).

(Day$_n$) could then be expressed as a percentage of this figure.

A correction for fluctuations of plasma volume was made by taking into account the difference on any day between the observed count of control cells and that expected if their number decreased by exactly $^1/_{110}$ a day. (All but one of the recipients were female: in the one male recipient a loss rate of $^1/_{120}$ a day was assumed.) The expected count of control cells on Day$_n$ is thus:

$$\text{Count of control cells, Day}_1 \times \frac{(110 - n)}{110}$$

where n = no. of days after transfusion

Thus an estimate of the absolute survival of the test cells on Day$_n$, as a percentage, is given by the formula:

$$\frac{\text{Observed count of test cells, Day}_n}{\text{Count of test cells equiv. to 100\% survival}} \times \frac{\text{Expected count of control cells, Day}_n}{\text{Observed count of control cells, Day}_n} \times 100$$

RESULTS

Clinical Observations

No febrile reactions were noted after the transfusions. One of the patients developed transient mild urticaria, but in the remainder no untoward effects were observed.

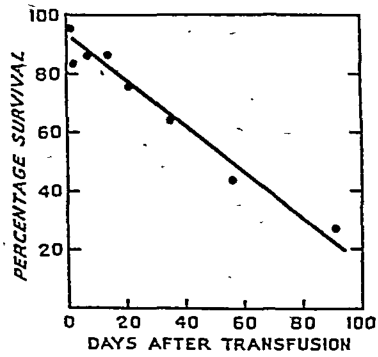

Fig. 6—Survival after transfusion of red cells stored at −15°C for seventy-seven days and at +4°C for ten days (case 9).

Loss of Red Cells during Storage and "Processing"

As previously reported, experiments with small quantities of red cells stored at −79°C have shown that the proportion of red cells recovered after thawing diminishes with time (Sloviter 1952a). In the present experiments with larger quantities of red cells the amount of red cells recovered after storage and processing was in most cases about 50% of the amount originally frozen. There were considerable variations between one batch and another. For example, in the present series the best yield (80%) was obtained from the blood which had been stored the longest time (eight to nine months). Hæmolysis is much greater after storage at −15°C than at −79°C. Thus after twenty-nine days at −15°C the yield was about 50%, and after eighty days about 20%. It must be emphasised that the data presented above relate only to recoveries of cells before transfusion and bear no relation to the results presented below, which deal with the survival in the circulation of those red cells which were transfused.

Survival of Red Cells in Vivo

To illustrate the method of calculation of results, the full protocol of a case is set out:

Case 2.—A man, aged 49, had severe hypochromic anæmia secondary to previous bleeding from gastric ulcer. Hb 6·4 g. per 100 ml. Blood group A, type M. Transfused with previously frozen red cells and with freshly drawn red cells.

Previously frozen red cells.—Group-A type-N blood drawn from donors on June 2, 1951; kept at + 4°C till June 5; then frozen and kept at − 79°C till Dec. 4; then thawed; cells recovered in the usual way and held at + 4°C till Dec. 12, 1951; then transfused. Amount transfused: 275 ml.; red-cell count 2,680,000 per c.mm.

Fresh red cells.—Group-O type-M blood drawn from donor one hour before transfusion; AB substance added. Amount transfused: 227 ml.; red-cell count 3,110,000 per c.mm.

Expected ratio of surviving cells:

$$\frac{\text{No. of test cells transfused}}{\text{No. of control cells transfused}} = \frac{275 \times 2{\cdot}68}{227 \times 3{\cdot}11} = 1{\cdot}044$$

Blank counts.—Before transfusion, when a suspension of the patient's red cells was mixed with an anti-A serum, all but 4000 red cells per c.mm. were agglutinated; with an anti-M serum all but 2000 red cells per c.mm. were agglutinated. These "blank" counts have been subtracted from the results which follow.

Ratio found, Day$_1$ (see column 4, table I):

$$\frac{\text{Count of test cells, Day}_1}{\text{Count of control cells, Day}_1} = \frac{123{,}000}{136{,}000} = 0{\cdot}91$$

Relative percentage survival, Day$_1$ (see column 5, table I):

$$\frac{\text{Ratio found, Day}_1}{\text{Ratio expected}} = \frac{0{\cdot}91}{1{\cdot}044} \times 100 = 87\%$$

Count of test cells expected on Day$_1$, if 100% survived:

$$\text{Count of control cells, Day}_1 \times \text{“Expected ratio”} \left(\text{i.e., } \frac{\text{No. of test cells transfused}}{\text{No. of control cells transfused}}\right)$$

i.e., 136,000 × 1·044 = 142,000 per c.mm.

Absolute survival of test cells, Day$_{50}$, uncorrected (see column 6, table I):

$$\frac{\text{Observed count of test cells, Day}_{50}}{\text{Expected count of test cells, Day}_1} = \frac{60{,}000}{142{,}000} = 42\%$$

Expected count of control cells, Day$_{50}$ (see column 7, table I):

$$\text{Count of control cells, Day}_1 \times \frac{120-50}{120} = 136{,}000 \times \frac{70}{120} = 79{,}000$$

Absolute survival of test cells, Day$_{50}$, corrected (see column 8, table I):

$$\text{Observed survival test cells, Day}_{50} \times \frac{\text{Exp. count control cells, Day}_{50}}{\text{Obs. count control cells, Day}_{50}}$$

$$= 42 \times \frac{79{,}000}{67{,}000} = 50\%$$

Further results are set out in table II and figs. 1–6.

To consider first the post-transfusion survival of red cells stored at −79°C relative to the survival of the

TABLE II—SURVIVAL OF PREVIOUSLY FROZEN RED CELLS AT VARIOUS TIMES AFTER TRANSFUSION, EXPRESSED AS A PERCENTAGE OF THE SURVIVAL OF A CONTROL POPULATION OF FRESHLY DRAWN RED CELLS

(No allowance has been made for the fact that the test cells were stored for 11 days at + 4°C whereas the control cells were freshly drawn; the values in this table should be increased by approximately 10% to allow for this)

* Definite evidence of survival but number of cells too small for accurate estimation of ratio.

control red cells (see table II): immediately after transfusion survival was 78–93%, mean 87%; at twenty-four hours it was 72–92%, mean 79%; in six out of seven cases there was a slight further fall at forty-eight hours, with a mean survival of 76%. Thereafter there was no tendency to fall any further—i.e., the test cells were removed from the circulation at about the same rate as the control cells. In one exceptional case (case 7) both test and control cells were eliminated within sixty days of transfusion (see below).

In the three cases in which blood stored at −15°C was transfused the results were similar to those in blood stored at −79°C (table II). Survival fell from 96% immediately after transfusion to 82% at twenty-four hours, and to 77% at forty-eight hours. Thereafter there was no increased loss of previously frozen red cells relative to that of fresh red cells.

Estimates of the absolute survival of the stored cells in cases 1–5 and 9 are plotted in figs. 1–6. The method of correcting the observed values to obtain estimates for "absolute survival" has already been described. It will be seen that the estimates from forty-eight hours onwards fit straight lines cutting the time axis at about a hundred and ten days after transfusion.

In the one exceptional case (case 7) referred to above, the number of previously frozen red cells fell rather rapidly after about the first week, with the result that at fourteen days the percentage survival was much lower than that of the control. However, the next blood sample taken from the recipient, forty-two days after transfusion, showed that the fresh red cells were also disappearing rapidly; the survival of the previously frozen red cells was now nil, and that of the fresh red cells, relative to their initial concentration, was less than 10%. A sample taken two months after transfusion contained no transfused cells at all. It was now apparent that the abnormality lay in the recipient rather than in the donor, and that the case was very like those described by Loutit et al. (1943), of which some further details were given by Mollison (1951). It is not proposed to discuss the matter further at present, except to say that it seems clear that the rapid disappearance of the red cells in this case was not due to any effects of storage.

DISCUSSION

The post-transfusion survival of the previously frozen red cells is expected to be lower than that of the fresh red cells because the frozen red cells were stored for ten or eleven days at + 4°C in addition to the period of storage in the frozen state. From previous work it may be estimated that the red cells of blood stored in *acid-citrate-dextrose* for ten or eleven days have about a 90% survival at twenty-four hours after transfusion (Gibson et al. 1947, Ross et al. 1947, Mollison and Sloviter 1951).

Another factor which would tend to make the survival values for the previously frozen cells low was the presence of an appreciable number of "ghosts" in the suspension of red cells transfused. These ghosts are not completely removed during the washing of the recovered cells after dialysis. In the present work, in determining the number of previously frozen red cells in the suspension prepared for transfusion, all red cells were counted even when they were ghost-like. It was estimated that less than 5% of the cells were ghosts.

When allowance is made for these two factors (eleven days' storage at + 4°C and the presence of ghosts), it is evident that the expected survival of the previously frozen red cells is about 85%, *if storage in the frozen state* has had no deleterious effect on the cells. The survival of the frozen cells at forty-eight hours after transfusion was in fact 70–90%. It seems therefore that very little, if any, irreversible change takes place during storage at −79°C in those cells which escape lysis. There is good reason to believe that the lysis which occurs during storage and processing is due to physical rather than biochemical processes. Biochemical activity at −79°C is expected to be negligible; and this belief is supported by the observation that those previously frozen red cells which are present in the circulation forty-eight hours after transfusion are capable of a normal life-span. As figs. 1–6 show, the estimates from forty-eight hours onwards, when plotted against time, fall on straight lines cutting the time axis at about a hundred and ten days.

The *advantage of comparing* the survival of one population of red cells with another is well illustrated by case 2 (table I). During the first twenty-two days after transfusion there was no apparent decrease in the survival of either population, owing presumably to shrinkage of the recipient's plasma volume. Confidence in the validity of the results is greatly increased by showing that the survival of one population relative to the other remained constant both during this period and during the subsequent period when the *concentration* of both populations started to diminish. In the present series it was particularly important to have a control population of red cells, since many of the recipients were recently delivered women in whom considerable changes of plasma volume were to be expected. The advantages of a control population are further illustrated by case 7: in this case the bad survival of the previously frozen red cells might have been ascribed to damage during freezing, had it not been possible to show that the same recipient rapidly destroyed fresh red cells.

It is a very interesting feature of the results obtained with red cells stored at −15°C that, although relatively few red cells were recovered after storage, these were capable of a normal life-span. Evidently, if appreciable ageing of the red cells took place at −15°C, cells recovered after storage for eighty days would be expected to be incapable of surviving for as long as a hundred days after transfusion. In fact, as clearly illustrated in fig. 6, those cells which are present in the recipient's circulation twenty-four hours after transfusion disappear at a rate indistinguishable from that of fresh red cells.

Practical Value of Storing Red Cells in Frozen State

At present there are two main obstacles to be overcome before storage of red cells in the frozen state can be of practical value in the field of blood-transfusion. First, a simpler and less time-consuming method for the removal of glycerol from the red cells must be devised, because the technique used in these studies is too cumbersome for general use. The process recently described by Lovelock (1952) may be the answer to this problem. Secondly, a higher recovery of red cells after storage at −79°C must be attained before the expense of storage at this low temperature can be justified. At present, after storage at −79°C for several months the recovery may be as low as 50%, and is even lower after storage at −15°C. However, recent work suggests that it may be possible to improve these yields considerably (Chaplin 1952).

The most important conclusion from the present work is that red cells recovered after storage at low temperatures have a normal post-transfusion survival. Therefore, if the number of cells destroyed by physical processes can be reduced, it may become worth while to store red cells in the frozen state for long periods.

SUMMARY

Human red cells stored in 15% glycerol at −79°C for six months are capable of normal survival after transfusion. When they are stored at −15°C for about eighty days, only a small proportion of the red cells can be recovered after thawing; however, these also have a normal post-transfusion survival. The implications of these observations are discussed.

It is a pleasure to thank Sir Charles Harington, F.R.S., and the Medical Research Council for hospitality to one of us (H. A. S.) at the National Institute for Medical Research; Mr. A. S. Parkes, SC.D., F.R.S., for his continued interest and advice; and Dr. A. A. Miles for his generous help on the bacteriological aspects of the present work. Prof. J. McC. Browne kindly allowed us to make observations upon patients in the department of obstetrics, Hammersmith Hospital, and Dr. J. D. James, director of the North London Blood Supply Depot, again arranged for a supply of suitable donors. We are very grateful to Miss Hal Crawford, B.SC., and Miss Marie Cutbush, B.SC., for much help, particularly in doing a great many of the Ashby counts; and to Miss Rita Lyons for skilful assistance in the freezing and processing of the blood.

"The Long Vacation is becoming in Cambridge an increasingly busy academic period, so much so that it is popularly, and quite improperly, known as the 'Long Vac. Term.' . . . it is a bad organisation of studies which would turn vacation into term; and it presses hardly upon that hard-pressed creature, the teaching don. It is a vivacious myth, that a don has leisure. He has not—the 'older model' don at least, who actually taught as well as studied and who was a characteristic of the older English universities. The chief importance of the Long was that it made possible his way of life. That it should continue to be possible is vital, for it will be catastrophic if the University is broken up into castes of persons who teach, who research and who administer, each of them exclusively."—*Manchester Guardian*, Sept. 3, 1952, p. 4.

OBSERVER ERROR IN THE INTERPRETATION OF CHEST FILMS*

AN INTERNATIONAL INVESTIGATION

A. L. COCHRANE
M.B. Camb., D.P.H.

L. H. GARLAND
M.D.

From the Pneumoconiosis Research Unit of the Medical Research Council, Llandough Hospital, near Cardiff; and Stanford University, U.S.A.

DURING the last five years there has been an increasing interest in methods of measuring, and if possible reducing, the effect of observer error in fields where its existence had previously been ignored. In particular this is true of medicine, although only in the radiological diagnosis of pulmonary tuberculosis, on miniature and on full-sized chest films, has a detailed investigation been made, and this has been done almost exclusively in the United States. It was clearly shown that radiologists and chest physicians, however well trained, show a considerable inter-observer and intra-observer error (Birkelo et al. 1947, Garland 1949, Yerushalmy et al. 1950). As a result, techniques for reducing these errors were found. It is surprising that this work has evoked so little attention in Great Britain. Recent figures suggest that in British mass miniature radiography the observer error should be studied and techniques for its reduction applied (Stewart and Hughes 1951).

In the measurement of observer error in the diagnosis of other respiratory diseases in chest films the British have been the pioneers. Fletcher and Oldham (1949) have noted how physicians varied in their interpretation of coalminers' films. This naturally led the film readers in the Pneumoconiosis Research Unit to treat their diagnosis of tuberculosis with some suspicion. The American work gave additional cause for anxiety, and it was decided, as a preliminary step, to find out how British observer error compared with the American by reading a short series of films which contained an unknown proportion showing reinfection-type tuberculosis. The British readers had every reason to fear the comparison with their American colleagues, and they were therefore pleasantly surprised to find that their errors were rather less than those published in the United States (Cochrane 1951). It was thought that this might be because the films were easier to interpret than those used by the Americans. Later, it was possible for the British films to be read by some of the American investigators.

TABLE Ia—AMERICAN READERS; DISTRIBUTION OF FILMS ACCORDING TO TUBERCULOSIS CLASSIFICATION

The original set of films was not selected with an exhaustive study in view. A short trial was prepared with the simple objective of comparing directly British and American observer error, and in this it was successful. This paper is presented as a report of these findings.

MATERIAL AND TECHNIQUE

The films used for the trials were 14 × 17 in. survey chest films, taken by a mobile unit on a radiography survey, which were very generously put at our disposal by Dr. Norman Tattersall, then medical director of the Welsh National Memorial Association. We asked Dr. Tattersall to provide about 100 chest films of good technical quality, of which between 5 and 30 should show some sign of reinfection-type tuberculosis. From these, 89 films were selected by another doctor, who did not take part in the trial, as technically adequate, and as containing a suitable proportion of films showing minimal disease. Six readers (see Appendix A) then indicated their interpretation on a prepared form (see Appendix B) so arranged that a *comparison* would be possible of the relative reproducibility of classifications based on the diagnosis of "active" tuberculosis and of "clinically significant"† tuberculosis. Readings were made on two separate occasions and were strictly supervised. The films were then mailed to San Francisco, where three members of the Chest [illegible] arch Committee read the films under [illegible]. Both sets of results were analysed in San Francisco and at the Pneumoconiosis Research Unit; the analyses were then exchanged, and agreement was reached on the basic conclusions.

TABLE IIa—AMERICAN READERS; AVERAGE AND RANGE OF "AGREEMENT" AND "DISAGREEMENT" (SEE TEXT) IN PRESENCE OF TUBERCULOSIS

—	Agreement on presence of tuberculosis	Agreement on absence of tuberculosis	Disagreement	Disagreement as % of all films	Disagreement as % of films called positive at least once
Between pairs of readers (inter-individual)	26·7 (24–32)	50·3 (50–51)	12·0 (6–15)	13·5 (6·7–16·9)	31·0 (15·8–38·5)
Between readings of individuals (intra-individual)	29·7 (27–31)	54·7 (52–58)	4·7 (4–6)	5·2 (4·5–6·7)	13·6 (11·4–16·2)

*Contact between the two groups was made when Dr. C. M. Fletcher, director of the Pneumoconiosis Research Unit, visited San Francisco in March, 1950, and Dr. L. H. Garland, chairman of the Chest Radiological Research Committee, visited the research unit in Cardiff in August, 1950. It became clear, in retrospect of course, that contact would have been more valuable before the readings than after. For instance, the Americans interpreted the phrase "*clinically significant*" differently from the British, and this would have been avoided by previous discussion.

ANALYSIS

A convenient way of measuring disagreement is to take each pair of readers in turn and to enumerate the films on which they agreed and disagreed. The number of films on which there was disagreement, averaged over all possible pairs of readers (15 if there are six readers), may be called the mean disagreement of the group, and it can be expressed as a percentage of either the total number of films or the total of films that were called positive by at least one reader.

Intra-individual disagreement is measured similarly by classifying the pairs of readings by each reader into agreements and disagreements, averaging the disagreements over all the readers, and expressing the results as a percentage of either the total number of films or the total number of films called positive at least once. Evaluation of disagreements in assessment of activity is made in an identical manner. Tables Ia, IIa, and IIIa show the results for the American readers, and tables Ib, IIb, and IIIb for the British readers.

TABLE IIb—BRITISH READERS; AVERAGE AND RANGE OF "AGREEMENT" AND "DISAGREEMENT" (SEE TEXT) ON PRESENCE OF TUBERCULOSIS

—	Agreement on presence of tuberculosis	Agreement on absence of tuberculosis	Disagreement	Disagreement as % of all films	Disagreement as % of films called positive at least once
Between pairs of readers (inter-individual)	22·7 (21–27)	59·4 (53–66)	6·9 (2–13)	7·7 (2·2–14·6)	23·2 (8·7–38·2)
Between readings of individuals (intra-individual)	24·5 (21–27)	60·7 55–68)	3·8 (0–8)	4·3 (0–9)	13·5 (0–22·9)

RESULTS

British readers called a smaller proportion of the films positive for tuberculosis than did the American readers, the mean being 26·4 positives for the British and 32·0 for the Americans (*tables* Ia and Ib). Similarly the British read "active tuberculosis" in 13·6 of films on the average, whereas the Americans placed an average of 20·7 films in this category. However, more "inactive but clinically significant" cases were reported by the British than by the Americans. The mean number of "negative for tuberculosis" cases found by the British readers was 62·6, compared with 57·0 by the Americans.

In conferences between representatives of the two groups, held first in San Francisco and subsequently in Cardiff, it became apparent that American readers tended to emphasise minimal abnormal shadows to a greater extent than did British readers. This may be due to the

---

† A film is classified as showing "clinically significant" tuberculosis if, in the opinion of the observer, the shadows in the film are such that he would recommend immediate medical action or that the subject should return for a second film in less than six months. Thus the definition can include films which would be classified as "inactive" in a simple "active/inactive" dichotomy.

TABLE IIIa—AMERICAN READERS; AVERAGE AND RANGE OF "AGREEMENT" AND "DISAGREEMENT" (SEE TEXT) ON ACTIVITY OF TUBERCULOSIS IN FILMS IN WHICH TUBERCULOSIS IS AGREED TO BE PRESENT

—	No. of films agreed to show tuberculosis	Agreement on activity of tuberculosis	Agreement on inactivity of tuberculosis	Disagreement	Disagreement as % of no. agreed to show tuberculosis	Gross disagreement; active tuberculosis v. tuberculosis absent
Between pairs of readers (inter-individual)	26·7 (24–32)	17·3 (16–20)	3·7 (1–7)	5·7 (5–7)	21·2 (15·6–29·2)	2·3 (1–5)
Between readings of individuals (intra-individual)	29·7 (27–31)	19·0 (17–23)	8·7 (7–12)	2·0 (1–3)	6·7 (3·2–11·1)	1·3 (1–2)

TABLE IIIb—BRITISH READERS; AVERAGE AND RANGE OF "AGREEMENT" AND "DISAGREEMENT" (SEE TEXT) ON ACTIVITY OF TUBERCULOSIS IN FILMS IN WHICH TUBERCULOSIS IS AGREED TO BE PRESENT

—	No. of films agreed to show tuberculosis	Agreement on activity of tuberculosis	Agreement on inactivity of tuberculosis	Disagreement	Disagreement as % of no. agreed to show tuberculosis	Gross disagreement; active tuberculosis v. tuberculosis absent
Between pairs of readers (inter-individual)	22·7 (21–27)	8·9 (3–17)	4·9 (2–10)	8·9 (4–15)	39·3 (17·4–71·4)	0·9 (0–2)
Between readings of individuals (intra-individual)	24·5 (21–27)	12·0 (4–18)	9·8 (5–15)	2·7 (1–5)	10·9 (4·2–22·7)	0·5 (0–1)

fact that the three American readers had previously conducted extensive studies on minimal pulmonary lesions and had become aware of the potential significance of very small and faint shadows, especially in surveys of groups, such as nurses and medical students. Conversely, in a comparable but unpublished joint study of some films of coalminers, the British readers would interpret certain minimal radiological changes as "category I pneumoconiosis," whereas the American readers tended to report such films as "negative—within normal limits." In this instance the British observers had been conducting extensive surveys on coalminers, and therefore were on the alert for minimal parenchymal alterations which may later develop into definite pneumonoconiosis.

The mean number of inter-individual disagreements on "tuberculosis present" for the British readers in their first set of readings was 7·7% of all the 89 films, or 23·2% of those films which were ever read as showing tuberculosis (table IIb). These figures are lower than those obtained from the American readings, which were 13·5% and 31·0% respectively (table IIa). The intra-individual comparisons, however, were about the same in both groups. The American readers showed inconsistency between their first and second readings on 5·2% of the films, on the average, and the British figure was 4·3%.

Inter-individual disagreement on activity (first readings only) was surprisingly low, but higher for the British readers than for the Americans (tables IIIa and *b*). The mean number of disagreements on activity was 8·9, or 39·3% of the films agreed to show tuberculosis, for the British, compared with 5·7 or 21·2% for the Americans. The inter-individual disagreements were also somewhat greater for the British, with a mean of 2·7 or 10·9%, compared with 2·0 or 6·7% for the Americans. There were fewer complete disagreements—i.e., one reader reporting "active tuberculosis" while the other reported "tuberculosis absent"—by the British readers; the average was 0·9 for such disagreements for pairs of readers and 0·5 comparing each reader with himself. The corresponding American figures were 2·3 and 1·3.

It is a point of interest for British readers that the observer error, when the films are classified on the one hand as "clinically significant" including "active" and "inactive, but clinically significant," and on the other hand as "inactive," is much less than when they are classified simply as "active" and "inactive." This does not hold for American readers, and the reason for this finding among the British readers is obscure; but, if it holds generally in Britain, the adoption of this method of classification might assist in introducing some order into the present chaos in the field of tuberculosis terminology, as well as helping to achieve consistent and

TABLE IV—ANALYSIS OF FILMS ON WHICH BRITISH AND AMERICAN READERS DISAGREED

Film no.	Readings during trial (1st and 2nd occasions)		Comments at joint conference*	Conclusion
	British readers	American readers		
1	12 tuberculosis negative†	3 tuberculosis negative; 3 tuberculosis positive, inactive	Questionable small scar at right first space, laterally (A), negative (B)	Understandable difference of opinion on significance of a small opacity; no major disagreement

5	6 tuberculosis negative; 3 tuberculosis positive, active; 2 tuberculosis positive, inactive but clinically significant; 1 tuberculosis positive, inactive, not clinically significant	4 tuberculosis negative; 1 tuberculosis positive, active; 1 tuberculosis positive, inactive	Faint opacity left first space, possibly active (A), possible lesion (B)	Difficult case with probable minimal lesion and inevitable difference of opinion among different observers; both groups of readers diverged; no significant international disagreement
6	9 tuberculosis negative; 2 tuberculosis positive, active; 1 tuberculosis positive, inactive, but clinically significant	1 tuberculosis negative; 2 tuberculosis positive; 2 tuberculosis positive, inactive, but clinically significant; 1 tuberculosis positive, inactive and not significant	Lesion, right second rib, dense and probably obsolete; adjacent lesion right second space, soft (active) (A); negative except for healed primary (B)	Difficult case with small soft lesion overshadowed by adjacent small dense one; subsequent review by independent British consultant reported "positive and significant"

* A, American; B, British. † That is, of 12 readings, all were recorded as negative.

reproducible diagnosis. A statistical argument in support of this conclusion is given in Appendix C.

In cross-comparison between British and American readers, first readings alone being used, it was found that of 52 cases called tuberculosis negative unanimously by the British, 42 were also called negative unanimously by the American readers, 6 were called tuberculosis positive by one American reader, and 4 were called tuberculosis positive by two American readers. The 6 films over which major disagreement was apparently occurring were subsequently studied at a joint conference at Cardiff, with the results outlined in table IV. In 5 cases there proved to be no major disagreement; in 1 case there was disagreement on the interpretation of a rather difficult lesion.

CONCLUSION

No considerable difference existed between American and British readers in the accuracy with which they read the films. The greater accuracy with which the series was read, compared with that found in earlier American trials, must have been due to the series as a whole being easier. On the whole it appears that the results of the more detailed American studies already published could be applied to the work of British readers. There is no doubt that the application of their findings would be entirely beneficial.

SUMMARY

Following American work on inter-observer and intra-observer errors in the radiological diagnosis of tuberculosis, a small-scale test of these errors was made by six British readers. Rather smaller errors were found than had been expected.

The films were then sent to a group of radiologists in the U.S.A. Their errors were of a similar magnitude to those of the British group.

The difference from previous results is most probably due to a rather easier group of films having been chosen, and it is concluded that observer error in the radiological diagnosis of tuberculosis should be reduced by application of the methods already fully developed in the United States.

We wish to thank the teams of readers who provided the data, and the statisticians who did the analyses, especially Mr. Oldham, who provided Appendix C.

Appendices

A.—COMPOSITION OF READER PANELS

The American group consisted of the following three radiologists:

L. H. Garland, M.D., clinical professor of radiology, Stanford University.

E. R. Miller, M.D., associate professor of radiology, University of California.

M. A. Sisson, M.D., clinical instructor in radiology, Stanford University.

The British group consisted of the following members:

L. R. West, M.D., M.R.C.P., consultant physician, Sully Hospital, South Wales.

K. J. Mann, M.D., M.R.C.P., D.P.H., member of the scientific staff of the Medical Research Council.

A. L. Cochrane, M.A., M.B., D.P.H., member of the scientific staff of the Medical Research Council.

V. H. Springett, M.D., Prophit scholar, Royal College of Physicians of London.

I. Davies, M.D., M.R.C.P., D.P.H., member of the scientific staff of the Medical Research Council.

T. W. Davies, B.SC., M.B., B.CH., D.P.H., consultant chest physician to South Wales Regional Hospital Board.

C.—RELATIVE MERITS OF DIFFERENT WAYS OF READING TUBERCULOSIS

P. D. Oldham
M.A. Oxfd
MEMBER OF PNEUMOCONIOSIS RESEARCH UNIT

In the trial whose results are reported here the readers were required to classify each film under one of the following headings:

A, tuberculosis absent.
B, tuberculosis present, active, and clinically significant.
C, tuberculosis present, inactive, but of clinical significance.
D, tuberculosis present, but inactive and of no clinical significance.

It is more customary to divide films into only two classes, but there is disagreement about where the dividing line is to be drawn. It usually lies between one or other pair of the headings given above, and systems that have been used are three:

(1) tuberculosis present or absent (A or B, C, D).
(2) tuberculosis active or inactive (B or A, C, D).
(3) clinically significant or not significant tuberculosis (B, C or A, D).

The results obtained from the British readers can be used to throw some light on the relative merits of these three systems.

By means of the technique known as analysis of variance, numerical results in a table with multiple headings can be analysed to show the significance of average differences between the different headings. In a table giving the results of multiple tests given to multiple observers the analysis could break down the total variance of the observations into sections corresponding to differences between the observers, differences between the tests, and a remainder. The ratios of the first and second of these to the third represent a measure of the success of the first and second headings in explaining the variation of results throughout the table. If we were to apply this technique to the results obtained from the British readers, our subdivisions of the variance would correspond to differences between the six observers and differences between the 89 films, with a remainder. A large ratio between the first and third could indicate a large inter-observer error, and a large ratio between the second and third, large differences between films. Clearly we would like the results to make the first ratio small and the second large.

The results actually obtained were of course not numbers but the classification referred to as A, B, C, and D above. We can nevertheless carry out the analysis of variance procedure in algebraic terms, the subdivisions of the variance emerging as quadratic expressions in A, B, C, and D. The three possible groupings to be examined can then be introduced by putting

(1) $A = x$, and $B = C = D = y$,
(2) $B = x$, and $A = C = D = y$, and
(3) $B = C = x$, and $A = D = y$.

The observer-error ratio and the film-difference ratio can then be calculated for each suggested grouping in turn, and these ratios will not contain x and y. Thus we may at once examine the merits of the different groupings as revealed by the size of the ratios. They are:

	System 1	2	3
Observer error	7·93	16·74	6·44
Film differences ..	56·50	22·04	65·80

It can be seen at once that system 2, corresponding to reading active tuberculosis only, is the worst. Systems 1 and 3 are very similar, but system 3 shows slightly smaller observer error and slightly better discrimination between different films. We may conclude that on the evidence of the British readings the best results would be obtained if films were classified on the basis of their clinical significance, though the system in which the criterion is the presence or absence of any kind of tuberculosis is almost equally good.

PRODUCTION OF HEPATITIS IN MICE BY THE COMBINED ACTION OF TWO FILTERABLE AGENTS

A. W. Gledhill
Ph.D. Camb., M.R.C.V.S.

G. W. A. Dick
M.D., B.Sc. Edin.

C. H. Andrewes
M.D. Lond., F.R.C.P., F.R.S.

From the National Institute for Medical Research, Mill Hill, London

A previous publication (Gledhill and Andrewes 1951) gave an account of the isolation from one strain of mice (P. mice) of a virus which caused fatal hepatitis in recently weaned mice of another strain, V.S. Rockefeller (Webster 1937). This mouse-hepatitis virus (M.H.V.) has been isolated from the blood and viscera of more than 50% of normal adult P. mice by 1–6 blind passes in just-weaned V.S. mice. Such passes were made at 7-day intervals with suspensions of liver and other viscera which were injected intraperitoneally. The disease in V.S. mice was prevented by aureomycin or terramycin when these were given not later than 48 hours after inoculation of the virus. Arising out of investigations into the action of terramycin in preventing mouse hepatitis, we made the rather bizarre discovery that the virus causing the disease could be resolved into two agents, each capable of being serially transmitted in susceptible mice. Either one alone rarely produced symptoms or lesions in the mice; yet together they gave rise to the typical disease. Mice infected either with the mixture or with the original M.H.V. died in 4–10—usually 5–7—days after infection when the dose was large. Their livers were necrotic, either uniformly yellow or, more often, strikingly mottled; their spleens were enlarged, the urine was dark, and there was sometimes visible jaundice. After smaller doses the liver damage might occur without death.

METHODS

The techniques used were similar to those described by Gledhill and Andrewes (1951) except that liver and spleen were used as the source of virus in place of liver and kidney. Suspensions and dilutions were made in 10% horse-serum broth with or without an equal volume of saline. The inoculum per mouse for all dilutions was 0·2 ml. given intraperitoneally. Terramycin (2 mg. per ml.) suspended in 5% gum acacia was given subcutaneously in a dose of 0·5 ml. V.S. mice weighing 8–10 g. were used for the experiments to be described.

RESULTS

Discovery of 'S.,' the Stable Component of M.H.V.

In our experiments with terramycin, we found that mice were protected by a single dose of the antibiotic given on the same day as a large dose of M.H.V. (more than 10^3 L.D.$_{50}$). Such a dose of terramycin had no effect when given 24 hours before the virus. It was next observed that mice treated with M.H.V. and terramycin on the same day became refractory to challenge with a large dose of M.H.V. 2 or more days later. In table I an experiment is recorded in which groups of mice were challenged with M.H.V. 1, 2, and 3 days after treatment with M.H.V. and terramycin on day 0; the controls of each group received terramycin only on day 0, followed by the challenge dose of M.H.V. 1, 2, and 3 days later respectively. It will be seen that mice show some refractoriness as early as 24 hours after the M.H.V.-terramycin treatment.

It appeared to us that the refractory state of the mice could possibly be induced by M.H.V. which had been rendered incapable of multiplying by the action of the terramycin. This possibility we showed to be improbable by the type of experiment (table II) in which groups of mice were challenged 8 days after receiving terramycin and falling tenfold dilutions of M.H.V. Since high dilutions of M.H.V. given on the same day as terramycin induced the refractory state, it seemed unlikely to be due to a non-multiplying agent. The rapidity of induction of the resistance suggested that we might be dealing with interference rather than with true immunity, and we therefore wondered whether an avirulent terramycin-resistant variant of M.H.V. could be interfering with the development of the fatal infection.

To test this possibility we killed, on the 5th day, mice which had received M.H.V. and terramycin, and passed liver-spleen extract to other mice, with a view to challenging them later. The unchallenged controls as well as the challenged mice developed hepatitis. When, however, we repeated the experiment giving five daily doses of terramycin, we harvested an extract which was not lethal to mice, yet which made them refractory to challenge 3 or 5 days later. We maintained the avirulent agent for five passes by treating daily with terramycin the pass mice injected with virus. This type of experiment was repeated a number of times with satisfactory results. In one such experiment in which five serial passages were carried out, the mice received a dose of 1 mg. terramycin on the third and again on the fourth day after injection with virus. At each passage another group of mice received virus but no terramycin; these mice were challenged as shown in table III. It will be seen that the mice which received extract and no terramycin at each pass and were challenged 3 and 5 days later mostly survived, whereas nearly all the controls of the challenge virus died. In some experiments the challenge controls received liver-spleen extract from normal V.S. mice, but such were not significantly protected against challenge. If, however, several passes of avirulent virus were made in mice untreated with terramycin, especially if these were made at 7-day intervals, virulent M.H.V. reappeared in some series. Nevertheless we had

TABLE I—PROTECTIVE EFFECT OF M.H.V. AND TERRAMYCIN AGAINST CHALLENGE WITH 1000 L.D.$_{50}$ OF VIRUS

Inoculum	Time of challenge (hours)	Mortality ratios
Terramycin	24	5/5*
	48	5/5
	72	6/6
Terramycin + 1000 L.D.$_{50}$ M.H.V.	24	6/8

TABLE III—RESULTS OF CHALLENGING MICE PREVIOUSLY INJECTED WITH TERRAMYCIN-RESISTANT VIRUS

No. of pass	Days between injection and challenge	Dilution of virus used to immunise	Mortality ratio	
			Challenged group	Control group
2	3	10^{0}	3/5	6/6
3	5	10^{0}	0/6	5/6*
4	5	10^{-2}	0/5	5/6

* 5/6 = death from hepatitis in 5 out of 6 mice.

passed an avirulent but immunising agent sufficiently often to feel moderately confident that our working hypothesis was correct in that we had a transmissible terramycin-resistant agent distinct from M.H.V. Later we found that an agent in no way distinguishable from this could be obtained much more conveniently by allowing M.H.V. tissue extracts to stand on the laboratory bench overnight at about 20°C. This we called "S." because of its relative stability on standing.

Discovery of "L.," the Labile Component of M.H.V.

One doubt remained: could the transmissible immunising agent consist after all of M.H.V. kept down by terramycin to a low level at which it could not produce disease? To test this possibility groups of mice were infected with virulent M.H.V. at dilutions higher than the lethal dilution and challenged several days later to see if they had become refractory; an example of such an experiment is shown in table IV. It was found that mice treated in this way not only did not become refractory but, when challenged several days later, died more quickly than controls. Thus, in table V, the challenged controls died in a mean of 5·9 days as against 4·4 days for the mice which received the double inoculation. The difference between these averages in this single experiment is statistically significant, owing to the small variability in the times of individual deaths. Amongst other experiments carried out when seeking an explanation of this finding, we injected mice which had received a sublethal dose of M.H.V., with S., the avirulent agent obtained from terramycin-treated mice. These mice died of M.H.V. hepatitis whereas the controls did not. Such an experiment is illustrated in table V. Experiments of this kind were successful whether the S. component was mixed with sublethal dilutions of M.H.V. or injected as long as 5 days later.

The high-titred labile component (L.) was obtained from M.H.V. without difficulty by passing at 3-day intervals M.H.V. diluted 10^{-5}, 10^{-6}, 10^{-7}, and 10^{-8} and finding the highest dilution producing hepatitis when mixed with the S. component; we hoped by this limiting dilution method to identify a preparation free from S. L. so obtained was propagated by passing it alternately undiluted and diluted 10^{-7} at 3-day and 4-day intervals.

Passage in Mice of S. and L. and their Recombination

Many of our earlier experiments gave inconclusive results because we could not guarantee that supposedly pure L. and S. would not kill a few mice. Thus in one such experiment 1 of 25 mice used in six serial passes of "L." died with hepatitis, and 5 of 30 mice died in the course of six serial passes of S.; by contrast, 27 of 27 died when L. and S. were recombined. More recently the method of passing L. twice weekly and diluting 1 : 10^{7} at every other pass has given us L. preparations which have killed none out of 46 mice in the course of twenty-two passes. If, however, such L. is passed at 7-day intervals in V.S. mice without any diluting, hepatitis due to M.H.V. has appeared, for by such a method S. can be picked up from V.S. mice and the virulent combination reconstituted. Similarly by a limiting dilution method we have now obtained from M.H.V. suspensions allowed to stand, an S. preparation which is perhaps pure as no specific deaths have occurred amongst 36 V.S. mice used in six passes. Deliberate recombination of these "pure" L. and S. lines produced fatal hepatitis in 100% of mice: this has occurred after five passes of pure S. and twenty-two passes of pure L.

TABLE IV—POTENTIATING EFFECT OF SUBLETHAL DOSES OF M.H.V. ON SUBSEQUENT CHALLENGE

Dilution of inoculum	Challenge L.D.$_{50}$	Mortality ratio	Average survival-time (days)
10^{-6}	Nil	1/10	6
10^{-6}	1000 (approx.)	10/10	4·4
None	1000 (approx.)	11/11	5·9

Properties of L. and S.

L. seems harmless even to newborn mice. S., on the other hand, will produce hepatitis, often fatal, in mice up to about 1 week of age. Passage from livers of these baby mice yields only S., not the complete M.H.V.

The filterability of L. and S. is still under investigation. S. has several times been passed through a gradocol membrane of 250 mμ average pore diameter (A.P.D.); on one occasion we failed to pass it through one of A.P.D. 110 mμ. L. seems to be somewhat larger; it has passed through a membrane of 350 mμ A.P.D. but failed to pass through one of 250 mμ A.P.D. M.H.V. itself was shown to pass through a membrane of 300 mμ A.P.D. but, like L., not through ones of 250 mμ A.P.D. (Gledhill and Andrewes 1951).

TABLE V—EFFECT OF S. UPON MICE PREVIOUSLY INFECTED WITH SMALL DOSES OF M.H.V.

1st intraperitoneal inoculation	2nd intraperitoneal inoculation 72 hr. later	Mortality ratio	Average survival-time (days) of mice which died
M.H.V. 10^{-6}	..	2/16	8·5
..	S	0/3	..
M.H.V. 10^{-6}	S	6/6	5·0

It is possible to measure the L.D.$_{50}$ of extracts of L. for a constant dose of S. and, likewise, the L.D.$_{50}$ of S. for a constant dose of L. This has been done on several occasions for L. (S. constant) and gave values of between 10^{-7} and 10^{-9} ml. as against 10^{-4} to 10^{-6} ml. for M.H.V. itself. The L.D.$_{50}$ of S. (L. constant) gave values of 10^{-3} to 10^{-4} ml.

L. and S. are both inactivated by heating to 56°C for 30 min.; and by treatment with 20% ethyl ether overnight at +2°C.

DISCUSSION

The experiments reported above are readily reproducible: their interpretation is far from clear. It is uncertain whether L. and S. are two unrelated viruses or whether they are alternative phases of one virus. A third, much less likely, possibility is that M.H.V. is a real entity, not merely a mixture of L. and S., and that L. and S. are variants of it. Our discovery that two components could be obtained from M.H.V. depended upon several fortunate chances, particularly the susceptibility of L. but not S. to terramycin. The demonstration that a virus can be so split may lead others to examine other virus infections from this point of view; if the possibility is not in mind, such a complex ætiology might long be overlooked. Plant pathologists are familiar with the idea that two relatively innocuous viruses may, when they co-exist in a plant, produce a serious disease: the infection of tomatoes by a combination of potato virus X and tobacco mosaic is an example (Bawden 1946).

It seems probable that L. is carried in the blood and tissues of a majority of P. but not V.S. mice. S. is probably carried by both breeds; but if it were present in only a small proportion of V.S. mice one could readily account for the varying number of blind passes necessary to produce hepatitis in the serial passage technique we have used (P.→V.S.→V.S. . . . &c.). Such a state of affairs would account for our failure to keep L. permanently pure and avirulent when passed in V.S. mice, except by the help of special precautions.

The production of hepatitis by inoculating blood of normal mice into other normal mice is an occurrence having obvious possible analogies with homologous-serum jaundice in man. M.H.V. is much more labile than the human virus, but the S. component is fairly stable, though even it does not resist 20% ether nor exposure to 56°C for half an hour: it is also a small virus, though its size has not yet been determined accurately.

The mechanism whereby these two agents act synergically to produce a fatal disease is still under investigation.

SUMMARY

Further work is reported concerning a virus causing fatal hepatitis in mice. This was obtained by taking blood or viscera or normal mice of one strain (P.) and making serial intraperitoneal passages in young mice of another strain (V.S.). The hepatitis could be prevented by a single dose of terramycin or aureomycin.

The mouse-hepatitis virus (M.H.V.) has now been resolved into two components, one relatively stable (S.) and one more labile (L.). S. is obtained from mice inoculated with M.H.V. and treated by terramycin, to which it is resistant; or by allowing suspensions of M.H.V. to stand at about 20°C for 24 hours; the L. then dies out. L. is present in M.H.V. suspensions to higher titre than S. and is obtained by passage at limiting dilutions. Neither L. nor S. when given separately to recently weaned V.S. mice produces any evident disease; when given together they cause fatal hepatitis. L. and S. are both transmissible in series and are presumably viruses—either separate entities or, less probably, phases or variants of one virus. S. is apparently smaller than L.

GUY'S HOSPITAL, LONDON

THE blood-iodine level was estimated as long ago as 1900, by Gley and Bourcet, and numerous techniques have been introduced for its measurement since then; but it is only within the past ten years that reliable methods have become available for clinical purposes. Practically all the work in this field has been done in America, and very little has been written about it in this country. The subject is fully reviewed by Rapport and Curtis (1950).

NATURE OF BLOOD-IODINE

The blood-iodine is predominantly bound to the plasma-proteins: 75% of it is present in the albumin fraction; some of it is found in the α-globulin fraction, and a smaller amount in the β-globulin fraction; but the γ-globulins play no part in binding iodine. The inorganic iodine content of the blood is usually negligible, but it varies considerably with the iodine content of the diet and is greatly increased by the administration of iodides (Bassett et al. 1941, Riggs et al. 1942, Taurog and Chaikoff 1948).

There is considerable evidence that the amount of protein-bound iodine in the serum is an index of the amount of circulating thyroxine, as shown by its chemical behaviour and by experiments with radioactive iodine (Chaikoff et al. 1947, Taurog and Chaikoff 1948).

MATERIAL AND METHODS

The series reported here consists of estimations of the level of protein-bound iodine in the serum of 30 normal people and 375 hospital patients. In 317 cases the basal metabolic rate (B.M.R.) was also estimated, and in 243 cases the serum-cholesterol level was determined.

The level of protein-bound iodine in the serum was estimated by the method of Barker (1948); 10 ml. of blood was collected at any convenient time of the day, with no particular time-relationship to meals. Barker's method is very sensitive and 0·01 µg. of iodine may be estimated relatively easily.

The apparatus was modified slightly by Mr. R. A. Adams who introduced a stoppered side-arm just below the condenser, so that sodium-sulphite solution could be introduced into the trap without disturbing the condenser. Our experience with the method agrees well with Barker's, but the following comments should be made: (1) our recoveries of iodine from thyroxine, added before digestion, were about 100% rather than 90%; we do not therefore make any correction for losses during distillation; and we believe that different stills vary slightly in efficiency; (2) The grade of sulphuric acid mentioned by Barker does not seem to be available in this country; in our experience the purity of this reagent is the most important factor in the attainment of low blank values; the most satisfactory grade that we have tried is the 'M.A.R.' grade of Messrs. Hopkins and Williams; this should be boiled with hydrochloric acid, as described by Barker, for at least two hours on the same day as the estimation is made.

The serum-cholesterol level was estimated by the method of Bloor (1916). In practically every case the levels of serum-cholesterol and protein-bound iodine were estimated on the same sample of blood.

The B.M.R. was determined by the method of Robertson (1944). A Kendrick apparatus was used. Estimations were made both on outpatients and on inpatients, and the subject rested for half an hour before each test. Two recordings of ten minutes each were made consecutively in all cases, a trial reading having been made on the preceding day in those cases in which the patient had not previously been tested. In most cases agreement between the two consecutive readings was within 5%. The B.M.R. was determined, so far as possible, on the same day as blood was taken for the estimations of cholesterol and protein-bound iodine, usually within a few days, and always within a week.

All the estimations of protein-bound iodine in the serum that were made in the past two years have been recorded here, except that we have only included those in which satisfactory duplicate readings were obtained, and that we have excluded cases of thyroid disorder in which previous treatment has prevented an adequate assessment of the thyroid state.

NORMAL RANGES

We obtained a range of 4–8 µg. per 100 ml. of serum for protein-bound iodine in 30 normal people, with a mean of 5 µg. per 100 ml. The duplicate determinations usually agreed to within 1 µg. per 100 ml., and the result was not accepted if they differed by more than this amount. Consequently the results have been expressed to the nearest microgramme, the decimal points being ignored. Most other workers have also found a normal range of about 4–8 µg. per 100 ml.

Though we found a range of 4–8 µg. per 100 ml. in normal healthy people, some patients who were clinically euthyroid showed levels as low as 3 µg. per 100 ml., and a few gave figures even lower than this. The lower level is therefore indefinite, and only figures of less than 3 µg. per 100 ml. can be regarded as abnormally low. On the other hand, the upper limit of normal in our series was remarkably well defined; any figure exceeding 8 µg. per 100 ml. could be regarded as significantly high.

The normal range of serum-cholesterol levels determined in our laboratories is 150–350 mg. per 100 ml. (Foote and Merivale 1949); a wider range than is usually recognised.

Our normal range for the B.M.R. is from 0 to −20%. The reason for this difference from the usually accepted range (from +10% to −10%) is probably that the Du Bois standards of height-weight-surface area and oxygen consumption per unit of surface area are calculated from American and not British people.

LIMITATIONS AND SOURCES OF ERROR IN DETERMINATION OF PROTEIN-BOUND IODINE IN SERUM

Administration of Iodine Compounds

The level of protein-bound iodine in the serum may be increased by iodine from various extraneous sources. If meticulous care is taken to exclude traces of iodine from the apparatus, the only important source of confusion is the previous administration of iodine to the patient. Small amounts of inorganic iodine should be eliminated from the serum by repeated and careful washings during the estimation. If large amounts of inorganic iodide are administered, iodine compounds are formed, which are apparently adsorbed on to the serum-proteins and increase the level of protein-bound iodine. This increase may persist for a week after the iodine therapy has been discontinued, and outlasts the rise in inorganic-iodide level in the serum; the thyroxine level is, however, not increased (Bassett et al. 1941, Salter 1947, Danowski and Greenman 1949, Danowski et al. 1950a and b, Starr et al. 1950).

The administration of organic iodine compounds is particularly likely to increase the amount of protein-bound iodine in the serum. This effect may persist for as long as three months or even a year after a cholecystogram (Riggs 1947, Starr et al. 1950), and for as long as five years, and even perhaps permanently, after the intrathecal injection of 'Lipiodol' (Hallman et al. 1951). The level of protein-bound iodine in the serum may also be raised after bronchography or salpingography, or after the injection of sinus tracts with lipiodol. Pyelography may have similar effects, but they are much more short-lived, since the iodine compound is rapidly excreted in the urine and disappears within 1–4 weeks (Riggs 1947, Starr et al. 1950, Hallman et al. 1951).

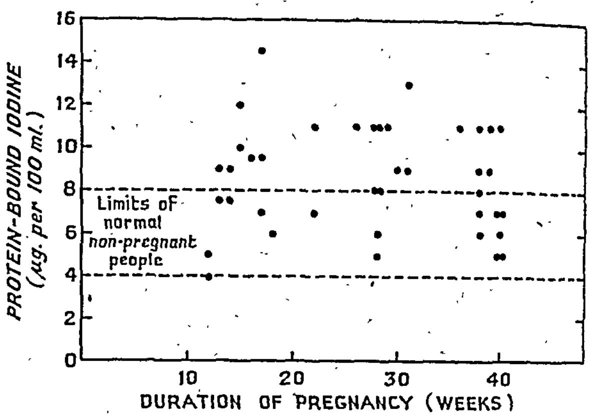

Fig. 1—Levels of protein-bound iodine in serum of 41 normal pregnant women.

Pregnancy

The protein-bound iodine in the serum was estimated in 41 healthy women with normal pregnancies. 22 (54%) of these showed levels exceeding 8 µg. per 100 ml. between the thirteenth and last weeks of pregnancy. The range of values was 4–20 (mean 8·8) µg. per 100 ml. (fig. 1). Similar findings have been made by other workers, who have found that the level may be raised as early as six weeks after conception (Man et al. 1951). It is interesting, in this connection, that the B.M.R. is also raised in normal pregnancy.

RESULTS

The values obtained for protein-bound iodine and cholesterol in the serum and for the B.M.R. in various disorders are recorded in the accompanying table and fig. 2.

Hyperthyroidism

The level of protein-bound iodine in the serum was raised in only 61% of the cases, whereas the B.M.R. was raised in all the cases. The serum-cholesterol level was reduced in only 11% of the cases. Each case was carefully assessed on clinical grounds (resting pulse-rate; tem-

perature and moisture of the skin; presence or absence of tremor, exophthalmos, or lid retraction; and response to treatment with iodine, thiouracil, or thyroidectomy) and, in surgical cases, by the histology of the thyroid gland. We have included in this group only those cases in which a diagnosis of the hyperthyroidism was established beyond doubt on the basis of these criteria.

In 2 cases with normal initial levels of protein-bound iodine the levels were found to be raised some weeks later, even though both patients had been treated with thiouracil during that period. It is likely that other cases would have shown similar fluctuations if repeated estimations had been made. Random estimations during anti-thyroid treatment gave varied results (fig. 3).

Non-toxic Goitre

The amount of protein-bound iodine in the serum was normal in 81% of the cases, the B.M.R. normal in 90% of the cases, and the serum-cholesterol level normal in 86% of the cases. Apart from the single raised value of protein-bound iodine included in the table, 2 other cases showed raised values attributable to the recent administration of iodine. The finding of levels below 3 µg. per 100 ml. in 8% of the cases is difficult to explain; none of these cases showed any other evidence of hypothyroidism.

Borderline Hypothyroidism

In many of the cases the amount of protein-bound iodine in the serum and the B.M.R. were not in agreement. The B.M.R. was estimated in 11 of the 12 cases with increased amounts of protein-bound iodine, and in only 6 of these was it increased; in only 5 of the 15 cases with a raised B.M.R. was the amount of protein-bound iodine in the serum increased. Since the B.M.R. was increased in all the cases of undoubted hyperthyroidism and was normal in 90% of the cases of non-toxic goitre, and since the amount of protein-bound iodine in the serum was increased in only 61% of the cases of proved hyperthyroidism and was normal in only 81% of the cases of non-toxic goitre, we place more reliance on the B.M.R. in the diagnosis of borderline cases.

Myxœdema

The level of protein-bound iodine in the serum and the B.M.R. was compatible with the diagnosis in all the cases, except one in which the level of protein-bound iodine was in the low normal range (3 µg. per 100 ml.). In another case two separate readings of 0 and 3 µg. per 100 ml. were obtained before treatment was started. The serum-cholesterol level was raised in only 56% of the cases. In another case, not included in the table, the amount of protein-bound iodine in the serum was 15 µg. per 100 ml. This patient had received several courses of thyroid extract in the past, but had had to discontinue the treatment each time after a week because she could not tolerate it. She had received no thyroid treatment since a year before the estimation was made; at that time she had been given crystalline thyroxine 0·2 mg. daily for eight weeks.

Panhypopituitarism

The level of protein-bound iodine in the serum was reduced in each of 3 classical cases of post-partum Simmonds's disease with clinical signs of hypothyroidism, in spite of the fact that 1 of them had been receiving gr. 1 of thyroid extract daily for eight years.

Acromegaly

The levels of protein-bound iodine in the serum were essentially normal in 5 of the 6 cases in spite of a slightly raised B.M.R. in 3 cases. In 1 case the level fluctuated in a most remarkable manner between 22 and 3 µg. per 100 ml. within a few weeks; the B.M.R. ranged between +11% and −4% during this period.

Other Endocrine Disorders

The level of protein-bound iodine in the serum was grossly reduced in 2 out of 12 cases of pituitary infantilism, but was normal in 2 cases of Cushing's syndrome, 1 case of Addison's disease, 2 cases of eunuchoidism, and 2 cases of ovarian agenesis.

Miscellaneous Disorders

The level of protein-bound iodine in the serum was reduced in 9 out of 50 patients with various skin disorders, including alopecia and keratosis pilaris. One of the

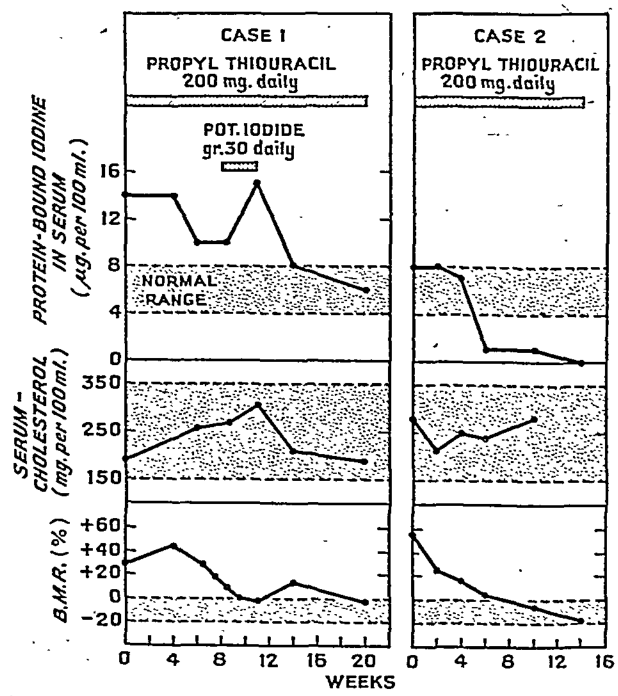

Fig. 3—B.M.R. and levels of protein-bound iodine and of cholesterol in serum in two cases of hyperthyroidism under treatment.

cases of keratosis pilaris was associated with myxœdema, but the other cases showed no evidence of hypothyroidism. Low values for protein-bound iodine were also obtained in 2 out of 52 cases of obesity and in 1 out of 5 cases of dystrophia myotonica. Raised levels were found in 6 other patients, 2 of whom had recently been treated with thyroid extract.

DISCUSSION

The table shows that the level of protein-bound iodine in the serum agrees with the clinical diagnosis less closely than does the B.M.R.: the over-all agreement is only 77% for protein-bound iodine, compared with 97% for the B.M.R. There is a considerable overlap between the values of protein-bound iodine obtained in euthyroid people and those obtained in patients with disorders of thyroid function. Though only about two-thirds of the patients with hyperthyroidism showed raised levels of protein-bound iodine, such raised levels as did occur were practically confined to hyperthyroidism or to pregnancy, or to patients to whom iodine-containing compounds had recently been administered. On the other hand, the level of protein-bound iodine was consistently subnormal in hypothyroidism and panhypopituitarism, though low values were also obtained in some euthyroid people with simple goitres and various non-endocrine disorders. This overlap severely limits the value of the estimation in the diagnosis of borderline cases; in our experience the B.M.R. is more helpful for this purpose.

Our findings therefore disagree with those of most American workers. Salter et al. (1941) found that the level of protein-bound iodine agreed with the clinical diagnosis in 98% of cases, whereas the B.M.R. agreed in only 71%. Riggs (1947) found the level of protein-bound iodine to be compatible with the clinical diagnosis in 85–89% of 325 cases. Winkler et al. (1946) and Salter et al. (1941) found it raised in 95% of cases of hyperthyroidism, and Hallman et al. (1951) in 100%. Starr et al. (1950) found it raised in 94% of cases of hyperthyroidism, but in a few cases they obtained values within the low normal range; in other conditions their findings were similar to ours, and, like us, they found some subnormal values in conditions other than hypothyroidism—e.g., diabetes mellitus, obesity, and heart-failure—in various psychoses, and in some elderly people.

We have found a rough correlation between the amount of protein-bound iodine in the serum and the B.M.R. at various levels of thyroid function, but when one set of values is plotted against the other the scatter is diffuse (fig. 4). Other workers have claimed a closer correlation than this (Salter et al. 1941, Bassett et al. 1941, Lowenstein et al. 1944, Winkler et al. 1946, Tucker and Keys 1951).

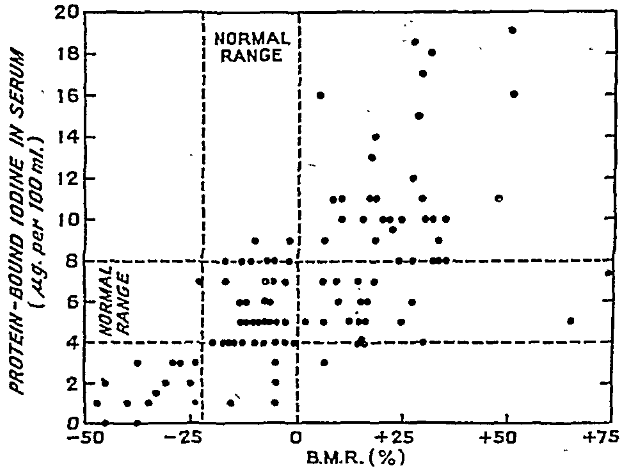

Fig. 4—Correlation of B.M.R. and levels of protein-bound iodine in serum in cases of hyperthyroidism, non-toxic goitre, and hypothyroidism.

There are three possible explanations of the poor correlation between the level of protein-bound iodine and the clinical thyroid state:

(1) It might be due to technical faults. We guarded against this by making duplicate determinations in all the cases, and by repeating the estimation if agreement was not within 1 μg. Moreover our normal range agreed closely with that of other workers, and very few raised levels were found in euthyroid people which could not be explained by previous administration of iodine or of thyroid extract.

(2) We have shown that the level of protein-bound iodine fluctuated in 2 cases of hyperthyroidism, 1 case of myxœdema, and 1 case of acromegaly. It is likely that this fluctuation occurs commonly, and that a single estimation may therefore not give a true reflection of the thyroid state. Since the metabolic response lags behind the changes in circulating thyroxine, fluctuations could occur without any change in the clinical picture. Starr et al. (1950) have shown that fluctuations occur in normal people as well, though these do not extend outside the normal range.

(3) Perhaps some patients will develop hyperthyroidism or hypothyroidism in response to levels of circulating thryoid hormone which would be regarded as normal in most people. Some cases of simple goitre have shown low levels of protein-bound iodine, and in such cases a rise of the level to within the normal range might well be followed by signs of hyperthyroidism. It is well known that endocrine function and dysfunction depend not only on the amount of hormone secreted but also on the response of the "target" organ or tissue.

We have not found the level of protein-bound iodine in the serum to be a reliable guide to treatment. The administration of iodine to patients with hyperthyroidism has tended to raise the level of protein-bound iodine still higher. Under treatment with thiouracil the level has in some cases fallen in parallel with the response of the clinical condition and the B.M.R., though in other cases it has preceded it. In 2 cases the level has actually risen during treatment. The level of protein-bound iodine may actually fall below the normal range without any clinical evidence of hypothyroidism (fig. 3). These findings are again at variance with those of other workers. Man et al. (1942) and Winkler et al. (1946) found that the administration of iodine to patients with hyperthyroidism reduced the level of protein-bound iodine, sometimes to within the normal range, thus reflecting the clinical response. Most workers have found that the fall in the level of protein-bound iodine during thiouracil therapy precedes the clinical response and fall in B.M.R. by some days or even weeks (Lowenstein et al. 1945, Engstrom et al. 1950, Hallman et al. 1951), and Engstrom et al. (1950) regarded a subnormal value of protein-bound iodine, at any stage, as an indication of over-treatment.

In the treatment of myxœdema we have found, as did Robertson and Kirkpatrick (1952), that the B.M.R. is a more accurate guide than the level of protein-bound iodine. The administration of thyroid extract may in itself increase the level of protein-bound iodine in patients who show no signs of over-treatment. A similar increase may follow the administration of thyroid extract to euthyroid people.

Perhaps the chief value of estimating the protein-bound iodine in the serum is in the diagnosis of thyroid disorders where determination of the B.M.R. is impracticable—e.g., in infants and young children, in elderly persons, in cardiac failure and chest disease, and in neurological and mental disease. It may also be helpful in distinguishing thyroid disorders from other conditions with a raised or lowered B.M.R.

There are two disadvantages of the estimation: (1) the technical difficulties are considerable, and it is essential that duplicate determinations should be made by two different people who are practising the technique constantly; and (2) the result may be vitiated by previous administration of iodine-containing compounds. Provided, however, that the latter can be excluded, and that the patient is not pregnant, a raised level of protein-bound iodine practically always indicates hyperthyroidism, though a normal level by no means excludes it. A low level does not necessarily indicate hypothyroidism, but a normal level virtually excludes it.

One could not do better than to sum up in the words of Means (1948):

> "Both the B.M.R. and blood-iodine tell something of thyroid function, but different things. The B.M.R. is an index of the total effect of the thyroid hormone on its end-organs. Its level would depend not only on the amount of hormone discharged, but also on the sensitivity of the end-organs. The protein-bound iodine of the blood merely represents the level of hormone in the blood, which is dependent on the rate of delivery of hormone to, and removal from, the blood. Collection of radioactive iodine is an index of the thyroid's hunger for iodine, which is probably related to its degree of stimulation. Therefore it is not a question of which of these measuring sticks is best. All are of value; the more of them which are used, the more understanding is to be derived from them."

SUMMARY

The levels of protein-bound iodine in the serum were estimated in 30 normal people and 475 hospital patients.

The normal range was 4–8 µg. per 100 ml.

Only 61% of the patients with proved hyperthyroidism showed levels above 8 µg. per 100 ml. With few exceptions, readings of more than 8 µg. per 100 ml. were confined to hyperthyroidism, pregnancy, or cases in which iodine had previously been administered.

The level was consistently reduced in myxœdema and panhypopituitarism, but some low values were obtained where there was no clinical evidence of hypothyroidism.

The B.M.R. was of more value in the diagnosis of thyroid disorders and in assessing the response to treatment.

The serum-cholesterol level was of little value in the diagnosis of hyperthyroidism; it was helpful, but less reliable than the level of protein-bound iodine, in the diagnosis of hypothyroidism.

It is technically difficult to estimate the level of protein-bound iodine in the serum, and the results are liable to be vitiated by previous administration of iodine compounds in any form.

Apparently the value may fluctuate between normal and abnormal levels.

The level of protein-bound iodine in the serum is merely an index of the amount of circulating thyroxine. The response to a given level of hormone apparently varies in different people.

The chief use of the estimation of the level of protein-bound iodine in the serum is in cases in which measurement of the B.M.R. is impracticable or subject to error.

In itself it is not a reliable index of thyroid function but, if used in conjunction with other tests and with sound clinical judgment, it may be of considerable value.

We are grateful to Dr. P. M. F. Bishop and Prof. R H. S. Thompson, in whose departments this work was done, for valuable advice; Mr. R. A. Adams for technical assistance in the estimations of protein-bound iodine; and Dr. W. H. H. Merivale and his technicians in the department of clinical pathology for the cholesterol estimations and for help with the B.M.R. estimations.

SOME EFFECTS OF LONG-CONTINUED CORTISONE THERAPY IN RHEUMATOID ARTHRITIS

H. F. WEST

M.D. Lond., M.R.C.P., D.T.M.

CONSULTING PHYSICIAN FOR RHEUMATIC DISEASES

G. R. NEWNS

M.B. Birm., M.R.C.P.

SENIOR REGISTRAR, RHEUMATISM UNIT

UNITED SHEFFIELD HOSPITALS

From the Sheffield Centre for the Investigation and Treatment of Rheumatic Diseases

OF six patients who began continuous cortisone-acetate therapy for rheumatoid arthritis twenty-one months ago, three are well, one is in a worse state than when she started treatment, and two are dead. We report here some revealing observations made on these patients. They do not necessarily detract from the value of cortisone acetate as a therapeutic agent.

THE SIX PATIENTS

The first three are females, aged 16, 22, and 36. They have received and still receive 50–75 mg. of cortisone acetate daily. The first remains well and fully active but has more joints affected now than at the beginning of treatment. The second maintains improvement but is still very thin and has little vitality. The third has so far responded very nearly perfectly. In all three cases the erythrocyte-sedimentation rates and hæmoglobin concentrations approached normal in the early weeks of treatment but have remained respectively above and below normal ever since. The menstrual function and feminine attributes have become and remained normal, suggesting that cortisone acetate, in the doses used, does not suppress adrenal functions which it cannot replace. This may only apply to women in the childbearing years. As so few have been treated in this way for $1^1/_2$ years this tentative conclusion may prove incorrect.

The fourth patient is a woman of 49 who is three years past the menopause.

In the early weeks of treatment an average dose of 50 mg. of cortisone acetate a day brought about really amazing improvement; but, as the months went by, larger doses became necessary. By the ninth month 150 mg. a day was barely sufficient to prevent the return of pain and swelling to all her peripheral joints.

On this high dose abnormal deposits of fat developed, and she became hypertensive (highest recorded blood-pressure 210/120 mm. Hg). Seven months on a lower dose averaging 75 mg. a day has led to the loss of much abnormal fat and the return of blood-pressure to normal, but the rheumatoid disease has increased, generalised stiffness and muscle weakness are pronounced, her knees are more painful and eroded, and her wrists and hands are constantly swollen and hot. Complications have included hæmorrhage from a duodenal ulcer necessitating blood-transfusion (fourth month), the appearance of severe hot flushes (controlled by œstrogen therapy), and at one stage the cortisone-withdrawal phenomenon—painful swollen joints that are eased by rest and made worse by use (rheumatoid symptoms in reverse). An unusual complication, associated with moon-face, has been the floating up of the lower denture.

This kind of response to high doses has been noted by some American physicians in postmenopausal women. In the present state of our knowledge it would be wise to avoid, for rheumatoid patients after the menopause, doses in excess of 75 mg. a day for more than a month. When worth-while control of the disease cannot be achieved with this restricted dosage, it would be best, theoretically, to change over to adrenocorticotropic hormone (A.C.T.H.) before tailing off the treatment. Such a change-over could not be completed for this patient, because she developed gross urticarial reactions to the injections. When A.C.T.H. is available free from carrier protein, this type of reaction may cease to occur.

The pathology of cortisone-withdrawal symptoms, other than those of adrenal insufficiency, has not yet been described. Perhaps some tissues become adapted to the changed environment caused by the prolonged administration of cortisone acetate and, as a consequence, manifest a new disorder when the hormone is withdrawn.

The fifth patient was a man aged 29.

His illness had begun three years previously as pericarditis and acute rheumatism, but this gradually changed to rheumatoid disease. His large joints were damaged, his feet deformed, and his hands practically useless. Six months before cortisone-acetate therapy began, a liver biopsy revealed no sign of amyloid disease.

After three months' therapy he was unwittingly given for three weeks an inactive preparation of A.C.T.H. During this time he became ill, jaundice appeared for a few days, and his liver enlarged rapidly. On the resumption of cortisone-acetate therapy he soon recovered, but his liver did not decrease in size appreciably. In the following nine months he received an average daily dose of 75 mg. At the end of a year's treatment he felt well and his rheumatoid disease was only mildly active, but his liver was enormous and he had little energy. His serum-protein levels were normal. Blood-counts showed leucocytes 20,000–30,000 per c.mm. (polymorphs 85%), hæmoglobin 12 g. per 100 ml.; and his bone-marrow showed an indeterminate picture. In the Congo-red test 99% of the dye was absorbed.

Shortly after this time he became ill suddenly. His blood-pressure fell from about 180/95 to about 80/40 mm. Hg, and he had transient abdominal pain, fever, and tachycardia. On the first day of this terminal illness his blood-electrolyte levels were normal. The dose of cortisone acetate was raised to 100 mg.; blood and, later, glucose saline solution were transfused and terramycin was given. His blood-pressure did not recover, and he died, with a falling heart-rate, on the fourth day, having passed during the four days only some 100 ml. of urine.

The liver weighed 6470 g. and about 95% of it was amyloid substance. The adrenal glands were replaced by amyloid substance save for a narrow rind of zona-glomerulosa cells. The spleen was moderately involved, but the kidneys only very slightly. Sections of the intestine, lung, heart, tongue, brain, thyroid, pituitary, and synovial membrane showed no amyloid deposit.

Many instances of amyloid disease associated with severe rheumatoid arthritis have been described; but as a gross manifestation it is rare. In the extensive literature of amyloid disease we have not found an instance of such an enormous deposition in the liver developing in so short a time. At least it may be said that in this case cortisone acetate did not retard the development of amyloid disease.

Some mice when fed, or given injections of, sodium caseinate develop amyloid disease (Smetana 1925). Our patient received calcium caseinate ('Casilan') daily for nine months. His intestines were not involved, whereas those of the mice were. Unlike man (Gallagher et al. 1951) mice excrete steroids into the intestinal tract (Dobriner 1952). This type of experimental amyloid disease is hastened by cortisone therapy, whereas ascorbic acid has the reverse effect, for in the guineapig a state of scurvy due to ascorbic-acid depletion leads to amyloid deposition (*Lancet* 1951). Our patient received 150 mg. of ascorbic acid daily throughout the cortisone-acetate therapy. One must remember, of course, that amyloid disease is not a definable entity. The name is applied to various states in which accumulations of unknown substances with similar crude staining properties are found between the formed elements of some connective tissues. In the more common secondary varieties the defect seems to belong to the organ affected rather than to the connective tissue. The little that is known of these protein substances and their small polysaccharide moieties suggests that they differ in various diseases and from species to species (Hass et al. 1943).

The terminal event for this patient did not resemble an addisonian crisis, nor was there any evidence of septicæmia. The abdominal pain may have been caused by a small peritoneal hæmorrhage which was found at necropsy. Patients with advanced amyloid disease do not usually die in this way. One is forced to relate his death, and the mode of his dying, in some way to cortisone-acetate therapy.

The sixth patient, a man of 48, had had rheumatoid arthritis for eleven years.

When treatment with cortisone acetate began he was "at the end of his tether." During twelve months' treatment he gained much benefit and was able to keep at work. After the first six months he developed, for the first time, symptoms of a duodenal ulcer. After a further six months the ulcer bled profusely. He responded normally to treatment but stopped taking cortisone acetate twenty-five days after the hæmorrhage. For the preceding six months the dose had been 25 mg. twice daily by mouth. On the thirtieth day, without premonitory symptoms of adrenal insufficiency, he fainted, recovered consciousness for a minute, vomited, and died. At necropsy the only macroscopical abnormality was the duodenal ulcer. It had been large but had healed. Microscopically the adrenal glands were normal; the thrombus in the vessel responsible for the hæmorrhage from the duodenal ulcer was organised and already partially recanalised; and the heart showed severe subendocardial and myocardial fibrosis.

The histologically normal adrenal cortex was a pleasant surprise.

Until more is known of the action of cortisone acetate and of the ætiology of peptic ulceration, it will be advisable to discontinue cortisone-acetate therapy when ulcer symptoms appear. The apparently normal clinical and histological recovery after the ulcer bled suggests that it is not essential to stop cortisone therapy abruptly in this circumstance. To lower the dose of cortisone at any crisis is, of course, unwise in theory. The question has arisen whether, in the presence of a bleeding ulcer, oral therapy should be changed to intramuscular. It was so changed in this case—for no valid reason. Our fourth patient had received only intramuscular cortisone acetate before her ulcer bled, and a year of oral therapy since has not provoked any further bleeding.

Was the fibrosis of the heart muscle sufficient to explain sudden death, or was the cessation of cortisone therapy a necessary adjunct? We do not think that the evidence justifies a conclusion but hope that this account may prompt others to relate their similar or dissimilar experience.

CONCLUSIONS

From these observations, in conjunction with those of other workers, it seems that for women in the child-bearing years, suffering from rheumatoid arthritis, cortisone acetate 50–75 mg. a day for periods up to twenty-one months does not upset normal function.

In women after the menopause 75 mg. of cortisone acetate a day should be the maximum for maintenance therapy.

The administration of cortisone acetate and a high-protein diet in the presence of amyloid disease should be avoided until more is known of their relation to this condition.

Intramuscular cortisone acetate 50 mg. daily does not prevent the healing of a bleeding duodenal ulcer (two cases only).

An average dose of 50 mg. a day of cortisone acetate continued for a year did not lead to any demonstrable abnormality in the adrenal cortex of a man aged 48.

Part of the cortisone used in this study was provided from a gift made jointly to the Medical Research Council and the Nuffield Trust by Messrs. Merck.

A NEW SYNTHETIC CURARISING AGENT

CLINICAL TRIAL OF COMPOUND 20 (LAUDOLISSIN)

R. I. Bodman
M.B. Brist., D.A.

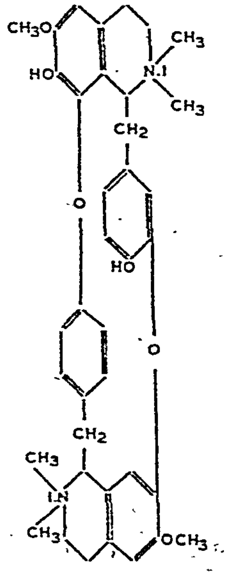
H. J. V. Morton
M.D. Camb., D.A.

ANÆSTHETISTS, HILLINGDON HOSPITAL, UXBRIDGE, MIDDLESEX

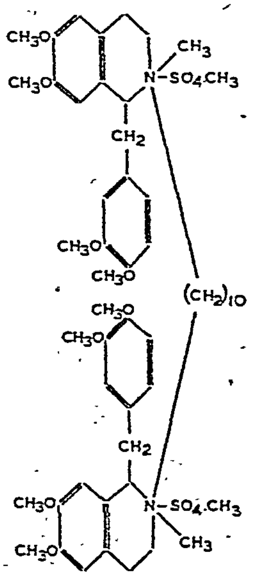
W. D. Wylie
M.B. Camb., M.R.C.P., D.A.

ANÆSTHETIST, ST. THOMAS'S HOSPITAL, LONDON

Taylor and Collier (1951), synthesising and investigating the muscle-relaxing properties of heterocyclic decamethylene *bis* quaternary ammonium compounds, produced one (Compound 20) which showed promise of being an effective substitute for *d*-tubocurarine in anæsthesia. This substance has been named 'Laudolissin.' Taylor (1952) described its chemistry, Collier and Macauley (1952) its pharmacology, and Bodman (1952) experiments with it in conscious volunteers. The structures of Compound 20 and *d*-tubocurarine are as follows:



d-Tubocurarine



Compound 20

Briefly, the workers cited above have established that Compound 20 is a true curarising agent, with a potency in man just half that of *d*-tubocurarine but with a duration of action slightly longer, and that it is antagonised by neostigmine.

Since no undesirable side-effects were detected during the work on volunteers, we decided to proceed with a trial in anæsthetised patients, and we record here our impressions of the clinical properties of Compound 20.

Compound 20 was substituted for the established relaxants in 186 procedures, as follows:

Operations	*No. of cases*
Partial gastrectomy	75
Cholecystectomy	14
Abdomino-perineal resection	6
Other major abdominal	47
Pneumonectomy	5
Valvulotomy	5
Other thoracotomies	9
Operations on the head and neck	10
Other major surgery	15
Total	186

Ninety-one patients were anæsthetised with nitrous oxide, with or without pethidine, and the remainder with cyclopropane. Induction was by thiopentone in all the cases.

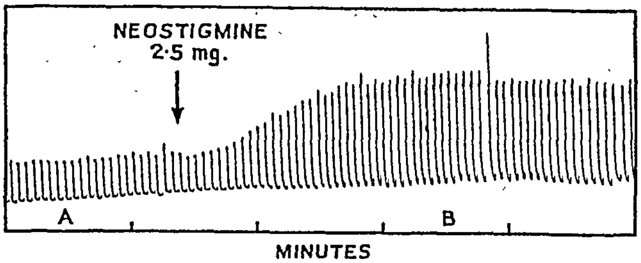
RESULTS

Muscle-relaxing Properties

In general the clinical impression gained has corroborated the experimental findings. A dose of 30 mg. of Compound 20 provided the same relaxation as 15 mg. of *d*-tubocurarine. But where the latter would have been expected to give adequate abdominal relaxation for thirty minutes, the relaxation with Compound 20 lasted forty minutes or more. Maximal abdominal relaxation was not evident until at least five minutes after the injection. The relative action on the abdominal muscles and the diaphragm seemed no different from that of *d*-tubocurarine. "Rectangular respiration" (Morton 1950) was often seen, and carried the same significance as when occurring with the established relaxant drugs.

Another aspect of a relaxant is its ability to paralyse the vocal cords. In a number of cases Compound 20 was given immediately after an initial dose of thiopentone, and intubation was attempted. In some cases relaxation of the cords was not obtained, even after several minutes and with doses which relaxed the abdominal muscles adequately. Conditions for intubating were certainly far less satisfactory than those obtainable with gallamine triethiodide. Consequently one inclined to the use of some other drug or technique for intubating, and reserved Compound 20 for maintaining surgical relaxation. A very satisfactory method was to use succinylcholine (with or without pethidine). Succinylcholine has a very short action, and does not seem to influence the effect of Compound 20 given after it; it has the additional advantage that the patient can breathe spontaneously while the preliminaries are being completed, before the surgeon actually starts the operation.

In experiments on animals Collier and Macauley (1952) demonstrated an antagonism between Compound 20 and succinylcholine, if given in that order: an appropriate dose of succinylcholine rapidly reversed the paralysis caused by Compound 20. With a larger dose a brief paralysis referable to the succinylcholine was followed by a rapid recovery from both drugs. We thus had reason to think that succinylcholine would be an ideal drug for producing additional relaxation for closure of the peritoneum. We have in fact used it with great success, in doses of 20–30 mg., on forty occasions after Compound 20, but as yet have been unable to obtain in anæsthetised patients a convincing demonstration of the antagonism seen in animals. On the other hand, we have seen no evidence of synergy between these two drugs, such as prolonged respiratory paralysis.



Effect of neostigmine on respiration of patient partially paralysed with Compound 20. Spirometer tracing, inspiration upwards. Tidal volume 300 ml. at A, 890 ml. at B.

In 13 cases we used ether for closure of the peritoneum, and it appeared to potentiate Compound 20.

There is no doubt about the antagonism in man between Compound 20 and neostigmine. The latter has been used on 35 occasions with satisfactory results. The accompanying figure illustrates such a case. But our present experience is insufficient for us to say whether this antagonism is greater or less than that between *d*-tubocurarine and neostigmine.

Side-effects and Incidental Properties

In 92 cases the pulse-rate and blood-pressure were recorded at five-minute intervals throughout the operation. In no case was there any change in either which could be attributed to Compound 20. In 3 cases electrocardiograms were made before, during, and after injection; they showed no change.

Of the signs which might be attributable to the release of histamine, bronchoconstriction was never evident, and no sudden or transient falls of blood-pressure were detected in association with the injection.

Experience with other relaxants led us to search for certain undesirable side-effects. Evidence of hæmolysis, such as hæmaturia and hæmoglobinuria, was not seen. The solution did not appear to irritate the vein, and there was no thrombosis or phlebitis. There was no action on the gut that could be seen by direct observation, and there was no ileus.

Compound 20 was not miscible with thiopentone, pethidine, or succinylcholine.

DISCUSSION

The properties of Compound 20 seem to be very similar to those of *d*-tubocurarine. So long as further trials with this drug confirm our findings, we think that Compound 20, of all the relaxants we have had occasion to use since their introduction into anæsthesia, could best take the place of *d*-tubocurarine for surgical relaxation.

The chief advantage of Compound 20 has not concerned us in this trial—it can be synthesised from materials readily available in this country.

SUMMARY

A clinical trial of a new muscle-relaxant has been described—Taylor and Collier's Compound 20, called laudolissin.

It has been used during general anæsthesia in 186 cases.

Its curarising properties are very similar to those of *d*-tubocurarine, except that its action lasts longer.

No important undesirable side-effects were detected.

Messrs. Allen Hanburys supplied the laudolissin used in this trial.

ADDENDUM

Since this paper was written Compound 20 has been used in a further 50 major procedures without incident.

SPONTANEOUS SEPARATION OF AN INTUSSUSCEPTION

FAUSET WELSH
M.B. Birm., F.R.C.S.
SURGEON, BIRMINGHAM UNITED HOSPITALS

SPONTANEOUS separation of an intussusception is described in the textbooks as a possibility, but it is rare. The case described here ran a subacute course after the onset, and the pathological processes were verified by recovery of the separated bowel and by laparotomy after the separation. The case was demonstrated at a meeting of the Midland Medical Society on Jan. 31, 1951, and three members at the meeting described other cases of spontaneous separation of an intussusception.

CASE-RECORD

An engineer, aged 74, of sturdy physique and vigorous habit, was taken ill on Sept. 4, 1948. He complained of upper abdominal pain while having his tea. Within a few minutes it became very severe, and he collapsed. He was found by Dr. C. Ramsdale shortly afterwards to be collapsed, grey, cold, with a clammy skin, almost pulseless, and with cyanosis of the lips, nose, ears, and fingers. His abdomen was soft and not tender, and no abnormality could be felt. Coronary thrombosis was provisionally diagnosed, and he was thought to be dying. Nikethamide and morphine were injected, and amyl-nitrite inhalations were given. After an hour he recovered sufficiently for Dr. Ramsdale to leave him.

On examination on Sept. 5 his circulation had fully recovered, but he was vomiting bile-stained fluid, and his abdomen was tense and distended, though not tender. He complained of vague pain in the lower abdomen. The diagnosis was altered to mesenteric thrombosis. I saw him that evening and agreed with this. The patient refused operation, and it was not strongly advised.

Progress.—During the next three days he remained distended, constipated, and vomiting. On one occasion the vomit had a fæcal smell. His temperature rose to 100°F on Sept. 6. On Sept. 10 he was transferred to hospital, and a good result was obtained from an enema. He continued to vomit bile-stained fluid. Dehydration was corrected with saline solution per rectum. I saw him again on Sept. 12 and found him very distended, and considered the possibility of a volvulus. A flatus tube was passed with a good result. His distension decreased, and vomiting became much less. He was walking about the ward after Sept. 24. Up to Oct. 2 he remained in hospital, and a gradual improvement took place, punctuated by occasional attacks of vomiting. Bowel action became regular, and he had a moderate appetite. Pain disappeared, and his abdomen remained slightly distended, but soft and not tender. The day after he went home he had a little diarrhœa, which continued with occasional vomiting. By Oct. 10 he had much improved, and did not vomit. On this day he had an excellent bowel action in the morning, and passed 2 ft. of macerated small intestine. Pathological examination of the gangrenous bowel which was passed showed a simple polypus. Next day vomiting of dark-stained fluid began again, and on Oct. 12 and 13 was profuse. He was now getting intestinal colic, and his abdomen was distended. On admission to hospital on Oct. 14 he was in fair condition, though rather sallow and dehydrated. His blood-pressure was 180/80 mm. Hg, temperature 98°F, and pulse-rate 80. A plain radiograph of the abdomen showed dilated coils of jejunum and ileum.

Operation.—At laparotomy on Oct. 15, distended gut was found. A volvulus of the jejunum was corrected, and the site of an obstruction was discovered 3 or 4 ft. proximal to the ileocæcal valve. At this point a stricture with surrounding adhesions was discovered. Side-to-side anastomosis was done.

Progress.—The patient made an uninterrupted recovery. He drove his own car to the meeting in January, 1951, where his case was demonstrated.

COMMENTS

In the ensuing discussion at the Midland Medical Society, Dr. H. W. Hickman reported that he had seen a young Indian vagrant who was operated on for ileocæcal intussusception which recurred after twenty-four hours. Conservative measures were adopted, and the patient passed the intussusception. A subsequent barium enema showed the appearances of an ileotransverse anastomosis.

Mr. K. O. Parsons reported a case of intussusception of the pelvic colon in a patient who presented with gangrenous bowel protruding from the anus. He had been previously diagnosed elsewhere as a case of prolapse. The patient passed the intussusception five weeks later. A barium enema showed no signs of the anastomotic level.

Mr. Wilfred Mills reported that he had been called to a patient in a mental hospital who was said to be "passing his uterus through his rectum." There was some reason for this description because the prolapsed bowel closely resembled a patulous cervix. Again this intussusception sloughed away, leaving a normally functioning bowel.

In children with intussusception, initial shock is well known, and recognised by quietness and pallor. In the present case in an adult, shock was disproportionate to the pathological condition present. An extreme degree of shock is not commonly seen in acute intestinal obstruction caused by strangulated hernia, or even by impaction of large gall-stones. Acute intestinal obstruction appears in this case not to have been complete until after the separation of the intussusception, when one would have expected recovery. It is possible that complete obstruction was caused by rapid cicatrisation at the site of separation, and was delayed by the presence of the bulky gangrenous mass.

One wonders if diagnosis could have been made in the early stages by barium contrast filling and X rays, but it is doubtful if operation would have been strongly urged even in the presence of an accurate diagnosis, because of the absence of complete obstruction. The total absence of blood from the stools at all times is noteworthy.

Reviews of Books

Eugenics: Galton and After

C. P. Blacker, M.C., G.M., M.A., M.D., F.R.C.P., general secretary, Eugenics Society. London: Duckworth. 1952. Pp. 349. 25*s*.

Dr. Blacker has combined a biography of Sir Francis Galton with a review of the development, after Galton's death in 1911, of the "science, practice and religion" of eugenics. In his description of the person and work of this remarkable cousin of Darwin, Dr. Blacker follows closely Karl Pearson's biography, and the first third of the book is a reliable account of the many interests of a highly gifted and well-connected Victorian gentleman. His account of developments since 1911 gives a better view of what Galton accomplished than can be found anywhere else, and sets it in a framework of modern views about genetics and eugenics. It would be a mistake, however, to regard the book as a detached and academic survey. It is written from a personal standpoint which many do not share. Since eugenics (and even genetics) offer such controversial themes this was inevitable, and the reader must allow for it. In addition, a fair amount of the controversy in this country on national intelligence and kindred issues is reported, and there are informative accounts of the demography of the peoples of the earth, of some recent general developments in genetics (but not in human genetics), and of methods of ascertainment.

The Scientific Paper

2nd ed. Sam F. Trelease, Columbia University. London: Baillière, Tindall, & Cox. 1951. Pp. 163. 20*s*.

Authors who worry about their manuscripts, and would gladly make them less of a burden to editors and more of a joy to readers, will be much helped by this little book. It deals with every aspect of collecting and presenting the results of scientific work: the use of the library, treatment of data, reliability and significance of measurements, the actual writing and the choice of headings, logical presentation, how to maintain interest, revision, typescript, correction, the estimation of length, good usages, tables, illustrations, the ways of editors, and proof-reading. Experienced writers will not find anything unfamiliar, but few books cover the problem so completely as this one. The introduction, Mr. Trelease says, should state the problem, describe its condition at the beginning of the study, tell the reasons for investigating it, and give the purpose, scope, and general method of the investigation. He also thinks it should state clearly and definitely the most significant result of the investigation; for this not only enables the reader to distinguish essential from non-essential evidence, but makes the writer face squarely at the outset what it is that he really wants to say—whether, indeed, he has anything to say. Like other advisers on scientific writing, he emphasises the need for numerous revisions. It is true that a revised manuscript is likely to be better than one which is "dashed off" and dispatched without revision, but there is a limit to the number of useful revisions: some much-revised papers show that their writers have grown sick of the sight of them and are no longer interested in correcting their faults. Before he begins to write, an author should plan his paper so that it conforms to the layout of the journal of his choice. He should then write with a two-inch margin and three spaces between the lines. He can do a great deal of correction on such a script without rendering it illegible to an intelligent typist. Two candid friends of good critical ability, knowledge of the subject, and experience of publishing papers should independently edit and freely comment on copies of the draft; and the author should weigh their observations, think his own second thoughts, and transfer the result to his correction copy. This should be retyped and sent to the editor. If writers would observe these sensible rules it is probable that the editorial staff of scientific journals would live much longer and look much younger than is usual for persons of this kind.

Atlas of Tumor Pathology

Fascicle 9. Rupert A. Willis, M.D., F.R.C.P., professor of pathology, University of Leeds. Pp. 58. 50 cents. Fascicle 16. Philip M. Le Compte, M.D., pathologist, Faulkner Hospital, Boston, Mass. Pp. 40. 45 cents. Fascicle 18. Hans G. Schlumberger, M.D., professor of pathology, Ohio State University. Pp. 88. 75 cents. Fascicle 29. Howard T. Karsner, M.D., medical research adviser, Bureau of Medicine and Surgery, United States Navy. Pp. 60. $1.00. Fascicle 34. Fred W. Stewart, M.D. Pp. 114. $1.10. Washington: Armed Forces Institute of Pathology. 1950 and 1951.

These helpful monographs are published at a reasonable price by the Armed Forces Institute of Pathology, under the auspices of the National Research Council, and are sponsored by various bodies, including the American Cancer Society and the National Cancer Institute of the United States Public Health Service. They form part of an atlas of tumour pathology, and the illustrations are very good though the subject matter is brief. They contain a surprising amount of information nevertheless, and contrive to survey prognosis and treatment into the bargain.

The fascicle by Prof. R. A. Willis is on teratomas, which he defines as neoplasms composed of multiple tissues foreign to the part in which they arise. He believes that they may represent areas of tissue which, during early embryonic development, escaped from the action of the primary organiser, and adduces evidence against the popular view that they are embryomas or distorted fœtuses, derived either from included twins of the bearers or from parthogenetic proliferation of the host's own germ cells.

Dr. Philip M. Le Compte writes on tumours of the carotid body and related structures. Since most carotid-body tumours are both clinically and histologically benign, he favours a diagnostic biopsy only. The surgeon who decides to operate should realise that "he has one chance in three of killing his patient and if the patient survives, about eight chances in ten of leaving him with some kind of temporary or permanent neurological disturbance." For tumours of the glomus jugulare, Le Compte recommends radical tympano-mastoidectomy when the diagnosis is established. He also gives brief accounts of tumours of the aortic bodies, and tumours arising in the *ganglion nodosum* of the vagus, and believes that there are probably two unverified instances of neoplasms arising in the paraganglion ciliare. Tumours of the chemoreceptor system are in general radio-resistant.

In his account of tumours of the mediastinum, Dr. Hans G. Schlumberger does not include an account of tumours of the thymus, œsophagus, heart, or pericardium; but he discusses the histogenesis of the many others met with in this situation, including those arising from misplaced organs. Every mediastinal tumour not known to be metastatic, he says, should be submitted to biopsy before it is irradiated; for this not only establishes the diagnosis but makes it possible to avoid those post-irradiational tissue changes which often increase the difficulty of surgical removal.

Dr. Howard T. Karsner, writing on tumours of the adrenal, includes an account of the tumour-like myelolipoma. He holds that a diagnosis of phæochromocytoma is not valid without a positive chromaffin reaction, because polygonal cells may be numerous in cortical adenoma while cells which resemble those of the cortex occur in phæochromocytoma.

The excellent section on tumours of the breast is written by Dr. Fred W. Stewart. Primary mammary cancer can occur, he says, in any postpubertal breast; in fact, with increasing experience a pathologist may employ the term "pre-cancerous" less and less. The youngest patient he had seen was twenty; the oldest were identical female twins over ninety years of age. Gross anatomy and the extent of disease, he holds, far outweigh in importance microscopical classification, although confirmation of the two may yield significant information. With involvement of the basal axillary group of nodes only, Dr. Stewart has found a 65% survival-rate at 5 years. If the midgroup are involved the survival-rate falls to 45%, while if the apical axillary nodes are affected the survival-rate is only 28%. The so-called medullary type of carcinoma with a lymphoid stroma has a better survival-rate than the average scirrhous cancer: in 5 years only 11·5% had died of their disease in the former group, as against 56% in the latter group.

Management of the Newborn

Arthur Hawley Parmelee, M.D., professor of pediatrics, University of Southern California. Chicago: Yearbook Publishers. 1952. Pp. 358. $7.

This excellent book on the newborn infant will be a welcome addition to the shelves of pædiatricians and obstetricians. Professor Parmelee has had intensive experience of the newborn for many years, and his approach is physiological and clinical. He is a keen and accurate observer, and he has produced a "story of the newborn" which is a pleasure to read. Fully half of the book deals with the normal infant, and the remainder is a comprehensive account of abnormalities and diseases of the newborn. The 83 illustrations are good, but such a valuable book is worthy of many more. It is a pity that American books are now so expensive in this country, but no-one who has regular care of the newborn can afford to be without this one.

Connective Tissues

Transactions of the Second Conference, May 24 and 25, 1951. Editor: Charles Ragan. New York: Josiah Macy, Jr., Foundation. 1952. Pp. 190. $3.50.

The second Josiah Macy conference on connective tissues has produced a volume even more interesting than the first; but when experts confer, new words and unfamiliar concepts, likely to be above the heads of some of us, are often taken for granted. Some small editorial explanatory notes in the present volume are therefore helpful, and more of them would be welcome in later books of the series.

Of the five main topics pain mechanisms in connective tissues, discussed by Travell, is the only one which represents the clinical approach. The other four are of more fundamental nature. Porter's valuable contribution on repair processes in connective tissue is illustrated by a series of beautiful electron micrographs showing the stages of collagen-fibre formation in relation to the cell-surfaces of chick embryo fibroblasts in tissue culture. Morrione deals with the regression of scar-tissue as seen in recovery from experimental cirrhosis of the liver, and advances several ideas which may bear on restoration of the normal state after fibrous-tissue healing in various other maladies, such as rheumatic heart-disease and nephrosclerosis. In discussing the chemical morphology of elastic fibres, Lansing is concerned with the chemistry of the individual fibres and the reasons for their spiral structure, which can be seen under both the light and electron microscopes. Gersh treats mainly of alterations in the appearance and staining reactions of ground substance in relation to the action of hormones or the mechanism of allergy, and also discusses its origin and fate.

Disease in Old Age

Robert T. Monroe, M.D. From the Medical Clinic of the Peter Brent Brigham Hospital and department of medicine, Harvard Medical School, Boston, Massachusetts. Boston: Harvard University Press. *London:* Oxford University Press. 1951. Pp. 407. 32*s.* 6*d.*

Dr. Monroe has made an elaborate analysis of the medical records of 7941 patients over the age of 61 who were admitted to hospital during the years 1913–43. The wealth of the clinical material he describes is impressive; though it would have been more useful if he had compared the incidence of disease in his patients and in those of lower age-groups. He points out that hospital management and practice must nowadays be adjusted to patients in the higher age-groups; for whereas, in 1913, 1 in every 16 patients admitted to hospital was over the age of 61, in 1943, 1 in every 5 patients admitted was of this age—an increase of 200% in 30 years. To those who hold that continued useful employment assists in the maintenance of physical and mental health, Dr. Monroe's figures are depressing, for 92% of men between the ages of 61 and 65 were in employment during the first decade under review, compared with 66% during the last. These figures help to confirm the trend which has been observed in surveys carried out both in this country and in the U.S.A. Dr. Monroe's views on the management of elderly patients are refreshingly humane, and he puts forward a sensible scheme for a comprehensive service for elderly persons, organised by the community, which would ensure an adequate supply of beds of various categories, linked with a central hospital. He emphasises the value of the geriatric clinic, and ends with a plea for an "age centre." This would include a supply of one- and two-roomed flats for about 400 people, where adequate medical and social services would be available.

Hospital Organisation and Management (4th ed. London: Faber & Faber. 1952. Pp. 1782. £8 8*s.*).—This standard work, first published in 1927, is now very portly. Captain J. E. Stone has amplified the facts and data gathered during many years of active work in the hospital field with numerous references to American experience, and to the changes brought about by the National Health Service Act. This has not been offset by sufficient compression and pruning. The appendices, too, which take up as much as 300 pages, could be shortened. Nevertheless this is a very good account of the development of the British hospital system, and of methods of hospital management. All departments of hospital organisation are covered, and the chapters on the law relating to hospitals could not be improved.

Applied Physiology (9th ed. London: Oxford University Press. 1952. Pp. 1190. 50*s.*).—The appearance of the new edition is as startling as that of an old friend who returns from a holiday with an unexpected moustache; but there can be no misgivings about Prof. Samson Wright's book. With the aid of Prof. Montague Maizels and Mr. J. B. Jepson, D.PHIL, he has rewritten more than half the text, and rearranged the presentation in drastic fashion. Though past readers may take time to find their way about again, they will readily agree that the new sequence of subjects is an improvement, starting as it does from "the outstanding generalization of physiology"—the constancy of the internal environment. Some 200 new illustrations have been added. What is virtually a new book will enjoy an even greater popularity.

THE LANCET

LONDON: SATURDAY, SEPT. 13, 1952

Family Size and Natural Selection

From time to time we should turn our attention from the triumphs of sanitary and medical science to consider the ultimate effects of these successes on the evolution of the human species. Bacteriologists and virologists are used to thinking of genetic constitution in terms of variation in the host's resistance and the parasite's virulence; and Sir Macfarlane Burnet, F.R.S.,[1] has sounded a salutary warning to those who think of human health purely in terms of environment. Applied microbiology, he notes, has overcome the high death-rate from infectious disease which has hitherto been a feature of urban civilisation; while the food-shortage that would otherwise have ensued has been largely prevented by deliberate restriction of the number of children.

> "Unfortunately this is not a satisfactory long-term solution of the problem that we have created by abolishing infective disease. If we ensure in general terms that each pair produces two children both of whom reach reproductive age and that the process continues indefinitely, we must inevitably come up against the problem of genetic deterioration. . . . The whole structure of the evolutionary process depends on the fact that mutation is constantly occurring and that only by a highly selective winnowing of the various gene-combinations that arise can evolutionary progress or even maintenance of quality occur. The vast majority of gene changes must of necessity be disadvantageous to the carrier. To maintain the normal character of the species every appearance of a deleterious mutation must be balanced by a 'genetic death.'"

The geneticist expects a constant tendency for the frequency and severity of a disease to return to a level at which the disadvantageous genes predisposing to the disease that are lost in each generation, from the relative infertility of those affected, will balance the new genes of this type appearing in each generation by mutation. Deterioration in environmental conditions will temporarily increase the mortality from the disease, but this fiercer selection will in time decrease the number of genes in the population predisposing to the disease until, without further change in the environment, mortality is brought back to the level which balances the constantly recurring new mutations. In the same way environmental improvement, such as a better method of treatment, will be followed by decreased mortality and accumulation of genes predisposing to the disease until once again the death-rate reaches the equilibrium level. Just how many deaths from diphtheria, for example, represent the equilibrium point it is impossible to say; this point will depend on the number of genes concerned, their mutation-rates, and the specificity of resistance to diphtheria. But, as with several other infectious diseases, deaths from diphtheria in this country are below equilibrium level after a century of adjustment of an originally rural population to city life during which mortality was much above this level. Immunisation against diphtheria is at present effective, but the capacity to respond to the toxin may well depend on past racial selection for resistance to the organism, and may be progressively lost after some generations in which there are no deaths from the disease. Where living organisms are used for immunisation, as in vaccination, the relative safety of the procedure probably depends on generations of selection for resistance; as the effects of this selection are lost, universal vaccination may come to cause as many deaths as did smallpox in a community long and freely exposed to infection by this virus. Few diseases will ever be exactly at the equilibrium point; and changes in bacterial and viral virulence will also for the time being upset the equilibrium. But in the long run environmental improvements, with one exception, are not by themselves likely to alter the mortality from any particular disease; they will merely lead to an increased morbidity-rate balancing a reduced case-mortality. The single exception is the elimination of the agent causing the disease. This is possible with some infectious diseases, and when it has been achieved genetic deterioration for resistance to the disease becomes irrelevant. But the number of diseases which can be controlled in this way seems limited—and this is true even of infectious diseases.

Human genetics is a new science, and little is known about the amount of selection needed to maintain equilibrium against the sum of disadvantageous mutations. One expert guess, by Professor Muller,[2] is that one gamete in five contains a new disadvantageous mutation. Whatever the selection needed, the human species has in the past more than held its own; and so selection must have been adequate. Until recently, however, there has been plenty of material on which selection could operate. At all periods except those of the most rapid population growth, less than half of natural families averaging six or seven children survived to have children in their turn. While some of these deaths may have been purely accidental, most were probably related in some way to the genetic constitution of the child or his parents. It is unthinkable that there should be a voluntary return to natural selection of this intensity. Fortunately, as Galton noted more than fifty years ago, as knowledge of human genetics grows, artificial selection is likely to prove both more humane and more efficient than natural selection; and Galton coined the term "eugenics" for artificial selection of this kind. If genetically ill-endowed individuals, kept alive by medical science or public hygiene, plan a family size 50% below replacement-rate, this gives as much gene-elimination as does the premature death of half of them. Further, artificial selection will be able to take account of the possession of genes in the heterozygous state, which when recessive are not subject to natural selection. In our kind of democracy eugenics must depend on self-selection by responsible parents, influenced in their choice of family size by genetic considerations. The present practice of planning families of only 2–4 children, with large families coming from the diminishing proportion of the population incapable of planning, probably provides insufficient scope for the maintenance of genetic standards, even with the best selection of those who aim at 4 and those who aim at 2 children. Probably even the family-size distribution suggested by the Swedish Commission on Population, with 33% of 3-child families, 27% of 4-child families, and 5% of 5-child families, though it would keep up the size of the population, would not provide adequate differentials to maintain genetic quality. General OSBORN[3] has suggested that, for this, family size should be distributed as follows: 19% 0 children, 15% 1 child, 16% 2 children, 18% 3 children, 18% 4 children, and 14% $5^1/_2$ children.

---

[1] *Med. J. Aust.* 1952, i, 801.

[2] Muller, H. J. *Amer. J. hum. Genet.* 1950, 2, 111.

Parents cannot be coerced into having children, and at first sight such a high proportion of large families might seem unattainable, since to achieve 14% large families a much higher percentage must aim at a large family. But in the next few generations in countries with planned families there will be intense selection for genes favouring genophilia—the desire for, and delight in, children. With few children conceived as the accidental by-product of sexual activity, it will mostly be genophilic impulses that decide family size. Those well-endowed in this respect will contribute an increasing proportion of coming generations; and those who aim at only 2 children for eugenic or other reasons will mostly be doing so unwillingly, with a sense of responsibility, and will need to find other ways to express their genophilic impulses. As some of the environmental causes of diseases are entirely eliminated, and it becomes no longer necessary to maintain selection for freedom from, or resistance, to these diseases, it will be possible to use selection with the much more attractive aim of improving human genetic standards for qualities which are desirable but not directly related to mere survival—for example, general and special types of intelligence, artistic gifts, and, more important still, worth-while qualities of character. To quote BURNET once more: "Whatever we feel about the present social and political impossibility of any programme of practical eugenics, we can be quite certain that decade by decade the importance of action will be progressively more widely realised. Sooner or later action will have to be taken and it is our responsibility to initiate the process of accumulating valid knowledge on which eventual action can be soundly based. I repeat that this is the most important task of medical research today."

Prognosis in Asthma

THE prognosis of asthma, like that of many other recurrent conditions, is still largely a mystery. Long-term follow-up studies are rarely completed, since the disorder waxes and wanes over the years, the patient tries one doctor or hospital after another, and, perhaps from delicacy, he may not answer the follow-up letter.

WILLIAMS[4] observes that in the twenty years between 1930 and 1949 the death-rate from asthma in England and Wales was 7·07 per 100,000 of the population, compared with 1·65 in the United States. In England and Wales during the years 1938–49 deaths from asthma amounted to 0·6% of all deaths, accounting for roughly 3000 deaths per annum; approximately 96% of those dying from this cause were over 30 years of age. WILLIAMS cites 110 reported cases of death from asthma in patients over 30 years of age. Of these patients 51 (46%) had had asthma for less than 5 years, and in this latter group 44 (87%) died within 2 years of the onset. The remaining 59 (53%) had had asthma for more than 5 years—including 36 (33%) for more than 10 years, and 16 (18%) for more than 20 years. WILLIAMS also shows that deaths from asthma have a seasonal distribution corresponding closely with the incidence of respiratory infections and bronchitis. BULLEN[5] studied a group of 176 asthmatics who died in hospital in a town in the United States. Of these patients 94 died during attacks of asthma. Of the total of 176 more than half died within 10 years of the onset, and one-fifth within 5 years. Of 13 patients in whom asthma started before the age of 5 years, 6 died within 1 year and 4 within 7–11 years. Nearly half the patients survived beyond the age of 60, but those whose asthma began when they were over 40 years of age had a much worse prognosis than those who first had symptoms before the age of 25. In a series of 500 asthmatics seen in private practice only 9% first had symptoms after 40 years, compared with 22% of the 176 patients who died in hospital. Thus hospital statistics, as might be expected, probably give an unduly grave impression of the proportion of all asthmatics who die of the disease.

RACKEMANN and EDWARDS[6] give some basic facts on prognosis in a twenty-year follow-up of 688 asthmatic children, most of whom were seen in private practice. All but 29 were traced by letter or interview, so that over 95% are included. 449 were first seen before the age of 13, while the remaining 239, though they became asthmatic before that age, were first seen later. Of the 449 children 4 (less than 1%) had died of asthma by the late 20s, whereas of the 239 older patients 6 (about 2·5%) had died after 20 years—1 at the age of 28, and the other 5 at ages between 40 and 50. Among the 449 children seen before the age of 13, boys outnumbered girls by about 2 to 1. In treatment the most important factor seemed to be withdrawal of feathers, animal dander, "inhalants," and certain foods, rather than specific desensitisation. Some 31% lost their asthma entirely during their 'teens, though not necessarily at puberty. Another 19% remained free of symptoms so long as they avoided the specific allergen to which they were still sensitive; and 21% were free of asthma but had developed another allergic condition, hay-fever being by far the most common. Thus about 70% of the children more or less lost their asthma during their 'teens. About 26% of the patients still had asthma, but only 10% had severe symptoms. One-fifth of the children had negative skin tests, and their attacks were associated with respiratory infections; whereas in the remaining four-fifths the disorder was ascribed to allergy. In the group of 239 patients who were first seen after the age of 13, the results were not so good. After 20 years about 22% were symptom-free, 26% were still sensitive but remained well when avoiding allergens, and 8% were free of asthma but had developed other allergies; about 10% were left with mild, and 25% with severe, asthma. Of 12 patients in whom polypoid sinusitis developed, 4 had died of asthma; so gross nasal disease is a bad prognostic sign.

[6] Rackemann, F. M., Edwards, M. C. *New Engl. J. Med.* 1952, 246, 815, 858.

The 688 cases are placed in five ætiological groups, depending on the clinical features and results of skin tests. Animal allergens account for 190 cases (roughly 29%), and foods for 48 cases (7%) mostly in young children with associated eczema. Pollen sensitivity was regarded as the important factor in 42 cases (5%), and mixed or unidentified allergens in 296 cases (42%). Skin tests were negative in 112 cases (16%), in most of which bacterial infection was thought to be the important cause. Of 86 children who had hay-fever, only 2 were free of symptoms by adult age. In 42 the hay-fever was mild; but in 28 (about a third) it was severe, and of these 13 developed pollen asthma and 7 asthma at any season. In 4 cases eczema recurred in adult life.

This important investigation shows that one child in four treated by a very experienced physician has continued to have asthma after 20 years of age, and about 2% actually died in asthmatic attacks. The proportion of failures is undoubtedly higher in children treated by palliative drugs alone. The prognosis is much graver in patients developing asthma when past 30 years of age; for then infection of the respiratory tract is common and may persist. This study should prompt us to discard the complacent belief that palliative treatment usually suffices. The asthmatic child or adult should be carefully investigated *at the onset* of symptoms and a rational régime instituted forthwith. This should include a serious effort to free the bedroom of dust and inhalant allergens, and to train the patient in remedial breathing exercises under the supervision of a physiotherapist.

Of Mice and Men

THE mills of virus research grind slowly, yet they grind exceeding small. Recent research on smallpox is a most instructive example of the tortuous, winding path that sometimes leads to practical progress. The story is a fascinating one, beginning with the discovery by HIRST [1] and MCLELLAND and HARE [2] that influenza virus agglutinates red cells from a number of animal species. It was soon found that vaccinia,[3] smallpox,[4] and other pox viruses also had this unusual property. The pox viruses have the distinctive property of agglutinating red cells from only 20–50% of fowls; and in 1946 BURNET and BOAKE [5] found that ectromelia virus also had this property and in other ways, too, resembled the pox viruses; and they proposed that ectromelia should be renamed mousepox virus. The next step can be readily pictured. Smallpox could not be studied easily in the laboratory, but mousepox might provide an excellent model of the behaviour of smallpox virus. FENNER was quick to seize the opportunity of learning about the epidemiology of mousepox, and the result was a series of painstaking and brilliant studies.[6] Before long practical applications [7 8] justified this roundabout road to progress.

When GLEDHILL and ANDREWES [9] described a virus which caused hepatitis in mice, it was at once apparent that this might be another instance of the way in which the study of a disease in mice may throw light on some of the difficult problems of epidemiology in man. Mouse hepatitis is an odd disease. The virus is apparently carried in the blood of one breed of mice (P.) which remain symptomless, but it can be transmitted to another breed (V.S.) which contract fatal hepatitis. The viruses of mouse hepatitis and of serum hepatitis in man have somewhat different properties, but superficially the analogy between the two diseases is striking. On an earlier page Dr. GLEDHILL, Dr. DICK, and Dr. ANDREWES describe further researches on mouse-hepatitis virus and reach the rather surprising conclusion that mouse hepatitis is caused by the combined action of two agents, which singly are non-pathogenic but cause fatal hepatitis when present together in the correct proportions. They were led to this conclusion by the results of experiments on the curative effect of terramycin on mouse hepatitis. From mice which had been inoculated with mouse-hepatitis virus and terramycin, a transmissible filterable agent was recovered which was non-pathogenic but immunised against mouse hepatitis; this agent was called S. (for stable). A second agent, called L. (for labile), was recovered by growing mouse-hepatitis virus at high dilution. L. and S. are both transmissible filterable agents which separately are non-pathogenic but together cause fatal hepatitis. We shall have to wait for further information on the lesions produced by these agents and any serological reactions that they evoke, and also for a final decision as to whether they are relations or just friends. Meanwhile the concept of viruses hunting in pairs should arouse great interest. There have been many well-substantiated reports of the simultaneous isolation of poliomyelitis and Coxsackie viruses from patients with poliomyelitis; and the interpretation by MELNICK et al.[10] that the Coxsackie virus may tip the balance towards paralysis accords with the known facts and with the findings in mouse hepatitis.

Experimental work with the viruses of hepatitis in man has also made big strides. Progress in this field still depends on that most unreliable laboratory animal, the human volunteer; and assessment of the results is always more difficult than with mice, which have learnt to say "yes" and "no" but not "maybe." Recently, however, DRAKE and his co-workers [11] have reported that a skin-testing antigen prepared from infective-hepatitis virus apparently protects people during an epidemic of infective hepatitis. In another paper these workers describe [12] results which lead them to believe that they have propagated the serum-hepatitis virus in eggs. Then again γ-globulin has been used successfully for protection against infective hepatitis. It seems, therefore, that the efforts of mice and men are not vain.

Annotations

TROPICAL FATIGUE

In the past the danger of tropical diseases was sufficient reason for Europeans to be advised to avoid long periods in the tropics. The gradual conquest of these diseases has largely removed this danger, but there is still a widespread belief that life in the tropics can lead to physical deterioration. The term "tropical fatigue" has been introduced to describe a decline in efficiency attributable to environmental conditions. The nature of this failure has often been discussed, but there has been little systematic study. During the war, however, tropical fatigue assumed considerable importance, especially in the Pacific area, and an investigation was carried out in the Australian and New Zealand Armed Forces; Lee and Macpherson have given a detailed account of this work.[1, 2] The first question that needed answering was: Does tropical fatigue exist? And the second: If it does, is it essentially physiological or psychological?

The investigations were carried out in the field in New Guinea and the adjacent islands. Some 1800 men, whose stay in the tropics averaged six months, were examined. Simple methods had of necessity to be used; weight changes, blood-pressure, pulse-rate, cardiovascular response to tilting, and Harvard pack test[3] scores were recorded. A man's efficiency was also assessed by getting his own opinion of how tropical service affected him, and by comparing his views with those of others in a position to judge his work—e.g., his medical officer, commanding officer, and N.C.O. The physical measurements showed no significant changes when compared with those of a control group; but the Harvard pack test score declined steadily with length of service in the tropics. The test consists in stepping on and off a stool every two seconds for five minutes, wearing a pack of one-third the body-weight. Scoring is based on changes in the heart-rate after stopping the exercise. The fall in the scores was slight, but it was correlated significantly with the duration of tropical service. Quite apart from this finding, Macpherson concluded from the subjective and objective assessments of personal efficiency that deterioration was general. Those in the tropical areas agreed, almost universally, that they were less efficient and that they felt less fit. As the physiological measurements showed no changes to explain this decline, it was thought to be largely due to psychological factors.

Ellis, who has published several studies on the effect of environment in the Royal Navy,[4] describes on another page of this issue his work on tropical fatigue in the Navy. His findings are very similar to those of Macpherson, for 80% of those serving in ships in tropical waters considered that they were less efficient than in temperate climates.

The position is still obscure: tropical fatigue may be entirely "subjective," but there can be little doubt of the belief in its existence. It is important to know more about the condition because it affects the whole way of life of the white man in the tropics. Macpherson, for example, attacks the siesta: "One of the cardinal rules for successful tropical living can be summed up in the sentence: keep off your back during daylight hours!" Moreover the social significance of the long-term effects of tropical climates is great, for these have a bearing on emigration policy and on the development of primitive tropical zones. It would be interesting to know whether the native population suffers from tropical fatigue. Ladell[5] has shown that there is no clear difference in acclimatisation to heat between Europeans and Africans in Nigeria; this confirms observations by Weiner[6] on Bantu mine-workers. On the other hand, Robinson et al. found that, among share-croppers in the Southern United States, the Negro workers were mechanically the most efficient; they concluded that the Negroes had a better temperature-regulating mechanism.[7, 8]

One of the main difficulties of the subject is the lack of adequate methods of measuring fatigue. Forbes,[9] in his summary of the work of the Harvard Fatigue Laboratory, emphasised this obstacle. When many observers agree that an effect is to be found, it probably exists. Failure to demonstrate the effect quantitatively usually means that the right parameter has not been measured.

CORTISONE VERSUS SALICYLATES

The striking biological effects of cortisone and A.C.T.H. are echoed, somewhat faintly, by the action of salicylates in heavy doses. In the clinical field the most obvious similarity is the antirheumatic action; and the reported development of Cushing's syndrome in a patient with rheumatic fever receiving 5 g. of aspirin a day[10] stimulated Hetzel and Hine[11] to investigate the effect of salicylates on the pituitary and adrenal glands of rats, using ascorbic-acid depletion as a measure of adrenal cortical response. They showed that sodium salicylate, in doses giving plasma-levels of 15–30 mg. per 100 ml., depleted the adrenal ascorbic acid to an extent related in linear manner to the dose, and that this effect was abolished by hypophysectomy; they also adduced evidence that the salicylate ion acted specifically in this respect, and they concluded that the therapeutic action of salicylates is mediated through the pituitary and adrenal glands. This view is supported by the inhibition of experimental serum arteritis by both cortisone[12 13] and salicylates,[14 15] and by the action of salicylates in increasing urinary output of 17-ketosteroids,[16] in increasing uric acid excretion[17] and in modifying the reversed passive Arthus reaction.[18]

Investigations of the effects of salicylates on the circulating eosinophils, however, have given conflicting results; for while Kelemen et al.[19] and Roskam et al.[20] found eosinopenia after administration of salicylate, Meade and Smith[21] demonstrated no such effect. These workers, moreover, have confirmed[22] Ingle's[23] finding that aspirin causes reduction of glycosuria in diabetic rats, whereas cortisone exacerbates the diabetes; and they challenge the general conclusion of Hetzel and Hine. Lately, Smith[24] has shown that while administration of cortisone to rats on a high carbohydrate diet leads to hyperglycæmia and glycosuria, this effect is much reduced

by simultaneous administration of sodium salicylate. In adrenalectomised rats cortisone produced a significant deposition of liver glycogen, but salicylates given in the presence of cortisone caused a contrary and significant depletion. There is, therefore, considerable evidence that the mimicry by salicylates of hormone effects is only partial, and that in experimental conditions salicylates may antagonise cortisone.

In claiming that the therapeutic action of salicylates is mediated through the pituitary, Hetzel and Hine point out that, according to Sayers,[25] a lowered blood-level of cortical hormone stimulates the pituitary to restore homœostasis, and they tentatively suggest that salicylates stimulate the pituitary in this way by increasing the utilisation of cortical hormone in the tissues. In support of this they report experimental evidence that preliminary treatment with cortisone abolishes the ascorbic-acid-depleting effect of salicylates on the adrenals. Conceivably, however, this is a further example of the antagonism between cortisone and salicylates.

THERMOMETERS

DOCTORS learn early that the clinical thermometer is a chancy little tool. If it is to register accurately it must be kept in the mouth for at least three, and in some circumstances, six or seven minutes. Indeed, some years ago in a correspondence on this subject initiated by Dr. Douglas McClean[26] one writer assured us that "ten-minute thermometry has long been the custom in the more efficient sanatoria,"[27] and Dr. E. L. Middleton[28] reported that he always replaced the thermometer in the patient's mouth after the first reading, and went on replacing it after successive readings until two consecutive readings were the same. With these precautions in mind doctors can use thermometers successfully as a guide to one aspect of a case. The general public, however, and even the nursing profession, are not so well trained in scepticism.

Thermometers are made with different sizes of bulb, the smallest being described by manufacturers as "½ min.," and larger sizes as "1 min." and "2 min." thermometers. These terms were intended to indicate the time the thermometer required to register the true temperature; but the manufacturers know as well as the doctors that the time taken is very variable, depending not merely on the size of the thermometer but on whether it has been kept in a cool or a warm place before use, whether the patient's temperature is high or subnormal, whether he has kept his mouth shut or has had it open for talking, and whether the thermometer is competently placed inside it. Thus it has long been desirable that descriptions by time of different types of thermometer should be given up. The British Standards Institution are now revising the specifications for clinical thermometers. They have never allowed any "time" designation to be stamped on British Standard clinical thermometers, but unfortunately they are now proposing to perpetuate this misleading usage as a trade term. Their reasons for doing so are exactly the same as those given in our columns, in 1943, by Messrs. G. H. Zeal Ltd.,[29] manufacturers of thermometers.

> "Unfortunately," this firm wrote then, "long-standing trade usage and the fact that clinical thermometers have always been sold to the medical profession and the general public as 2 min., 1 min., or ½ min. patterns stand in the way of any change; and while this system of marking is admittedly misleading it has served to differentiate between slow, medium and rapid registering varieties. . . ."

The British Standards Institution, though also admitting that time designations can be (in their own words) "extremely misleading," are nevertheless proposing in their draft that the terms "½ min. pattern" and "1 min. pattern" should be retained, the inverted commas and the word "pattern" being added, they say, "to show that these designations are, so to speak, trade terms, and are not to be taken as specifying the time required for the thermometer to register correctly." But the housewife, offered the choice of the two "patterns" by a chemist, will have no chance of seeing the inverted commas, and no means of knowing that she is hearing a trade term. She will take a "½ min. pattern" in good faith, believing she need only keep it in her child's mouth for half a minute to get a reliable reading. The public should not be misled merely because the manufacturers have contracted a bad habit and are unwilling to give it up.

The Association of Scientific Workers, in a comment on the British Standards Institution draft, suggest that the terms "rapid," "medium," and "slow" should be substituted for the misleading terms "½ min.," "1 min.," and "2 min."; but there are obvious trade objections to marketing a thermometer described as "slow." Moreover, the B.S.I. draft specifies only the "½ min. pattern," the "1 min. pattern," and the "stubby-bulb pattern"; which suggests that the "2 min. pattern" is no longer on the market. Perhaps appropriate names for the two remaining types would be "long-bulb rapid" and "long-bulb medium" (to distinguish them from the "stubby-bulb pattern"). The A.S.W. make an alternative suggestion—that there should be only one standard clinical thermometer, and that it should have a minimum reading-time of 3 min. stamped on it, with a recommendation that this time should, if possible, be exceeded. Perhaps the device "3 min. +" would suffice. Certainly the public have been trained so consistently to believe that an accurate reading can be taken in half a minute that this piece of re-education is thoroughly necessary.

NEW RELAXANTS

RELAXANTS are nowadays an essential part of anæsthesia. There are a very large number of drugs that interfere with neuromuscular transmission; indeed, pharmacological chemists would probably have little difficulty in synthesising many more of them, for a great deal is known of the relation between chemical structure and relaxant action. The difficulty is to select compounds that will be useful in clinical practice and to assess their value. Studies on animals help greatly; but, because of species difference and the very considerable environmental differences between the pharmacological laboratory and the operating-theatre, the ultimate test must be on patients undergoing an operation.

So far, relaxants seem to be of two main groups. Those in the first group resemble in action the alkaloid *d*-tubocurarine, interfering with the depolarising action of acetylcholine. The others, acting like hexamethonium, cause persistent depolarisation, inhibiting the activity of the neuromuscular junction.

With regard to *d*-tubocurarine, the original relaxant in anæsthesia, there seems to be little real cause for dissatisfaction, though it is generally believed to cause increased oozing owing either to its histaminic effect or to ganglionic block. Its main action persists for about half an hour; this may sometimes be too long, but neostigmine will cut the time short. Of the curare-like relaxants, only gallamine has so far proved a satisfactory substitute for the natural alkaloid. Gallamine is cheaply made and presumably will always be readily obtainable—which tubocurarine may not be. To its discredit it quite often gives rise to tachycardia owing to a vagolytic action.

Of the depolarising group, hexamethonium had a brief period of popularity. It is potent and has a fairly short-lived action, and it was said to be antagonised by pentamethonium. Unfortunately, however, in clinical practice this antagonism cannot be relied on. Nearly a year ago a newcomer to this group, succinylcholine, was introduced. It was reputed to be the safest of all relaxants because of its very short action and rapid disintegration, and the absence of after-effects. Here again early hopes have not been completely fulfilled; for lately there have been many reports of unexpectedly long-continued effects from this "short-acting" relaxant. The criticism that such untoward effects were largely due to overdosage has not wholly stilled uneasiness about the safety of this drug. The latest synthetic relaxant to be tested, known as Compound 20 or 'Laudolissin,' is described in this issue by Dr. Bodman and his colleagues, who report that it acts in a true curare-like manner, is antagonised by neostigmine, lasts a little longer than the natural alkaloid, and apparently has no side-effects. This objective and encouraging report will no doubt stimulate other clinical research-workers to study this drug further.

---

[25] Sayers, G. *Physiol. Rev.* 1950, 30, 241.
[26] *Lancet*, 1943, i, 446.
[27] *Ibid*, p. 539.
[28] *Ibid*, p. 725.
[29] *Ibid*, p. 510.

There is perhaps a danger that successful preliminary tests such as these, made by skilled workers, will be taken by anæsthetists in general as evidence that the drug investigated is the best. That this is not necessarily so is suggested by the story of other relaxants. The somewhat disastrous effect of pentamethonium given to "neutralise" hexamethonium, the unexpected and alarming complications from the use of mephenesin, and the sometimes far from short action of succinylcholine, suggest a need for caution and an open mind.

THE SHAPE OF THE CHEST

COMMUNICATION between humans might be much improved by a collective inward eye. A mental image of a face, a scene, or a patient's physical signs can be so vivid that we itch to pass it on entire. But since visual memories are as subject as other memories to erasions, distortions, and decorations, it is perhaps as well that we rely, for scientific purposes, on less subjective records. The trouble is that some visual images are curiously awkward to record; and among these the shape of the chest ranks high. Dr. H. R. E. Wallis,[1] who has had trouble with it, points out that a photograph does not readily lend itself to accurate measurement; and though funnel chests are fairly easily shown by the camera, Harrison's grooves, to be demonstrated successfully, need a highly skilled photographer. When the subject is a child aged three or four he may also have to be a combination of naturalist, psychologist, and acrobat. Radiography, of course, will show localised deformities of the ribs or spine, and the inclination and spacing of ribs in emphysema and collapse; and lateral views show pigeon and funnel chests. Casts of the chest are useful for following the development of abnormal shapes, such as the bulges associated with congenital heart-disease; but casts are expensive to make and difficult to store, and young children are frightened by the long process of their construction. Even the old-fashioned tape-measure is defeated by this oddly shaped part of the body, this "irregular frustum which ceaselessly expands and contracts in several directions."

Callipers will measure diameters of the chest, and the amount of anteroposterior and lateral respiratory expansion; but since, in children, the expansion is small and the errors in reading apt to be large, the measurements are not of great value. The depth of Harrison's grooves or of a funnel-shaped depression can be measured by a small sliding ruler, attached at right angles to a bar; the bar is laid across the groove, and the ruler pushed in until it touches the bottom of the crater. This measurement, however, tells nothing about the width or slope of the groove: to record these a cyrtometer is needed.

Cyrtometers measure curves, and there are several kinds of them. Strips of soft lead are commonly used, which can be moulded round the chest wall and then removed to a sheet of paper, on which the curves can be traced with a pencil. The two sides of the chest may then be easily compared by superimposing the drawings; and tracings can also be made of the vertical contours of depressions and prominences. Lead, however, is rather stiff, and the physician may find the ribs of a pliable young child fitting themselves to the lead rather than the other way about. Moreover the method is tedious and dirty, and exposes the operator, Dr. Wallis suspects, to a new occupational hazard—chest-physician's colic. He has therefore devised a multiple-rod cyrtometer, composed with great ingenuity from two ebonite plates, 14 in. long and 3 in. wide, and 13 dozen aluminium rods, 9 in. long and $^1/_{16}$ in. in diameter, obtained from the manufacturers of a well-known children's building-set. The lower plate is grooved transversely, and the rods lie side by side in the grooves, projecting on either side of the plate. On top of them is a strip of 'Sorbo' rubber, and then the upper plate; and the plates are held together by two nuts and bolts which allow the rods to be made loose or firm. In practice the rods are loosened, and their free ends are pushed gently against the front of the chest just below the nipple line; they adapt themselves to the shape of the chest wall, forming a line shaped to its contours. The plates are then screwed together, and the outline of the chest wall is traced on paper by running a pencil along the tips of the rods. This little instrument, Dr. Wallis remarks, is easy and quick to use, does not seem to frighten children, and comes in handy when cutting linoleum to fit against moulded corners.

Even an outline of the chest wall, however, does not call up a very lively mental picture of a child's chest. The posture-recorder, used as an aid to physical training in schools, contributes something more.

This consists of a movable lens, a mirror, and a ground-glass screen contained in a box with a flap which acts as a screen against the light. The child stands against a white background, and an image of him in profile is thrown on the glass screen, as in a reflex camera; the outline of this image is traced off on tracing-paper. The method gives a very clear idea of habitual stance, and if the child is shown the tracings they often encourage him to stand better. But small children find it hard to keep still long enough to be drawn, and defective draughtsmanship can influence the result.

Pursuing his ideal of the perfect record, Dr. Wallis has also made use of the optical contour apparatus, designed to facilitate the carving of portrait heads in wood.

It consists of two lamps, each containing two 'Photoflood' bulbs and a parabolic reflector. The lamps are placed opposite each other a foot or so apart, and the light from each of them passes through a screen of plywood strips, $^1/_4$ in. wide and $^1/_{32}$ in. apart. There are 48 strips and 47 spaces; and when anyone stands between the two lighted lamps he is striped with light and dark bands like a zebra. The stripes, of course, follow the contours of his body, and demonstrate very strikingly not only its curves and hollows but any asymmetry between the two sides.

Photographs of children illuminated in this way record accurately the shape of the chest and its movement with respiration; and Dr. Wallis suggests that the apparatus could also be used to record the movements of individual ribs in health and disease.

THE European Congress of Cardiology, which is meeting in London this week, held its first session on Sept. 10. After Sir JOHN PARKINSON, the chairman, had welcomed the delegates, Prof. CHARLES LAUBRY (Paris), the honorary president, delivered his inaugural address. Prof. GUSTAV NYLIN (Stockholm), the president, also spoke.

THE INDEX and title-page to Vol I, 1952, which was completed with THE LANCET of June 28, is now in preparation. A copy will be sent gratis to subscribers on receipt of a postcard addressed to the Manager of THE LANCET, 7, Adam Street, Adelphi, W.C.2. Subscribers who have not already indicated their desire to receive indexes regularly as published should do so now.

HOT-CLIMATE FATIGUE IN THE ROYAL NAVY

A REVIEW OF LAY OPINION

F. P. Ellis
O.B.E., M.D. Manc., M.R.C.P.
SURGEON COMMANDER, ROYAL NAVY; DIRECTOR, MEDICAL RESEARCH COUNCIL'S ROYAL NAVAL TROPICAL RESEARCH UNIT, UNIVERSITY OF MALAYA, SINGAPORE

Opinions vary concerning the relative importance of the climate as a cause of the increased mental inertia and reduced mental stability which affect some persons who come to the tropics from more temperate zones. When mental breakdown occurs, psychiatrists often find that the hot climate is a less important factor than family separations, failure to readjust to new domestic and social circumstances, economic worries, and over-indulgence in alcohol; but they derive this information from the histories of persons who have already succumbed to the circumstances of their tropical environment—the less robust personalities, the overworked, the convalescent, the unhappily married, and the misfits.

The only way to discover how healthy people react is to ask them, and it is desirable to choose persons who are able to relate their tropical experience to previous experience in a temperate climate. Naval officers and men are appropriate subjects for such an investigation. They are usually selected at random to come to the tropics from a temperate zone. Apart from the difference in climate the other environmental stresses of life in a ship are not very different from those experienced in the Home Fleet and are common to all. Moreover, as the thermal environment between decks is considerably warmer than in residences or offices on shore, the effects of different levels of warmth can also be studied.

Naval opinion on these matters was obtained by means of a voluntary questionnaire distributed in March, 1950, to officers and senior ratings in an aircraft-repair ship who had been serving in tropical waters for six months. The replies were sufficiently interesting to justify the distribution of the same questionnaire to men in a cruiser who had been serving on the East Indies Station for twenty months. It was then circulated to those officers and senior ratings on the staffs of the Commander-in-Chief of the Far East Station, of the Flag Officer of the Malayan Area, and of the Royal Naval Barracks, Singapore, who had been living on shore in the tropics for more than six months.

METHOD

The questionnaire used in each of these investigations is shown in table I. The design enabled those questioned to say whether, in their opinion, they were more or less efficient or more or less healthy in the tropics than in a temperate climate, and to indicate the character of any deterioration they recognised. Leading questions, such as "Have you lost or gained weight?" were avoided. The aim was to identify the features which were most prominent in the mind of the healthy layman without professional prompting. The descriptions of ill health, or of the ways in which efficiency deteriorated, were not necessarily those to which a clinician would attach most emphasis after a careful interview, but they were the features which were most obvious to the men who reported them.

Because of the many differences between naval life on shore and afloat, it was undesirable to compare experiences at sea in the tropics with shore life in a temperate climate. Questions 1 and 4 were designed so that the effects of climate experienced on shore in the tropics could be related to earlier experiences on shore in England, and so that the effects of climate afloat in the tropics could be compared with the effects experienced by the same persons afloat in home waters or in the Mediterranean.

The replies to questions 3 and 5 were sorted together to avoid reduplication when loss of efficiency and loss of health were attributed to the same symptom. The factors to which tropical deterioration was attributed were divisible into those which contributed directly, and others which contributed indirectly, to loss of efficiency. The latter were subdivided into adverse effects associated with excessive sweating and adverse effects not obviously associated with excessive sweating.

RESULTS

About 70 voluntary replies were obtained from each of the ships and from the Singapore establishments. Half of the replies from the aircraft-repair ship and two-thirds from Singapore were from officers, and the rest were from senior ratings. The replies from the cruiser were mostly from ratings (93%), including some junior ratings. In this respect the groups are not strictly comparable.

Reduced Efficiency

Of the men who replied from the ships, 88% thought they were less efficient in the tropics than when serving afloat in a temperate climate (table II); and two-thirds of those who were living on shore held the same opinion. The views of officers and ratings, and of men in different age-groups, were in good agreement.

Impaired Health

In the two ships 72% of the men thought they were less healthy than thay had been when serving in the Home Fleet or the Mediterranean (table III). Several considered

TABLE I—THE QUESTIONNAIRE

CLIMATE AND EFFICIENCY QUESTIONNAIRE

1. Do you consider you are more efficient or less efficient serving afloat on the Far East Station ("afloat on the East Indies Station," "on shore in Singapore") than you were when serving afloat
   (*a*) * in the Home Fleet ?________ (*b*) in the Mediterranean ? ________ or (*c*) when living on shore in England ?________
2. If you consider you are less efficient in the tropics, do you consider this to be mainly due to the effects of the climate and temperature conditions between decks (climate), or do you consider it to be due to other domestic, economic, or related factors with which this questionnaire is not concerned (other factors) ?**________
3. If you consider that your efficiency is impaired on this station because of the effects of climate, can you give 3 examples of the ways in which you consider the prevailing climatic conditions affect your efficiency adversely ?
   (*a*)
   (*b*)
   (*c*)
4. Do you consider you are more healthy or less healthy serving afloat on the Far East Station ("afloat on the East Indies Station," "on shore in Singapore") than you were when serving afloat
   (*a*) in the Home Fleet ?________ (*b*) in the Mediterranean ? ________ or (*c*) when living on shore in England ?________
5. If you consider you are less healthy on the Far East Station ("East Indies Station," "in Singapore") than you were previously, will you indicate in broad terms the general nature of your decline in health :
6. What is your age ?________
7. Are you married ?________
8. How long have you been in H.M.S.________ (stationed in the tropics this commission) ?
9. Remarks (please enter on back of form).

Signed :

* Insert "more efficient" or "less efficient," or N.A. (not applicable) if you have served on only one or neither of these stations as appropriate.

** Insert "climate" or "other factors" as appropriate.

TABLE II—NUMBERS WHO CONSIDERED THEY WERE LESS EFFICIENT IN THE TROPICS THAN IN A COOLER CLIMATE

Age-group (yr.)	Cruiser (20 mos. in tropics)			Repair ship (6 mos. in tropics)			Shore bases in Singapore (more than 6 mos. in tropics)		
	Officers	Ratings	Total	Officers	Ratings	Total	Officers	Ratings	Total

that they were more healthy but less efficient in the tropics. On the other hand 63% of those who were living and working on shore thought that their health was as good as, or better than, it had been in a temperate climate.

Direct Causes of Loss of Efficiency

The subjects' descriptions of the ways in which climate affected efficiency are classified in table IV according to the main symptom groups which they suggest.

The frequency with which these features were reported in the two ships and by the shore-based subjects is shown in table V. The outstanding complaint was lethargy or tiredness in some form or other. In the cruiser 51 out of 63 (81%) reported reduced efficiency (table II), and lethargic symptoms were referred to. Memory defects were reported by 78% of those who were questioned (table V). The office workers on shore were more aware of memory defects, and also of slowing of their mental processes, than those in ships, although fewer of them reported lethargic symptoms. Officers and ratings replied in very similar terms, with only a few differences worthy of mention. Whereas five times as many officers as men in the repair ship commented on a lowered sense of responsibility, five times as many ratings as officers reported symptoms indicating retardation. These changes in emphasis were largely due to differences in relative responsibilities and occupations. Responsibilities of the officers were greater than those of the ratings. The ratings included many skilled technicians and mechanics who were more likely to observe retarding effects in their work.

Indirect Causes of Loss of Efficiency

The reported complaints which were probably associated with excessive sweating are summarised in table VI. The men who were living on shore had few complaints other than mild skin disease. In clear contrast about half the replies from ships referred to discomfort, unsatisfactory sleep, and skin diseases, caused or aggravated by unevaporated sweat on the skin or in the clothing or the bedding.

Discomfort was reported in nearly 60% of the replies from the ships but in only 10% of replies from men living on shore. It was referred to in various ways: "excessive perspiration"; "skin irritation due to sweating"; "physical discomfort off duty"; "physical discomfort reduces will to work"; "heat increases the unpleasant effects of overcrowding"; "unable to relax"; "sweat runs in the eyes"; "perspiration interferes with bench work"; "paper work gets covered with sweat"; "perspiration interferes with the playing of string and wind instruments."

Disturbed or inadequate sleep was mentioned by 44% of the men in the ships but by only 4% of those on shore. Typical observations were: "sleep is interrupted"; "too hot to sleep well"; "continuous feeling of lack of sleep"; "more sleep is required"; "wake up feeling tired."

The complaints not obviously associated with sweating are summarised in table VII. The volunteers living on shore had few complaints. After six months in the tropics, however, a proportion of men in the repair ship reported loss of appetite and weight. These features were referred to in nearly 25% of the replies from the cruiser after

TABLE IV—SUBJECTS' DESCRIPTIONS OF WAYS IN WHICH THEIR EFFICIENCY WAS REDUCED

SYMPTOM	SUBJECTS' DESCRIPTION
Lethargy	Lassitude. Lack of energy. Listlessness. Fatigue easily. Less staying-power. Tire quickly. Less stamina. Easily exhausted. Lack of vitality. Lack of alertness. Physical and mental fatigue. Capacity for long hours less. Hard to stay awake, especially in afternoons.
Reduced concentration	Cannot concentrate. Hard to concentrate on intricate jobs. Hard to think profoundly. "Grasshopper mind." Reduced concentration in the afternoons.
Retardation	More effort is required. Think more slowly. Manual work is more difficult. Reactions are slower. Work takes longer. Output of work is less. Inclination to go slower. More difficult to learn new subjects. New problems must be tackled more slowly. Slowing of mental and physical activities. Capacity for work is less.
Lowered responsibility	Tendency to leave or rush work in hot spells. Neglect of detail. Less incentive to explore responsibilities in hot situations. Procrastination. "Couldn't care less" attitude. Less drive. Accept reports without scrutinising them. Too hot to "jump to it" and "dash around." Tendency to avoid physical effort. Tendency to avoid office work. Make hasty decisions. Lack of interest. Lazy mentally. Harder to maintain discipline. Less keen to get out of the office and see for oneself. Inclined to take the path of least resistance. "Slap-dash" methods.
Personality change	Short-tempered. Irritable. Impatient. Depressed. Neurotic. Anxious. Apathetic. Inclined to worry more. Minor troubles are magnified out of all proportion to their real importance.
Memory defects	Forgetfulness. Forget simple things. Absent-minded. More effort is required to remember.

nty months' service on the East Indies Station, and % complained of headaches.

he reported loss of weight in the cruiser was supported a review at random of the weights of 35 members of ship's company obtained during their PULHEEMS minations after about six months and eighteen iths in the tropics. There was an average weight loss ·7 lb. for the group, which was statistically significant. s did not include any initial losses on arrival in the pics, and was due mainly to losses by those who were ve average weight, for 17 men above the average ght of 145 lb. lost 2·8 lb. on the average, which was also ificant; whereas the average loss by 18 men below rage weight was only 0·66 lb., which was not significant. nly 2 men referred to dizziness, and only 2 to swollen and swollen legs; 7 men (2 in the cruiser, 2 in the ir ship, and 3 on shore) commented on the unpleasant ts of sun glare on the eyes.

portance of Climate

he great majority (over 80%) of those who thought were less efficient in the tropics, either on shore or at, considered that loss of efficiency was due mainly limatic factors (table VIII). Only 4 out of 157 men %) considered that domestic, economic, or related ors were more important than the tropical climate. remainder thought that climate and other factors implicated equally.

DISCUSSION

It is of value to see how far these statements of opinion are supported by accounts of war-time experience. The resemblance is close between the picture of "hot-climate" fatigue in these ships and that described as "tropical fatigue" by Macpherson (1949) in the New Guinea area in 1944. The term "hot-climate" fatigue is used here because symptoms attributed directly to the effects of excessive warmth were so prominent, and also because the climate in the tropics is very pleasant for much of the time, particularly at the higher altitudes, and because unpleasantly warm climates are encountered outside the tropics.

Macpherson obtained his information by the examination and systematic interrogation of "fit men" in their units. The majority had only been in the tropics about six months. The characteristic complaints were sleepiness, headaches, vague abdominal pain, loss of appetite, pains in the back, loss of weight, and dizziness on standing up. He devoted special attention to dizziness, and found that this symptom was in fact less common (33/1257, or 2·6%) than the reported incidence of "blackouts" suggested. The incidence of dizziness in the present naval replies was even smaller (2/209, about 1%), probably because the subjects were not questioned directly on this point and because the psychological stresses of war were removed. Macpherson's objective observations, including tests for circulatory instability, reduced ability to carry out a set physical task, and periodic weighing, did not suggest a serious degree of physical deterioration. He concluded that tropical fatigue was partly physical, because ill health, particularly skin disease, was more prominent than in a control series of men not serving in the tropics, but that it was psychological to a very much greater extent. The climatic factor was important in its causation, although isolation, boredom, conditions of service, and the moral fibre of the men had to be considered as well.

In an account of naval psychiatric cases observed at Bombay and Trincomalee, Cameron (1945) gave the clinician's viewpoint. He described first the vague symptoms encountered commonly outside the consulting-room:

> "Lassitude, tiredness and awareness of the temperature . . . a somewhat lowered tempo of performance and the need to accept slightly lowered standards in oneself and others. The effects on work and interests, at first, are not markedly significant, and a good performance and healthy outlook are maintained with two exceptions, immediate memory and capacity for concentration are impaired. . . . A serious consequence of impaired attention and anxiety . . . is irritability."

So far the comparison with the present replies is again close. In a contemporary account Critchley (1945) considered that to a newcomer to the tropics the syndrome of undue irritability, alcoholic indulgence, mild hypochondriacal preoccupation, and a tendency towards paranoid feelings of resentment was suggestive of a mild dementia with personality deterioration—but for the clear insight of those affected and the fact that the condition was cured after leave at home.

Cameron then described a "prepsychotic tropical syndrome" which emerged occasionally from this broad backcloth. This was typified by dullness, apathy, unwillingness to confide, tremulousness, conscious anxiety, and paranoid outlook, but not by failure of the intellectual faculties, disorientation, or hallucinosis. Established psychoses (conditions certifiable by British law) were responsible for 1 in 7 of the total number of patients he interviewed. Nearly all the patients seen at Trincomalee came from ships, and nearly half of them showed physical evidence of an adverse reaction to heat, such as prickly heat or some other form of skin disease, in contrast with only 10% at Bombay, where the majority were based on shore. The history was not usually that of an unstable person. The usual progress was towards recovery though the patient remained in the tropics. The peak incidence occurred among those who had been less than six months or more than eighteen months on the station. An unduly high proportion were men aged more than 40. Marital unhappiness was a factor in 25% of the cases. Cameron probably saw a more severe state of affairs than he would have encountered in peace-time, because of the more strenuous climatic and operational conditions of the war afloat, and the larger numbers of older and conscripted men exposed to these stresses.

The emphasis laid by Cameron (1945) and Critchley (1945) on the importance of psychological deterioration in the tropics was not supported by the monthly returns of sickness from the Eastern and British Pacific Fleets between February, 1944, and August, 1945, when the average monthly incidence of fresh patients reporting for treatment who were diagnosed to be suffering primarily from a psychoneurotic disorder never exceeded 0·1% of those at risk (Ellis 1948). On the other hand, skin diseases, excluding uncomplicated prickly heat, caused 10% of ships' companies to report for treatment each month. It has been suggested that, if you eliminate the psychiatrist, psychiatric illness will not figure largely in routine sickness returns; and psychiatrists were in short supply in the Eastern Fleet. This is not to say that psychiatric complaints ceased to exist but that greater prominence was probably given by those living in ships to coincidental physical complaints.

The incidence of the more common causes of ill health was nearly twice as great in ships as in shore establishments. The time lost by air-crew in a fleet aircraft-carrier because of sickness was three times as great in the tropics during the third quarter of 1944 as in the second quarter of that year when the ship was operating off the Norwegian coast (Rogerson 1945). The average working time lost through sickness in a cruiser and a battle-cruiser during five and eight months respectively in the Eastern Fleet in the same year was nearly thrice that lost in the previous period when these ships were in the Mediterranean (Ellis 1946). In the first year after the war the weekly sickness returns from all ships revealed that total sickness was more than doubled in tropical as contrasted with northern temperate waters, and diseases of the skin were increased by three or four times (Fraser Roberts 1948).

There was little doubt that efficiency was also reduced because of the warmth of the environment between decks, although it was not easy to prove this. Men decoding signals in cypher offices, accountants, store officers, and others engaged in sedentary mental work described how, after short periods in their hot offices, they were unable to think and either felt drowsy, made unreasonable mistakes, or failed to concentrate altogether. Others remarked how mistakes were made often without the knowledge of the person making the mistake. Officers in charge of gunnery-control positions noticed that the crews of transmitting stations and calculating positions made more individual errors and their team-work was not so good as it was in home waters. Engineer officers reported that the work of skilled technicians was of a poorer quality than the work turned out in a cooler climate, and the winding of electrical armatures in electrical repair shops took longer, although more men were occupied on this work. Heavier work, such as "bombing-up" a wing of 24 aircraft in a carrier, took half as long again in the tropics.

Experimental evidence also supports the view that efficiency was reduced. The average effective temperature (Bedford 1946) on the mess-decks in the Eastern Fleet was 84°F, and much warmer conditions were encountered in most places where the crews worked between decks (Ellis 1948). Mackworth (1951), in a series of experiments carried out under controlled climatic conditions at Cambridge, showed that the level of performance of men carrying out tasks simulating those of wireless telegraphy, radar, and gunnery ratings deteriorated when the effective temperature of the climate in which they were working was raised from 81° to 86°F.* Observations made at Singapore by Pepler (1951) on naval ratings acclimatised to the tropics also confirm Mackworth's assumption that the performance of certain tasks will deteriorate with increasing warmth at these climatic levels, although he found rather more variability than Mackworth in the levels of warmth at which these effects were observed.

Hot-climate fatigue, though less obvious, was probably just as common as prickly heat in the Eastern Fleet during the war, and when the latter was rife in a ship's company it was a useful indicator of the presence of the former. Under operational conditions it was the rule rather than the exception in many ships, but it did not lead to serious breakdown very often, as it might have done in a less stable community. A man affected by hot-climate fatigue does not necessarily feel ill; indeed his attitude is at times euphoric rather than gloomy. He is unlikely to call on the doctor because he feels more lethargic, less responsible, more forgetful, or more irritable than he is accustomed to be; nor will he seek in the sick-bay a cure for incessant sweating, for these are accepted as unavoidable concomitants of life in an excessively warm climate. When practically everybody is affected to some extent, such features of abnormality are often accepted as normal within the community, although they may appear strikingly abnormal to a trained observer fresh from a temperate climate (Critchley 1945). These men were fatigued by chronic discomfort from continuous sweating, chronic skin diseases, lack of sleep, salt deficiency in some cases, and the body's never-ending struggle to maintain itself in thermal equilibrium with its environment, added to the cumulative effect of four or five years' vigorous naval warfare. When they obtained relief from their hot living and working conditions they usually recovered quickly. When the occasion demanded it, either in action or for the captain's rounds or other inspections, the very great majority would "snap out of it" for the time being, although between times a relaxation of standards, general appearances, and responsibilities, which could not be conducive to full efficiency, might be accepted without comment. The truth probably lay somewhere between the sorry story told by the few psychiatrists in their overcrowded clinics and the more optimistic statements of executive officers who were impressed by what they saw at inspections or by efficiency in action when men were keyed up to give their best performance.

The thermal environment between decks is much warmer than in offices and barracks on shore. In the tropics the average temperature of the air in the living-spaces, which are the cooler parts of a ship, is about 7°F higher than that of the outside air. At these levels of warmth this makes all the difference between a climate which is tolerable and one which is too warm for comfort (Ellis 1952). Adequate methods for controlling the climate within warships are available today; but the necessary modifications in design must be compatible with the other requirements of a fighting ship, and acceptable in other climates.

---

* The actual environments used by Mackworth were dry-bulb and wet-bulb temperatures of 90/80°F and 95/85°F when the average air movement was about 100 ft./min. and the men were stripped to the waist.

SUMMARY

Naval officers and ratings serving afloat and on shore in the tropics answered a questionnaire about the effect of climate on their efficiency and health.

The great majority of those serving in the ships thought that they were less efficient in the tropics than when serving afloat in more temperate waters, and two-thirds of those living on shore thought that they were less efficient than when serving on shore in England. Climatic factors were regarded as the main cause of this loss of efficiency by over 80% of 157 men who thought they were less efficient, and only 4 men (2·5%) considered domestic, economic, or related factors to be more important than climate. The views expressed by officers and men were in close agreement.

Whereas over 70% of those in the ships thought that they were less healthy in the tropics, nearly two-thirds of those living on Singapore Island thought that they were equally healthy or more healthy in the tropics than in a temperate climate.

When healthy men serve for a long time in an unduly warm climate, some of them will suffer from hot-climate fatigue, typified by lethargy, mental retardation, reduced powers of concentration and sense of responsibility, irritability, and mild changes in personality and forgetfulness, which are associated often with excessive sweating, unsatisfactory sleep, skin diseases, loss of weight, loss of appetite, and ill-defined digestive disorders. This syndrome develops when men live and work at levels of warmth which result in the presence of unevaporated sweat on the skin and in the clothing or bedding. The majority of men exposed to these conditions will suffer in one way or another after a time, but in a healthy community serious breakdown will not be encountered very often, and there will be little reference to the condition in routine sickness returns. Most of these effects can be surmounted temporarily when it is necessary to make a special effort, and are relieved by resumption of life in a cooler climate.

The evidence available suggests that hot-climate fatigue does not raise many serious problems among the male naval community in Singapore Island but becomes increasingly prominent with long service afloat in a tropical climate.

This account is published by permission of the Admiralty and the Medical Research Council's Royal Naval Personnel Research Committee. I am indebted to the Commander-in-Chief, Far East Station, and the Flag Officer, Malayan Area, for permission to circulate the questionnaire; to Surgeon Commander T. Barlow, R.N., who arranged for its distribution and collection in the cruiser; to the officers and men who provided the answers; and to Sir Frederic Bartlett, Dr. R. K. Macpherson, Dr. J. O. Irwin, and Dr. K. Cameron for helpful advice.

THE HEALTH OF THE ARMY

In the complexities, stresses, and strains of modern warfare, health has become increasingly important to the fighting Services; and the switch of emphasis from the prevention of disease to the attainment and maintenance of health is shown by the change of title of the Directorate of Hygiene to that of Army Health. This tendency can also be seen in the recently published Report on the Health of the Army in the years 1946–48, which covers the period of demobilisation and run-down from the war-time peak.*

HEALTH EDUCATION

An accurate definition of "health" and a satisfactory method of assessing it are essential; and the chapter on recruiting and medical classification is important. The introduction in 1948 of the PULHEEMS system of medical classification into the three Services improved the assessment of physical and mental health; and the Interdepartmental Standing Committee on Medical Classification, set up in the same year, was given the responsibility, among others, of keeping the PULHEEMS system up to date. The lead given by the Services in medical classification and in personnel selection might with advantage be followed in civilian life to a greater extent than at present.

During these post-war years physical training was modified in accordance with the Army's changing requirements. Coöperation between physical-training staffs and the medical services became closer; and medical supervision of the recruit and the trained man in their basic and battle training, and tests, was intensified. The remedial aspect of physical training for the sick and wounded and for the substandard recruit was also developed, especially at the three physical-development centres, where the physique of substandard recruits was built up. In 1946 these three centres were amalgamated in one centre at Chester, accommodating 1800 recruits. In 1948 man-power shortage led, unfortunately, to its closure. Presumably mobilisation plans provide for these centres to be reopened. But it might be worth considering whether these substandard recruits should not be detected long before call-up, and given physical-development courses under civilian auspices before they leave school.

The Army tackled health education vigorously. All cadets and recruits, and all officers, N.C.O.s, and trained men received essential instruction, planned according to their needs, from medical officers, and instructors trained at the Army School of Health. At the school and in centres abroad, courses were held for unit sanitary and water-duty personnel. Instruction on service in the tropics and subtropics was given on all troopships proceeding to the Middle and Far East. All possible use was made of films, filmstrips, models, pamphlets, books, and the like. The difficulty was to ensure that, in the welter of training and instruction which the soldier received, sufficient time was set aside for education in health. In this the support of the military training authorities was invaluable.

ENVIRONMENTAL RESEARCH

During the late war personnel research was carried out under the ægis of the Military Personnel Research Committee, which lapsed in 1945. In 1948, in view of the increasing complexity of modern equipment and of the wide range of environments in which the soldier of today has to serve, a new committee was formed, under the chairmanship of Sir Charles Lovatt-Evans, F.R.S., to consider applied physiological and psychological research. The members include civilian physiologists and psychologists as well as representatives of the three Services and of the Ministry of Supply. Four subcommittees deal with special aspects of the work, such as clothing and equipment, fighting vehicles, and steel helmets and body armour. Some progress has been made, but the personnel and resources for the large amount of applied research required seem inadequate. Fundamental research remains the responsibility of the Medical Research Council through its Interservices Personnel Research Committee.

---

* This report is not on sale, but copies have been sent to learned societies.

Of recent years soldiers have been increasingly exposed to industrial hazards owing to the formation of large workshops, light-aid detachments, and similar units. It became clear that to combat these hazards the Army needed outside help; and a committee was set up, under the chairmanship of Dr. E. R. A. Merewether, H.M. senior medical inspector of factories, which included representatives of the three Services and of the Ministries of Health, Supply, Labour, and National Service.

PREVENTION OF DISEASE

No striking advances in prevention were made in the period under review, but research was continuously in progress.

In 1948 proguanil was substituted for mepacrine in prophylaxis against *malaria*. Proguanil causes no skin discoloration, and a shorter period of build-up is required.

A sharp increase in *diphtheria* among troops in Germany at the end of 1945 led to an inquiry into the immunisation state of recruits; and in 1946 instructions were issued for the Schick-testing, and immunisation when necessary, of all recruits. This measure is now normal practice; and in Germany, along with other more local measures, it resulted in a drop in diphtheria incidence from 3·06 per 1000 in 1946 to 0·95 in 1948.

In Germany and Austria *acute ulcerative gingivitis* also caused much anxiety. Here the only certain method of prevention was a high standard of oral hygiene and, in treatment, penicillin.

Native food-handlers in kitchens and messes were considered to be responsible for small localised outbreaks of the *enteric group* in the Middle East. It was difficult to trace the carriers owing to the intermittency of the condition. A contributory factor was the relatively low standard of accommodation and sanitation in many parts of the Middle East. Together with fly infestation, this was also responsible for much of the dysentery in the Middle East. In fact, in the years under review the incidence increased from 24·05 per 1000 in 1946 to 33·01 in 1948. The dysentery-rates for the Middle East were higher than those for the Far East. The failure to improve this situation, despite adverse factors, should be investigated further.

In 1947 there was not a single case of *cholera* in British troops or their families, though in Egypt they were living in the closest proximity to the outbreak in the Canal area; all those concerned deserve the highest credit. Reliance was placed mainly on general measures, and on the coöperation of the Forces in these measures. It was at a late stage in the outbreak, when the battle was already almost won, that popular anxiety at home led to inoculation of the troops with cholera vaccine.

Venereal disease in Germany and in the Far East caused concern in 1946. Since then there has been a steady improvement in the Far East and a dramatic drop in Germany. In the Middle East the rates were comparatively low, and in the United Kingdom low.

The introduction of chloramphenicol in 1948 completely changed the outlook for *scrub-typhus*.

Skin diseases remain, as in the past, an important cause of sickness and inefficiency. Apart from scabies, which runs parallel with venereal disease, the type of case varied with the Command. In the Far East fungus infections caused the most trouble, in the Middle East septic conditions. In 1948 a team visited the Far East to study improved methods of prevention of skin diseases. An investigation at Aldershot in the same year showed that in a random sample of 1016 newly joined National Servicemen 3·67% had tinea pedis. Communal showers and swimming-pools were thought to be more important causes than hyperhidrosis.

The average incidence of *tuberculosis* in overseas theatres was less than 1 per 1000 per annum. In the United Kingdom it was about 3 per 1000 owing to the inclusion of recruits found by mass miniature radiography to be infected on entry. Mass miniature radiography was carried out mainly by 10 mobile Army teams, but the Ministry of Labour and National Service has now agreed to this work being done at the initial medical board. Owing to shortages of staff, apparatus, and accommodation, the take-over by the Ministry is gradual, and it will be some time before the transfer is complete.

The war-time emergency vaccine laboratory at Everleigh has been transformed into an independent unit, with the title of Army Vaccine Laboratory. It has a mixed military and civilian staff divided into a bacteriological department for the preparation of immunising vaccines and diagnostic sera and suspensions, and a transfusion department for the preparation of crystalloids and the servicing of transfusion-sets. In 1948, 960 litres of T.A.B. vaccine were produced, and 198 litres of other kinds of vaccine.

PROBLEMS OF INTAKE

Psychiatric disorders accounted for 9 discharges per 1000 of the strength each year—far in excess of any other cause. Every effort was therefore made to screen thoroughly the recruits at intake centres. Personnel selection officers interview each recruit and refer to a military psychiatrist all who are so dull as to be unlikely to absorb military training or who appear to be of doubtful stability for a Service life. The rise in the percentage of intake referred from 10% in 1946 to 17% in 1948 was due rather to an increasing awareness of the value of the psychiatric screen than to deterioration in quality of the intake.

The problem of the employment of men of low intelligence remained as difficult as ever, as also the special problems of the S.G.5 group—i.e., the lowest group in terms of ability to learn—into which approximately 13% of the Army's recruit intake fell. About 5% of the Army's recruits were unable to assimilate normal training and had to be allocated to the Royal Pioneer Corps for simple labouring duties.

HOSPITAL PROBLEMS

On the surgical side in 1946–48 there was a steady decline from a first-class and fully staffed specialist service in the Royal Army Medical Corps to an overstretched service of doctors with minimum specialist cover. Furthermore, there was the general difficulty of recruiting doctors for the R.A.M.C., on account of unsatisfactory pay and conditions of service. At the same time overseas responsibilities increased greatly; for in certain commands British civilian members of the Control Commission became entitled to treatment, and the number of military families increased greatly. A high standard of surgery was, however, maintained, and a policy adopted of evacuating early from overseas long-term cases and those needing highly specialised forms of treatment.

The hospital admission-rates per annum among British troops in the four large commands over the three years were as follows (per 1000 strength):

	1946	*1947*	*1948*
U.K.	432	360	311
Germany	499	586	456
Middle East	479	390	473
Far East	685	571	551

CONCLUSION

The progressive attitude of the Army medical authorities shown in this report can reassure us all that the soldier is in excellent hands. The National Serviceman should return to civilian life physically and mentally improved, and the cumulative effect of this on the nation as a whole must be considerable. Inter-Service coöperation and liaison with the civilian medical world, which was such a profitable feature of the war years, has continued and indeed increased. Moreover, the opportunities for research in the controlled community of the Army are clearly not being lost.

In England Now

A Running Commentary by Peripatetic Correspondents

WE are daily assailed by warnings that the population is ageing, and that in 40 years a handful of wage-earners will be attempting to support a ponderous agglomeration of unproductive and senile citizens. A colleague recently pointed out to us that attention has not been adequately drawn to the increase in the rate of advance of old age, and adduces as evidence the fact that for him the millennium is here and now. Though a man of only some 48 winters, his ulcer is already well established, and his asthma and his rheumatism trouble him at night. His discs do not prolapse in a well-conducted way, but moulder away quietly, and already he has reached a stage of forgetfulness which would do credit to a stage professor. The crowning blow came the other day, when he went to his dentist for a regular check-up and was told that his teeth were being attacked by a disease of old age.

Unfortunately the potential wage-earners in his family are not yet of an age at which he can hand on the torch to them, being 6 and 2 respectively, so he is battling on despite his manifestly outworn mental and physical equipment—a man in advance of his time.

* * *

Last week I had a kind of busman's holiday attending the British Pharmaceutical Conference at Nottingham, and I found that the buses our pharmacist brethren drive are pretty complex affairs. Early in the proceedings a paper on the structural requirements for antibiotic activity in the chloramphenicol series showed me how little I know of modern pharmacological chemistry; after which the coup de grâce was administered by a discussion on polarographic determination of riboflavine. I gathered from the cognoscenti that the standard of the more esoteric papers was as high as the standard of those I could understand. In a symposium on the pharmacy of antibiotics there were some interesting remarks on what the pharmacist can teach the doctor; and, though some dissentients thought that physicians resented any such attempt, I for my part am willing to learn about all new drugs from any informed person—as indeed most of us are.

One speaker quoted Sir A. V. Hill's recent praise at the British Association for the scientific attitude of industry in this country, and claimed that the section which most deserved approbation was the pharmaceutical. There might have been a little of the "Here's tae us, wha's like us!" spirit in this, but nevertheless the conference was itself good evidence in support of the claim.

* * *

I have always prided myself on an ear for accents. I used to boast that I could spot a patient's origin and upbringing after about three sentences. But never again. After that young woman who has just left I've finished with country and class spotting for good.

"Aim a little worried about meh haht," she said. (Ah, English public school of course—Roedean, Wycombe, Cheltenham. One of those.) But the lady had not been registered before. How was that? "Well, as a metter of fect, Aim not English."

"No, no, of course not. Your name is, let me see, ah yes. Miss Pumpernickel. You will be German then?"

"Er ner, Aim not German."

"No? What are you then? You ought to be English by your accent."

"Ai expect Ai picked up meh accent from the English girls in Geneva. As a metter of fect Aim an American, and Ai wanted to awsk you if meh haht——"

* * *

The trial of suramin in cases of ocular onchocerciasis in the Gold Coast has been encouraging, but the treatment often has unpleasant side-effects—œdema of the feet and hands, severe pruritus, and sometimes loss of taste. Here is one patient's story, in his own words.

"I get four injections it begin me small. I feel from the foot it come for my hand it come for the body the skin no good at all it be tight. I get five injections it get me down I no fit get up. My tongue he bigger but no sore. I am feeling cold. If you chop something you never savvy he be good or no good. You savvy pepper. Sweet thing you never know him at all. You no fit bend your hand at all. Skin be like alligator. You feel scratch—too much, he no be small thing. All my foot make sore sore.

"That time you never inject me I never see fine. I fit shoot to here (*10 yards*). Now I fit shoot guineafowl as far as the school (*100 yards*). My eye get strong proper. Long time I never fit do this before."

This patient has at least recovered the full use of his limbs. He recently returned, on foot, from a visit forty miles away, and has been fined for beating his wife. I have no evidence on his savvying or not savvying sweet things; his wife might perhaps hold decided views.

* * *

I have to report two serious cases of hat-addiction. The first is that of a harbourmaster aged 75 who is convinced that to be bareheaded except when indoors is for him synonymous with death. Two years ago he and his son Daniel spent many anxious hours of darkness in a dinghy picking up craft of various kinds which had broken from their moorings during a heavy storm, and towing them to places of comparative safety. In the middle of one of these trying and dangerous manœuvres the harbourmaster's hat blew off. He clapped his hand in despair to his bare, bald head. "'Tis all over," he cried, "I'm gorn." Acting with prompt devotion Daniel snatched off his own hat and crammed it on to the old man's head. "No, father," he shouted, "you'm all right!" The old man is certain that his life was thereby saved.

The second case is that of a stonewaller aged 82 whose just pride it is that the walls he builds never fall down. He also works with his son, a promising kid of about 45 who should, according to his father, make a good stonewaller one day. The son states that only once has he seen his father without his hat, a battered bowler worn indoors and out, and even in bed. Five years ago the old man had to have a prostatectomy, from which he made an uneventful recovery. While he was in hospital his son visited him and walked straight past his bed. "Diddn reckernise 'im, y'see," he explained. "'E addn got 'is 'at on."

* * *

Which is the better reformer—the reasoner or the agitator? Most of us, I suppose, would say the reasoner, but when it's a matter of getting something done quickly, I fear the agitator has it. Our son, aged two and five months (2·416 yr.) obviously thinks so. My wife had dragged him into the local fish-shop, though he wanted to be at the level-crossing; and she was expecting crescendo screams of "want to see trains." But with the distractibility of children he soon noticed the flies hovering over the fish, and since he is scared of flies he informed the queue that they wouldn't hurt. Passing from the pragmatic to the more purely conceptual aspects of the fly-cloud, he said "Look at the nasty flies! What a lot of nasty flies! One, two, six, eight" (his scale of numbers has got some missing rungs). He thought this was a good word-collection, and kept on using it loudly and clearly. Most of the queue laughed, but some looked embarrassed, and others began to mutter "There *are* a lot of flies." The fishmonger himself made no comment, but he had an electric fan put in the next day. Another triumph of agitation?

* * *

The window-cleaner poked his head in. "Better now, sir?" "Much better, thank you, Tom." "What exactly is the matter, sir?" I began my prepared statement in monosyllables. "You know the bones in the back? Well, between them there are bits of . . ." "Oh, it's a disc, is it?" "So they say, Tom." "I know just what it's like: a cold wind goes right through you like a knife. It strikes the kidneys, no matter what you wrap up in. It proper doubles you up. It's quite the fashion these days, though I never heard tell of it before. It could be these artificial fertilisers they put everywhere, don't you think so? Myself, I think it's rheumatics. Well, so long sir, take it easy." He disappeared down his ladder.

Letters to the Editor

SELECTION OF MEDICAL STUDENTS

SIR,—In the interesting discussions on this subject in your issue of Aug. 30 little or no attention was given to the *size* of the problem.

About 2700 medical students are accepted annually; no-one seems to know what is the total number of applicants. At University College it seems that 600 students apply for 60 places; at less well favoured schools the ratio of applicants to places is apparently 7, 6, or 5 to 1. But it is well known that students generally apply to many schools, sometimes to all, in the hope of being admitted somewhere. The total number of university undergraduate students in all faculties is about 84,000—or, say, about 25,000 in each year of study. Is it to be supposed that all or even a substantial proportion of the students in the faculties other than medicine wanted to do medicine but failed to find a place? One occasionally meets a student who failed to be accepted anywhere, but there is no evidence that such cases are numerous; there is, for instance, no association of indignant rejected applicants. The matter could easily be settled if all candidates were required to fill in their application forms in duplicate, and one of the copies was sent to a central registry which collated the information. I gratuitously suggest that such a registry might be set up by the General Medical Council, the Royal Colleges, the ever helpful Nuffield Trust, or one of the universities. I hazard a guess that such an inquiry would show that the majority, perhaps the great majority, of those wanting to do medicine find places, although not necessarily in the school of their first choice.

I think we are too ambitious in our attempts at student selection: we aim at choosing the best; we should be satisfied to exclude the worst. We, of course, all know the ideal student: tall, handsome, of great personal integrity, beautifully mannered, cultured, highly intelligent, a tireless worker, original, good with his hands, skilful in exposition, a good mixer, athletic, devoting his spare time to extramural activities, with a good family background, and so on and so forth. But, of course, such students do not exist. The qualities required for success in the many occupations which a doctor can take up are so varied that I imagine that no group of selection tests, however elaborate, can be reliable. How is one to select, say, the future editor of THE LANCET, the medical officer of a Polar expedition, or an able academic research-worker? What, however, we can and must do is to exclude the student who is unlikely to display a certain minimum standard of intellect and industry; I suggest that this minimum might be the ability to get a pass or a near-pass at the 2nd M.B. at the first attempt and to get through without undue effort at the second attempt (should that be necessary). As some of your correspondents have pointed out, a candidate's school record and an honest report from the school authorities are a fair guide; the standard of performance at the 1st M.B. or the higher school certificate is even more helpful. But one should always allow for a margin of error of, say, 10–15%; and some deans, in deciding the number to be admitted, assume that a small proportion of their students will fall by the wayside for one reason or another.

The statistical inquiry that I have suggested will probably show that more students of the minimum standard set out above apply than there are places for. I doubt whether it is worth trying to sift them too thoroughly. Any method used will reject candidates who are as good as those who are selected. By allowing deans or selection committees scope for their individual whims and fancies we shall probably get students with the wide range of valuable supplementary qualities that the community needs.

HÆMOPOIESIS IN THE FŒTUS

SIR,—When I first became interested in hæmatology some thirty years ago, it was customary to describe megaloblastic blood formation as seen in cases of pernicious anæmia as a reversion to an embryonic or fœtal type of hæmopoiesis. Presumably this conception was largely based on the original description by Ehrlich, who gave the name of "megaloblast" to certain primitive nucleated red cells in the embryo. The modern view is that megaloblastic blood formation results from a deficiency of certain hæmopoietic factors (vitamin B_{12}, folic acid, &c.). Since there is no reason why the fœtus should be deficient in these factors, it seemed to me difficult to understand why fœtal hæmopoiesis should be megaloblastic.

Accordingly, I decided to examine films made from the bone-marrow and from the juice expressed from the cut surface of the liver of embryos of different ages. The films were stained with Leishman's stain. Dr. Agnes [illegible] was able to provide me with [illegible] liver-juice films from one fœtus of 16 weeks, one of 20 weeks, two of 22 weeks, two of 26 weeks, and one of 34 weeks. In every instance blood formation was normoblastic in type, and most of the nucleated red cells were late normoblasts with late pyknotic nuclei.

A.C.T.H. AND ASCORBIC ACID

SIR,—Since the preliminary communication by Lewin and Wassén[1] there have been many reports concerning the action of ascorbic acid on rheumatoid and formalin arthritis. On the basis of our observations on the potentiation of the thymolytic effect of A.C.T.H. by ascorbic acid (unpublished data), we performed the following experiment.

In normal male albino rats, weighing 130–150 g., formalin arthritis was produced by injecting 0·1 ml. of 2·5% solution of formalin beneath the plantar aponeurosis of the right hind-leg. The inflammation of the joints was assessed by measuring daily the volume of the extremity by Bacchus's method.[2]

In the first part of the experiment 25 animals with formalin arthritis were divided into five groups and treated daily with A.C.T.H. (Armour) subcutaneously and ascorbic acid (A.A.) intraperitoneally. The data are briefly presented in table I.

TABLE I—EFFECT OF A.C.T.H. AND ASCORBIC ACID IN ARTHRITIC RATS

Group	Daily treatment	Swelling of the leg (c.cm.)*
1	1 mg. A.C.T.H. in 0·5 ml. 1 ml. 0·9% NaCl	0·314 ±0·024
2	0·1 mg. A.C.T.H. in 0·5 ml. 1 ml. 0·9% NaCl	0·356 ±0·039
3	50 mg. A.A. in 1 ml.	0·343 ±0·016
4	1 mg. A.C.T.H. in 0·5 ml. 50 mg. A.A. in 1 ml.	0·125 ±0·014
5	0·1 mg. A.C.T.H. in 0·5 ml. 50 mg. A.A. in 1 ml.	0·209 ±0·025

* Mean value of all measurements over a period of 6 days and standard error of the mean.

There was a significant difference between the animals treated with 1 mg. A.C.T.H. daily, and the group that received the same dose of A.C.T.H. combined with ascorbic acid ($p<0·001$). In the same way the addition of ascorbic acid

2. Bacchus, H. *Endocrinology*, 1951, 49, 789.

TABLE II—EFFECT OF CORTISONE AND ASCORBIC ACID IN ADRENALECTOMISED ARTHRITIC RATS

Group	Daily treatment	Swelling of the leg (c.cm.)
1	1 mg. cortisone in 0·5 ml. 50 mg. A.A. in 1 ml.	0·440 ±0·013
2	1 mg. cortisone in 0·5 ml. 1 ml 0·9 %-NaCl	0·420 ±0·013

increased the effect of a dose of 0·1 mg. A.C.T.H. ($p<0{\cdot}01$). Finally, there was a significant difference in the presence of ascorbic acid between 1 mg. and 0·1 mg. A.C.T.H. ($p<0{\cdot}01$), whereas without ascorbic acid there was no statistically significant difference between these doses ($p>0{\cdot}05$). Ascorbic acid alone did not modify the formalin arthritis more than A.C.T.H. alone.

In the second part of the experiment we tried to exclude a peripheral synergism of cortisone (Merck) and ascorbic acid. 10 adrenalectomised animals with formalin arthritis were given cortisone subcutaneously and ascorbic acid intraperitoneally. The results are given in table II.

This table shows that the activity of cortisone applied in these doses cannot be potentiated by ascorbic acid ($p<0{\cdot}05$). This experiment indicates that there is neither a peripheral synergism of corticoids and ascorbic acid, nor a peripheral sensitisation of the tissues by ascorbic acid to the action of corticoids.

These experiments accord with the well-known, but not generally accepted, assumption that ascorbic acid acts at the level of the adrenal gland on the synthesis of corticoids.[3] There is, however, still another possibility—that A.C.T.H. is inactivated at a slower rate in the presence of large quantities of ascorbic acid.

These experiments were carried out at the Institute for Industrial Hygiene, Yugoslav Academy of Science, Zagreb.

OBSERVATION ON WHOOPING-COUGH

SIR,—I should like to record a personal clinical observation.

At the end of August, 1951, I had the misfortune to develop whooping-cough, having caught it from my 3-year-old daughter, who in turn had caught it from her 5-year-old cousin. During the 2nd week of my attack, I developed an area of hyperæsthesia in the posterior part of each external auditory meatus, and any stimulus (such as the introduction of an aural speculum) to this area induced a typical attack of paroxysmal coughing. After about 6 weeks this phenomenon ceased, and stimulation of this area did not produce any cough at all.

I suggest that this observation adds, although slightly, to the evidence in favour of the paroxysmal stage of whooping-cough being due to a toxin produced by *Hæmophilus pertussis,* rather than to the accumulation of secretions following damage to the cilia[4] or to enlargement of the tracheobronchial glands. Damage to the cilia and enlarged tracheobronchial glands occur in many other conditions, but the typical paroxysmal cough terminating in vomiting is rare except in whooping-cough.

That *H. pertussis* produces an endotoxin has been known since the original papers of Bordet and Gengou (1906). More recently Evans and Maitland[5] have studied the characteristics of a thermolabile toxin, and Flosdorf and Kimball[6] have described a thermostable toxin. Thompson[7] prepared an endotoxin which he used therapeutically. He noticed that a few hours after subcutaneous injection there was exacerbation of coughing paroxysms. Many physicians believe that convulsions and encephalitis may sometimes be due to the toxin[8]; and Laurent[9] and Dolgopol[10] hold that on rare occasions a secondary encephalitis reaction may be observed in addition to the circulatory lesions. There is, therefore, evidence for the production of a neurotoxin, and some workers[8] consider that this toxin sensitises nerve-endings in the respiratory mucosa to external stimuli. In consequence of the observation recorded above, I would suggest that the toxin acts on the vagus nerve, after the fashion of tetanus toxin, the (?) toxin of eclampsia, and strychnine, all of which sensitise the nervous system so that it reacts violently to trivial stimuli.

Further circumstantial evidence to the hypothesis that the catarrhal stage of whooping-cough is due to local infection with *H. pertussis* whilst the paroxysmal stage is due to a neurotoxin is found in the reports on treatment of whooping-cough with the modern antibiotics. Most workers agree that the best results are obtained if chloramphenicol is given within the first 2 weeks of the disease, the treatment having little effect once the paroxysmal stage is really established.[11] This observation is analogous to the neuritic complications of diphtheria, in that by the time the paralyses develop in diphtheria the local bacterial infection has usually ceased to be significant. The action of the pertussis neurotoxin, however, would appear to be excitatory rather than depressant.

London, W.5. M. D. WARREN.

BOXING CONTESTS

SIR,—I would be interested to know if Dr. Blonstein could justify his statement last week that boxing fosters a high physical and moral standard in the nation's youth.

Physically the muscular development produced by training will raise the performer's ability for muscular work, but much of this is temporarily or even permanently offset by injuries. I do not know of any evidence that muscular development protects an individual against disease. During my Service life in the R.A.F. I looked after a physical-training school, where the sickness-rate was as high as among other airmen and the accident-rate much higher.

As regards moral betterment I feel that Dr. Blonstein has a much weaker case. The training of individuals to dominate each other by physical force is surely a poor training in social adaptation and peace.

The educational effect of watching such contests is about as high as that of reading the baser comics.

HICCUP DURING ANÆSTHESIA

SIR,—Most of the letters on this subject have referred to hiccup during upper abdominal operations. I should like to describe a case where it occurred during an appendicectomy.

A healthy male European, aged 32 and weighing 12 st. 8 lb., was admitted with lower abdominal pain and vomiting of 2½ hours' duration.

At operation he was given sodium thiopentone (1·5 g.) and 'Flaxedil' (80 mg. followed by 60 mg.). The operation lasted 40 min. He started to hiccup when the appendix was pulled upon, and he stopped when the appendix was severed.

The second dose of flaxedil was given during the period of hiccup; nitrous oxide was given to dilute the oxygen, but had no effect.

I can offer no explanation of this case, but I think it is worth recording.

Jokai Central Hospital, Assam. D. A. H. MCNAUGHT.

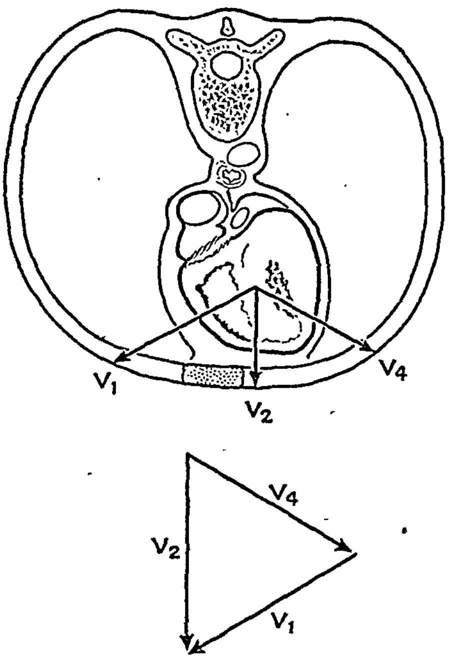
LEADS IN ELECTROCARDIOGRAPHY

SIR,—We would like to make some comments on your leading article on this subject (May 31).

The different leads used in electrocardiography can be set out usefully and clearly by a geometrical method. The classical Einthoven's triangle is an example of how to represent the three standard leads. But any lead can be defined by a segment of a straight line orientated in space [1]: we call this line the axis of the lead. The axis of a unipolar lead lies on the straight line connecting the centre of the heart with the exploring electrode. The axis of a bipolar lead does not always lie on the line connecting the two electrodes, but can be found in a simple geometrical way.

What we record in any lead is the projection of the electrical vectors upon the axis of the lead. The axes of the standard leads are situated in the frontal plane, and therefore they record the electrical activity of the heart, projected on the frontal plane. The axes of the precordial leads are situated in the horizontal plane, and therefore one would expect them to record the same phenomenon as the standard leads, projected on the horizontal plane. But a different conception has been widely accepted: these leads have been thought to record almost exclusively the activity of the myocardium immediately beneath the exploring electrode. This conception may seem justified by the fact that the precordial leads are unipolar and the exploring electrode is near the heart. In fact such a fundamental distinction between bipolar and unipolar leads is not justified. What defines any lead, either unipolar or bipolar, is its axis.



It has been shown experimentally, for instance, that a unipolar and a bipolar lead record the same tracing when their axes are parallel.[2] Actually the similarity usually seen between I (bipolar and limb lead) and V6 (unipolar and precordial lead) is due to the similar orientation of their axes.

We submit that the proximity of the exploring electrode to the heart is quite relative, and does not allow any great "selectivity" in differentiating the various parts of the heart.

It has been shown [3] that, as a rule, the precordial leads record the activity of the heart in toto, and not of a single part of it. Moreover it is well known from physics that to put an electrode very near to an electrical source of energy is not always the best method of recording a higher potential; if the electrode is, for instance, on the perpendicular to the vector representing the electrical source—i.e., equidistant from its negative and positive sides—there will be no potential recorded, however near to the electrical source the electrode may be. Other objections have been raised to the so-called "local effect" theory.[4–6]

We think it is unjustifiable to consider the precordial leads to be so different from the limb leads as to need the interpretation that has been given them in English-speaking countries. Both the standard and the precordial leads obey the law of the projection of the electrical vectors upon the axes of the leads, and they record the same phenomenon; only the plane of the projection is different.

In other words, the same relationship exists between standard and precordial leads as, for instance, between anteroposterior and lateral or oblique views of the thorax in radiology. The analogy between standard and precordial leads is such that it is possible to find a system of three precordial leads which form, with their axes, a horizontal equilateral triangle, similar to the frontal one of Einthoven.[7]

The accompanying figure shows the axes of these three leads, and the equilateral triangle formed by them.

With the "local effect" theory one must always accept the possibility that a part of the heart may have escaped exploration, however numerous the precordial leads; but we feel that the examination can be satisfactorily carried out with these three leads alone. We think therefore that the precordial leads should be interpreted in the same general way as the standard leads.

COMPLICATIONS OF CONTROLLED HYPERTENSION

SIR,—In your leading article of July 5 you refer to a report of mine [8] on the effect of intravenous hexamethonium bromide on kidney function.

I should like to correct the impression conveyed by your article that the dose used each time was 100 mg. In fact, this very large dose was used in only one patient, who had already become habituated to the drug. In the remainder the dose varied from 15 to 50 mg.

NICOTINIC ACID AND BURNING FEET

SIR,—A 31-year-old man with lupus vulgaris of the face was treated with isonicotinic acid hydrazide 150 mg. daily by mouth. After one week's treatment he developed a severe burning sensation of the soles of the feet—"as if there was a fire under my feet." This sensation continued for 2 days after the tablets were discontinued. He then, of his own accord, took a reduced dose of 50 mg. daily for 3 weeks without ill effect. The patient has always had hyperhidrosis of the feet, and on one occasion he developed a mild burning sensation in the feet while taking medicine of unknown nature.

The symptoms in this case recall the "burning feet" syndrome described in India and in Japanese prisoner-of-war camps. This syndrome is characterised by severe burning or freezing sensations in the feet, accentuation of the reflexes, and hyperhidrosis of the feet. While accentuation of the reflexes is a well-recognised effect of isonicotinic acid hydrazide, burning feet has not been reported before, as far as I am aware, as a toxic effect of the drug. The hyperhidrosis was present already in this case and so cannot be ascribed to the action of the drug. Gopalan [9] has ascribed the "burning feet" syndrome to deficiency of pantothenic acid, but the findings in the case described here suggest that nicotinic-acid deficiency may play a part in the ætiology of this condition, since isonicotinic acid hydrazide may conceivably block the action of nicotinic acid by competitive inhibition.

CHLORAMPHENICOL IN ERYSIPELOID OF ROSENBACH

SIR,—I have found that chloramphenicol inhibits in vitro the growth of *Erysipelothrix rhusiopathiæ*, and I recently gave the drug to 4 patients with erysipeloid of Rosenbach, 2 of whom had not responded to treatment with penicillin.

Doses of 2 g. per day produced rapid resolution in 3 cases; in fact, after the first day of treatment, pain, œdema, and erythema quickly subsided, and after the third day only pigmentation and desquamation remained.

The 4th case was more resistant, and vivid-red erythematous areas persisted at the circumference of the lesion. But healing was complete after five days' treatment. Supplementary local treatment with 2% chloramphenicol in a base of 'Carbowax' produced no local or general intolerance.

This is insufficient evidence for a definite conclusion, but it justifies further study of the drug in erysipeloid.

MALARIA

SIR,—I feel humble and appreciative in respect of your review (Aug. 30) of my book on *Malaria*. One point, however, disturbs me. I want to make it clear that I have the highest respect for, and I accept, the work of Shortt and Garnham and their colleagues on the pre- and exo-erythrocytic stages of malaria plasmodia. My term "in the shadows," referring to these early forms of the parasite, seemed fair when I wrote it because the earliest development following the sporozoite had not been described by any observer. Even today, although further progress has been made, there remain points that are not clear. It was not my intention to reflect on the fundamental studies mentioned, to which in fact I gave full credit in the short historical chapter of the book.

PAUL F. RUSSELL.

SORE THROAT AND RHEUMATIC FEVER

SIR,—In his letter (Aug. 16) Dr. Collis asserts that "Schlesinger's contribution was his observation of the silent period between the initial throat infection and the subsequent rheumatic-fever attack, or relapse, and the effect on the subsequent attack of salicylate if given during the silent period."

Schlesinger, as far as I know, has never claimed that he first observed the silent period, although he was an ardent advocate of salicylate therapy, as he made clear in his Milroy lectures of 1938.[1] I suggest that the chief credit for observing the silent period goes to C. Haig-Brown, who in *Tonsillitis in Adolescents* (1886) wrote:

> "An attack of acute rheumatism is very frequently preceded by one of acute tonsillitis, it may be by as long a time as five or six weeks, but more usually ten days or a fortnight; while, as has been already stated, the two may be coincident in time. In fact, it is rare to meet with a case of rheumatic fever which has not been recently preceded by a sore throat; and though I am not prepared to say that tonsillitis is the fore-runner or the companion of every case of rheumatic fever, the last eleven cases of the latter which I have had to treat have, within six weeks of the onset of the joint-pains and fever, been under my hands with sore throats."

This was probably not the original description, for Haig-Brown modestly says:

> "As has been observed by others than myself, it is very frequently found that the subject of articular rheumatism has had a 'sore throat' perhaps a month, but more commonly ten days or so, before he felt pain in his joints, or that simultaneously with the joint-affection, there is tonsillitis."

MEPACRINE AND RHEUMATOID ARTHRITIS

SIR,—We have read with interest the preliminary communication by Dr. Freedman and Dr. Bach (Aug. 16). Since Page's[1] report appeared, we have used mepacrine on a limited scale in selected cases.

A young woman with acute lupus erythematosus was dangerously ill when treatment with A.C.T.H. was started. She improved rapidly, but on account of side-effects of A.C.T.H. we tried mepacrine with apparently good results. The withdrawal of mepacrine was followed by deterioration.

We have given mepacrine to 11 patients with rheumatoid arthritis. The longest period of observation is five months and the shortest six weeks. All of the patients declared that their pain gradually eased, and in 5 there is already definite objective improvement. Treatment with mepacrine is not followed by eosinopenia or increased excretion of 17-ketosteroids; nor is the erythrocyte-sedimentation rate or temperature influenced in our experience.

During the last two years, 2 patients with bronchial asthma have been admitted to our hospital repeatedly on account of status asthmaticus. Several times we have had to use A.C.T.H. for short periods. Six months ago we started giving these 2 patients mepacrine. Follow-up examinations have shown that both are entirely free of symptoms and signs of bronchial asthma.

We agree with Freedman and Bach regarding dosage and length of treatment. The variable course of rheumatoid arthritis and bronchial asthma makes it very difficult to differentiate between a spontaneous remission and an effect of administering mepacrine. We hope that extended trials of mepacrine will soon solve this problem.

ARNFINN ENGESET.

AVERSION TO ALCOHOL

SIR,—The chance observation by Dr. Walker and Dr. Boyd (Sept. 6) that a heavy beer drinker exposed to tetraethyl lead (T.E.L.) abruptly stopped drinking (and also developed a voracious appetite) a few weeks before being admitted to hospital for T.E.L. poisoning, is of great interest to those engaged in the study and prevention of alcoholism. The same voracious appetite and distaste for alcohol was observed in 1938 in a number of workmen exposed in a clay pit to hydrogen sulphide.[2] The advent of 'Antabuse' (not 'Antabus' as recently adopted by THE LANCET) has stimulated interest in substances—of which there are quite a number[3]—causing aversion to or distaste for alcohol, which are not the same things.

In the case of antabuse it is an aversion, for one avoids contact with alcohol because of the unpleasant symptoms which then supervene. A similar aversion appears to exist in the initial stages of Hodgkin's disease, where pain, cough, and itching become intensified on taking even small amounts of alcohol.[4] On the other hand, hydrogen sulphide appears to produce a distaste, no other symptoms except the voracious appetite being reported.

Chance observations such as these may help us eventually to find a means of readjusting physiological imbalance as the cause of alcoholism. This society is anxious to collect further observations of the kind, especially on substances producing distaste or disinclination for alcohol.

ANTITHYROID ACTION OF P.A.S.

SIR,—Clausen and Kjerulf-Jensen[1] have described three cases of thyroid enlargement with myxœdema during *p*-aminosalicylic acid (P.A.S.) therapy, and Komrower[2] has reported another. I should like to add a further case.

An unmarried woman, aged 23, was admitted to hospital on July 3, 1951, with pulmonary tuberculosis of two years' duration, clinically affecting the right lower lobe. A chest radiograph showed, in addition to the disease at the right base, some apparently new lesions at the left base. In view of this, chemotherapy was decided upon. Thiosemicarbazone ('Ethizone') (starting dose 50 mg., then 150 mg. daily) and sodium P.A.S. (3 g. four-hourly) were given.

On Sept. 17 (eleven weeks later) she complained of a swelling in the neck, and a soft diffuse, non-pulsatile, slightly tender swelling of the thyroid gland was felt. The pulse-rate was normal and the blood-pressure was 100/70 mm. Hg. There was no exophthalmos or sweating. Both drugs were stopped immediately; a total of 1170 g. of P.A.S. and 7·75 g. of ethizone had been given. She was watched for further signs of disturbed thyroid function, but none developed.

Five weeks later (Oct. 23) the swelling had subsided. The chest radiograph was unchanged. Further progress was uneventful; the left basal signs subsided, leaving the right side unchanged.

On June 18, 1952 (about eleven months later), the thyroid gland was just palpable. Her weight had remained steady at 7st. 7½ lb.

The patient has an immature and hysterical personality. She has had an unhappy home life with life-long episodes indicative of instability and insecurity. She is prone to temper-tantrums and on Jan. 1, 1952, had a prolonged episode of this sort. A psychiatrist advised certification if she proved difficult to manage, but she has since been quiet and coöperative.

Investigations.—Sept. 22, 1951: Sputum contained scanty atypical acid-fast bacilli; barium swallow normal; laryngoscopy, no gross tracheal compression; erythrocyte-sedimentation rate 4 mm. in first hr. (Westergren) at room-temperature; white blood-cell count 4400 per c.mm. (polymorphs 61%, lymphocytes 20%, monocytes 4%, eosinophils 14·5%, basophils 1%); blood-cholesterol 270 mg. per 100 ml.; basal metabolic-rate −22 (a further test was refused); weight 7 st. 9 lb.

Dec. 18: Hb 87%; blood-cholesterol 100 mg. per 100 ml.; weight 7 st. 13 lb.

It was natural to speculate whether either of the two drugs had caused the thyroid depression.

Bergqvist and de Mare[3] described a patient who died of hypothyroid goitre and cerebral œdema after treatment with 'Conteben,' and another who had definite hypothyroid symptoms after prolonged treatment with P.A.S., dihydrostreptomycin, and conteben. Domagk[4] however had never heard of an instance during conteben therapy. Mertens and Bung[5] did not mention thyroid enlargement in a review of conteben toxicity, neither did the report of the pilot trial of the British Tuberculosis Association[6] or Nagley's review of thiosemicarbazones.[7] A full account of anti-thyroid drugs by Suter[8] also made no reference to it. For these reasons, ethizone was discounted.

That P.A.S. could be responsible is borne out by Komrower's case[2] and the 3 Norwegian cases.[1] In the case described here, apart from the thyroid swelling, lowered B.M.R., and high normal blood-cholesterol, there were no overt signs of hypothyroidism, unlike the other reported cases. Unfortunately the patient refused a further B.M.R. test, and return to normal had to be judged clinically. The high eosinophil-count is interesting and may be evidence of drug allergy.

Kjerulf-Jensen and Wolffbrandt[9] have shown that rats fed with P.A.S. and *m*-aminophenol developed moderate cellular hyperplasia of the thyroid gland. Using radioactive iodine, Hanngren[10] found that uptake of iodine in the thyroid gland during P.A.S. therapy was inhibited in 3 patients. He thought that enlargement of the thyroid was compensatory, and caused by increased formation of pituitary thyrotropic hormone. He considered that when P.A.S. is given therapeutically a certain blood concentration will inhibit thyroxine synthesis just as thiouracil does. Doses in excess of the patient's thyroid sensitivity may cause myxœdema.

As in the other cases, the therapeutic effect of P.A.S., if any, did not appear to be antagonised by its antithyroid effect, which may even be beneficial in itself. The metabolic-rate is usually normal in active tuberculosis,[11] but whether a decreased rate is an advantage is debatable.

Nash[12] however gave thiouracil to 3 patients in 1947, with unexpected spread of the tuberculous lesions as a result. I remember a girl, aged 16, with thyrotoxicosis and pulmonary tuberculosis who was treated with thiouracil in 1945, and the tuberculosis became worse. *It is interesting to note that* Madigan et al.[13] suggested that the B.M.R. might rise during P.A.S. therapy, though whether a rise precedes a fall is speculative in the absence of serial tests.

The effect of myxœdema on tuberculosis is of interest. Pagel[14] merely stated that affections of the thyroid are reputed to be associated rarely with tuberculosis—i.e., they are antagonistic to its development. Other authorities[15-17] are more pessimistic, and say that untreated cases of myxœdema may die of intercurrent infections such as tuberculosis—i.e., their resistance to the disease must be lowered.

In the case reported here gross swelling of the thyroid subsided within five weeks of stopping the drugs, though it was still palpable after one year. Obviously the longer administration is continued after the thyroid swelling has appeared, the greater is the risk of myxœdematous change. Komrower's case developed after nine months' treatment. The short period of three months in this case perhaps explains the minimal thyroid changes. Whether irreversible damage can occur is speculative.

Alternatively the thyroid swelling could be ascribed to an unstable endocrine system associated with mental *instability, but the lowered B.M.R. is against this.* Nash[12] wondered whether the antithyroid effect of P.A.S. could exist *without clinically obvious hypothyroidism.* This case suggests that it can.

I should like to thank Dr. J. Spencer and Mr. J. Mallard, A.I.M.L.T., for the metabolic investigations, Mr. L. Whittaker, A.I.M.L.T., for the other investigations, and Dr. G. L. Brown for his help.

Chadwell Heath, Essex.

I. M. LIBRACH.

AMŒBIC ABSCESS OF BONE

SIR,—Amœbic abscesses have now been described in many tissues of the body. In this part of West Africa, where amœbiasis is heavily endemic, it has to be considered in the differential diagnosis of many clinical conditions.

I have recently had under my care an African man of the Mende tribe who complained of a hard painful lump in the middle of his thigh. Two years ago he was treated at this hospital for amœbic dysentery with a course of 6 injections of gr. 1 of emetine. There was no recurrence of dysenteric or other symptoms until the onset of fever, malaise, and pain in the left thigh one month before I saw him.

The patient was emaciated and looked ill; on the middle third of the left femur there was a tender mass about 8 cm. long; it was fixed to the bone, and though firm it was not bony hard; there was no detectable fluctuation, although the mass was clearly palpable through the wasted muscles. X-ray

examination was not available; the fæces contained mature cysts of *Entamœba histolytica.*

After several days' rest in bed with hot fomentations to the thigh, the mass began to soften and was explored with a needle. 3 ml. of a thick, dirty white pus was aspirated, and this contained many active *E. histolytica*; no other organisms were found in stained smears.

Six daily injections of gr. 1 of emetine were given, after which the mass had subsided, leaving no apparent thickening of the bone nor any tenderness. The patient was seen one month later when he was in much better health and gaining weight. The thigh appeared normal and had given him no trouble.

This is a case of metastatic amœbic abscess occurring, presumably, deep to the periosteum of the femur. There was no history of trauma to explain the site of the lesion; and although it had been there at least one month there can have been little, if any, new bone formation around it. The rapid and apparently complete cure also implies the absence of bone destruction on any large scale. In view of the extensive destruction of other tissues exposed to the cytolytic powers of this amœba, it would be interesting to know its action on bone in the absence of secondary infection. This case again raises the question of the mode of spread of the organism within the body. It also indicates that it is not, perhaps, so effective in its attack on bone as on, say, the liver.

Methodist Hospital, Segbwema,
Sierra Leone.
J. R. ROSE.

PROLONGED APNŒA

SIR,—There have been several reports of prolonged apnœa following "balanced" anæsthesia with thiopentone together with succinylcholine.

After carefully reading these reports I cannot see that a clear case against succinylcholine has been established in any one case. In my experience of administering thiopentone with a relaxant there have been a few instances of prolonged apnœa; and in each such case the mode of recovery, and the signs accompanying it, have clearly pointed to thiopentone as the cause.

In my experience the response to, and the recovery-time from, a given dose of a relaxant drug varies very little with either the age or the physical condition of the patient. Indeed I have repeatedly been surprised at the tolerance to these drugs of aged and very sick patients, including some aged over 70 and desperately ill with intestinal obstruction. It has been my impression that these patients require relatively more relaxant than the fit younger patients. My experience with thiopentone is quite the reverse of this; not only is there a progressive decrease in the tolerance of patients for this drug with advancing years and deteriorated physical condition (either from shock or toxæmia), but there is also a disconcerting variation in the tolerance of individual patients in the same age-groups irrespective of their physical condition. For these reasons, if my observations are correct, prolonged apnœa after administration of thiopentone together with a relaxant is many times more likely to have been caused by the thiopentone than by the relaxant.

In no case in my experience, nor in the cases reported, has consciousness returned before the restoration of breathing —a state for which I have many times been profoundly grateful. We know from experimental evidence that even massive doses of relaxant drugs have no effect on consciousness, provided that artificial respiration is adequate; and the same is true of suspended respiration due to the action of local analgesics or of the virus of anterior poliomyelitis on the motor nerves. Thus when unconsciousness accompanies and outlasts suspended respiration after the administration of a relaxant and a hypnotic, which is also a powerful respiratory depressant, the cause must surely be the hypnotic.

Once active respiration is suspended and controlled respiration has been instituted, other factors tend to prolong apnœa. Manually controlled respiration by compression of a reservoir bag usually tends to maintain a tidal volume much in excess of the normal. If this controlled respiration is carried out with an absorbing canister in circuit, as it should be, the overventilation causes such hyperoxygenation, carbon dioxide depletion, and exhaustion of the Hering-Breuer reflex that it may prolong apnœa indefinitely. Many a seemingly interminable apnœa can be ended by discontinuing controlled respiration for a few minutes. I think that apnœa produced by overventilation may have played a not inconsiderable part in prolonging apnœa initiated by either the relaxant or the thiopentone. It should be remembered that it is more easy to produce apnœa by overventilation in the presence of central respiratory depression than to abolish the peripheral neuromuscular mechanism by the same means.

I have observed two signs which determine whether the apnœa is primarily due to central or to peripheral respiratory depression.

The first sign of restoration of the neuromuscular mechanism following full curarisation is rhythmical tone in the muscles of respiration. This muscle-tone appears some time before active muscular contractions take place; its presence is indicated by the feeling of resistance when the reservoir bag is compressed out of phase with the returning respiratory rhythm. This resistance to inflation may be mistaken for evidence of the return of abdominal-muscle tone and lead to the administration of a further dose of relaxant: or, if the bag compressions are completely out of phase, the resistance to inflation, in the presence of a relaxed abdomen, may lead to a diagnosis of bronchial spasm.

I have found this sign both useful and reassuring. It fails to appear only when there is simultaneous and complete central respiratory depression.

Emergence from respiratory arrest due to central respiratory depression is first indicated by another sign.

Gentle handling of the bag will elicit a point at which the very lightest compression initiates a slow but full diaphragmatic contraction followed again by respiratory inactivity until another gentle touch on the bag again causes a further diaphragmatic contraction. After a few repetitions of this manœuvre spontaneous respiration returns. The feeling in eliciting this response is of toppling over a very finely balanced mass by the lightest touch; and I have named this sign the "trigger response" because the lightest touch sets it off. I have elicited it during emergence from the depression caused by both thiopentone and pethidine. For some reason, for which I am unable to account, it is more readily and constantly elicited in the emergence from depression due to thiopentone.

If this response is caused, as it would seem to be, by stimulation of the stretch receptors in the lungs, it would appear to be a reversal of the Hering-Breuer reflex by which stimulation of the stretch receptors terminates the act of inspiration and initiates expiration. Furthermore, since the separate central respiratory centres are depressed in the reverse order of their evolution, and recover in the order of their evolution, may it not be that this "trigger response" represents the most primitive of the respiratory reflexes; and, if this is so, may not the stimulus of the atmospheric pressure acting, through the open mouth, on the stretch receptors of the infant's lungs play an important part in initiating respiration in the newborn?

To modern methods of anæsthesia have been sacrificed one by one the cherished signs of anæsthesia, by which we used to teach the art and upon which we relied to pilot our patients through rough waters to safety. To the onlooker the plight of the patient, completely paralysed and apnœic, with pulse-rate disrupted by gallamine and the blood-pressure "controlled" at some near-catastrophic level, must seem extreme. Electroencephalography will perhaps come to be our Radar; but meanwhile these two signs may prove useful. By their help I have been able to determine the nature of respiratory arrest; and with unduly prolonged arrest the final emergence of the "trigger response" has almost invariably pointed to thiopentone as the causative agent.

Bournemouth.
S. F. DURRANS.

CURE OF TOBACCO-SMOKING

SIR,—I suggest that the gist of Dr. Lennox Johnston's article last week can be expressed in a few words:

> Smoking is a modern social habit; it is expensive, and not obviously detrimental to health. The habit can quite easily be broken by the exercise of a small amount of self-control, provided that there is a real desire to stop smoking.

I have yet to find the smoker who is an addict in the sense that a drug-taker is an addict, or the smoker who has been adversely affected in bodily or mental health when through force of circumstances tobacco has been denied to him.

I would suggest that smokers who fail to give up the habit after they have been advised to do so, or have expressed some intention of so doing, invariably have no real intention of abstaining. In my experience the provident man or woman who finds smoking too expensive a luxury, and definitely decides to stop the habit, always succeeds without great difficulty.

Louth, Lincolnshire. E. C. CORDEAUX.

SIR,—Dr. Johnston has given one account of the effects of giving up smoking. Let me, from a much shorter experience of abstinence, give another.

For thirty years I smoked heavily. The threat of lung carcinoma affected me not at all; I would willingly risk that possibility to continue to have the pleasure and comfort of smoking. But about six weeks ago I decided, for financial reasons, to stop smoking.

Instead of a "sustained uplift of spirits and of general interest" I have been morose, irritable, and unable to concentrate. Time hangs heavily on my hands, I have lost interest in my work and my hobbies, and I have nothing to look forward to. I have acquired an enormous appetite which is impossible to satisfy, and a great increase in flatulence and flatus. I have become lazy and depressed, and only my sexual potency, of which I had no complaints, remains unaffected.

Until I read your contributor's article I was well content not to touch my many comforting pipes. Since reading it my resolve has weakened, and I can see no reasonable future without tobacco.

TEMPORARY NON-SMOKER.

PS.—My colleagues disagree with this and say that at work I am much better tempered.

SIR,—Dr. Lennox Johnston, in his erudite paper, has told us everything about tobacco-smoking, except the cure.

Vague psychotherapy, in which the physician has to be patient (and the poor victim more so), reinforced by the induction of a cancerphobia, is, in my opinion, unlikely to overcome the habit. Dr. Johnston has, however, illustrated the suggestive element of smoking, and this, I believe, provides the answer. About 50% of people can be cured of the smoke habit by simple suggestion, used rapidly, under varying degrees of hypnosis, and the figures are higher if hypnotherapy and re-education are used.

Prince of Wales's General Hospital,
London, N.15. GORDON AMBROSE.

SIR,—I found Dr. Lennox Johnston's article more interesting as an account of the development and perpetuation of the tobacco habit than helpful to those desirous of emancipating themselves. He touches on all the relevant points under "how to stop smoking," but in my view does not sufficiently emphasise auto-suggestion.

Before going to sleep one should think of smoking as an unnecessary, expensive, somewhat offensive, and physically deleterious habit. One should concentrate on the obvious disadvantages of smoking—such as irritation to the respiratory passages, eyes, and tongue, interference with appetite, staining of teeth and fingers, risk of damage to the eyes from hot particles of ash while driving, the destruction caused to paintwork and carpets by careless guests, the pollution of the consulting-room atmosphere by nervous patients and colleagues who chain smoke, and so on.

Some effects of smoking are more resented than others; so the patient is advised to concentrate on those aspects of the habit which particularly annoy or repel him, and these should constitute his main auto-suggestive theme. After a few sessions of counter-suggestion the smoker finds his cigarettes less enjoyable, and within a matter of days will be smoking less and more frequently refusing the offer of cigarettes from others.

He does not require to be adamant about giving up smoking but should just set about altering his attitude towards the habit. He should continue to carry cigarettes but should endeavour to remember to ask himself if he really wants one before actually lighting up.

The object is to develop an awareness of the desire to smoke and then to elect to have a cigarette or not. Even if one fails to achieve this awareness, the distaste for cigarettes, which is inevitable after a period of counter-suggestion to smoking, may enable one to bring the habit well into consciousness. At that point the decision to continue the cigarette or not can be made.

I do not agree with Dr. Johnston that "it is necessary to do much more than merely decide to give up smoking." One can start to toy with the idea of giving it up. One need not forswear smoking. The greater the determination to abandon the habit the more the desire for a smoke is made conscious and the law of reverse effort operates—i.e., the harder one tries the less one succeeds. Why try so hard? The habit should not be given so much importance. *If one decides to give it up* one should proceed with the ritual of auto-suggestion which will bring the habit into consciousness. It is a habit which is much more readily abandoned than is commonly appreciated. I entirely agree with Dr. Johnston that smoking is harmful. "Is smoking bad for one?" should always be answered with an unequivocal "yes."

London, W.1. ELLIS STUNGO.

WHAT OF GENERAL PRACTICE?

SIR,—Your leading article of Sept. 6 states:

> "The medical student, trained in scientific method, naturally measures the general practitioner's opportunities by the precise yardstick of science—and shakes his head. What may escape him is that the good family doctor laces science's cold portion with the warmer stuff of humanism. Some of this humanism is being formalised in the doctrine of social medicine, which is finding its way into curricula; but, even so, the general practitioner's twofold technique remains essentially empirical, . . . Dons, especially those who pursue scientific disciplines, are not remarkable for their tolerance of the empirical."

This seems to imply that science and empiricism are antitheses and that science must be inhuman. According to the *Concise Oxford Dictionary* empiric means "based, acting, on observation and experiment, not on theory." Excellent examples of empirical studies are, therefore, provided by those numerous *controlled experiments* which demonstrate the value, or lack of value, of drugs, and which are such a feature of modern medicine. The antithesis of empiricism is doctrine based on theory alone, and much medical treatment of the past, and even of the present, rested on such a basis. Our forefathers performed phlebotomy to get rid of the phlegms which could be seen when the patient's blood was allowed to stand; they starved the feverish patient to prevent the fires of his fever burning more fiercely; and they purged people to rid them of noxious matters. We refrain from giving lettuce to the subjects of peptic ulcer, because lettuce leaves will erode the ulcer; we make dropsical patients thirsty because we deduce that if we allow them to drink freely their dropsy will increase; and we still give freely—or at least are advised to do so *in the very latest articles—brisk purges* to the subjects of innumerable conditions, from boils to acute tonsillitis, to minimise their toxæmia. And witchdoctors mutter imprecations and go through elaborate ceremonial to get rid of the evil spirits which are responsible for the patient's illness. Is it then to be supposed that these remedies are scientific, and that giving penicillin (the belief in the value of which is based on innumerable observations on mankind) is not scientific ? No-one, of course, adopts such a view, and all would agree that controlled experiments to illustrate the value of drugs are scientific. But it is still commonly believed that the use of remedies depending solely on theory is scientific; in fact such remedies should always be suspect.

So far from his technique being "essentially empirical," the general practitioner is at a disadvantage by comparison with those who work in hospitals because it is difficult for him to make sound empirical observations. The general practitioner who says he is convinced that a tonic has benefited a patient is making unjustified deductions from his observations; all he should deduce legitimately is that the patient has apparently improved over the period in which he has taken the tonic. To assess the value of the tonic requires a large series of similar cases, half of whom are given the tonic and the other half an inert but similar-looking preparation, and all of whom are questioned closely and consistently. The general practitioner can hardly perform an investigation of this kind, and he has to depend on the empirical observations of others.

The view in your leading article that science is inevitably inhuman suggests that a doctor is being scientific when he looks at a patient with numerous persistent complaints and profound personal problems from a purely organic angle—as a conglomeration of organs, disease of which must either be identified or excluded by means of a large number of investigations with expensive apparatus. And if in the end disease is excluded, he concludes that the patient must have "nothing the matter." But why should such a performance be called scientific ? It is certainly folly, and it is strange that folly should be given the name of science.

Farnham, Surrey. JOHN W. TODD.

PARACOLON BACILLUS SEPTICÆMIA

SIR,—Dr. Kernohan's[1] account of this disorder reminds me of a similar case I saw earlier this year.

A man, aged 52, was admitted to hospital on Feb. 25 after moderate hæmatemesis that morning. He gave a history of two previous hæmatemeses, the last one, in 1947, being definitely preceded by ingestion of aspirin tablets for lumbago. On this occasion, he had had "gastric influenza," with anorexia, malaise, nausea, and retching for the previous 10 days; and the day before admission he had taken some brandy and aspirins. He had had no dyspepsia.

He was moderately febrile (100°F) but there were no signs of recent severe blood-loss (blood-pressure 110/70 mm. Hg, Hb 110%). There were no abnormal physical findings except for a very furred tongue and moderate abdominal distension. Expectant treatment was adopted.

Next morning his temperature had risen to 102°F, and it remained at this level until next day (Feb. 27) when the pulse-rate fell to 66 per min (Faget's sign). Enteric fever was now seriously considered, and was suggested further by absolute constipation for 5 days past, tympanites, and increased lethargy with absence of physical signs in the chest or elsewhere. There was no splenomegaly, but there were several faint dusky "rose red" spots on the trunk.

On Feb. 28 the white blood-cell count was 4300 per c.m. (polymorphs 36%, lymphocytes 61%) and next day 4600 (polymorphs 40%, lymphocytes 40%, monocytes 18%, eosinophils 2%); erythrocyte-sedimentation rate 3 mm. in 1st hr. (Westergren). Blood-culture was sterile after 3 days, but confirmatory evidence of a septicæmia was obtained from the urine and stools, which yielded a non-lactose-fermenting gram-negative bacillus, identified provisionally as *Salmonella paratyphi B* by agglutination, but by the Salmonella Reference Laboratory as a paracolon bacillus.

With treatment by chloramphenicol the patient's temperature fell and his general condition improved dramatically. He was discharged fit on March 17.

It was thought that this patient's hæmatemesis had resulted from gastric irritation produced by aspirin, together with increased gastric vascularity associated with gastritis due to infection with paracolon bacillus.

I should like to thank Dr. R. B. Niven for permission to publish this case.

Winchester. P. G. CRONK.

EMPLOYMENT OF REGISTRARS

SIR,—At a meeting of the consultants and specialists of the Bromley group, held on July 31, the proposals for the employment of senior registrars (including the exchange scheme) and registrars as agreed between the regional hospital board and the teaching hospitals were considered.

The meeting was very concerned to learn that it had been laid down that all candidates for the position of senior registrar must have held the post of registrar in a teaching hospital for 2 years. If this was correct it seemed clear that registrarships in non-teaching hospitals would be "dead-end" jobs, that there might very soon be difficulty in filling such posts at all, and that candidates for such posts would be of a poorer type than formerly, with the inevitable result that the health service would suffer.

The following resolution was therefore unanimously passed:

(*a*) That a strong protest should be made against the decision that candidates for the post of senior registrar must previously have held the post of registrar in a teaching hospital for 2 years.

(*b*) That the present proposal that of senior registrars should be selected entirely from the registrars of teaching hospitals would mean that doctors applying for registrarships in non-teaching hospitals would be of a poorer type than formerly, and that the health service would inevitably suffer as a consequence.

(*c*) That senior registrarships and registrarships should both be interchangeable between teaching and non-teaching hospitals.

SALT-LOSING NEPHRITIS

SIR,—Recently attention has been drawn to a phase or type of nephritis in which loss of salt in the urine is a prominent feature. In your issue of Sept. 6 Dr. Joiner and Dr. Thorne describe 3 cases in which this diagnosis was made. A second possibility present in 2 of their cases is that the salt loss was related to the presence of pulmonary tuberculosis.

Westwater et. al.[1] found the serum-sodium to be less than 137 m.eq. per litre in 55 out of 169 cases of pulmonary tuberculosis admitted to a sanatorium. 21 of these cases came to autopsy, and, apart from amyloid disease in 1 instance, no renal disorder was discovered. These patients had weakness, skin pigmentation, hypotension, diarrhœa, and vomiting, many of which symptoms occurred in the cases described by Dr. Joiner and Dr. Thorne.

Furthermore we cannot agree that their second case showed chloride depletion, whether the levels are taken in milligrammes per 100 ml. or in milli-equivalents per litre (the values given do not appear to correspond). The diagnosis in their third case would appear to be based solely upon a single serum-sodium level of 131 m.eq. per litre, which was obtained after a period of eight days in which added salt was excluded from the diet. In a patient with chronic nephritis some fall in the serum-sodium level might be expected to occur.

---

[1] Westwater, J. O. Stiven. D. Garry, R. C. *Clin. Sci.* 4, 73.

Evidence of long-standing pyelonephritis is a not infrequent finding at autopsy; and in our view the presence of active pulmonary tuberculosis is more likely to account for the salt loss in cases one and two. In case three the evidence of salt loss submitted seems insufficient for it to be included in the group with excessive loss of salt in the urine.

MALARIAL FEVER THERAPY

SIR,—The article by Mr. Shute (Aug. 16) draws attention to an undesirable practice. This states that malarial infection by intramuscular inoculation of whole blood is an alternative to the technique of using parasites.

As one who has witnessed the tragedies of hæmolytic disease of the newborn, and transfusion morbidity, from untimely disregard for the known facts of Rh sensitisation, I would ask the Malaria Reference Laboratory to bear in mind the inadvisability of using this method to infect girls and also women of the child-bearing years. If the method is to be retained, then due regard should be paid to the possibility of such sensitisation.

Uxbridge, Middlesex.

JOHN PRICE.

DEFORMING FACTORS IN POLIOMYELITIS

SIR,—I have read with great interest Mr. Mitchell's analysis last week of "muscle spasm" and allied disorders and also the treatment he advised in his earlier communication.[1]

In this connection I feel that we should report some recent experiences in the treatment of acute poliomyelitis at Stoke Mandeville Hospital isolation block, where, during the present outbreak of the disease, we have had the benefit of the services of a nurse trained at St. Thomas's Hospital who has recently studied poliomyelitis in the U.S.A.

This experience has led us to institute very frequent passive movements with gentle stretching of tight muscles, and frequent changes of position in bed, from the first day of the disease. The physiotherapist treats the patient once a day, but on at least five other occasions in each 24 hours passive movements are carried out by the nurse, who is trained to do them. In addition the posture of the patient in bed is changed on about ten occasions during the 24 hours, the supine, lateral, semi-prone, and prone positions all being used. This plan gets rid of most muscle tightness within 2–3 weeks, and seems to be entirely satisfactory in practice. The nursing methods used could be demonstrated to a limited number on application to the Matron, Stoke Mandeville Hospital, Aylesbury, Buckinghamshire.

Public Health

Neglecting the Countryman?

IN his report for 1951, Dr. D. P. Lambert, divisional medical officer for the North Craven division of the West Riding of Yorkshire, says:

> "Country folk are becoming increasingly conscious that most of the benefits of the Welfare State are concentrated in the cities, and . . . it is felt that some things could and should be better shared. Medical services are especially wished for; and the demand for mobile clinics and for mobile consultation facilities increases each year. For major surgery and for prolonged medical investigation patients will always have to go to the big hospital centres; but there is a great deal of diagnostic work . . . that could be as well done in a mobile clinic as in a hospital outpatient department."

Appointments

CONNOLLY, M. R., L.R.C.P.E.: first asst., anæsthetic department, Royal Free Hospital, London.
SALMON, L. F. W., M.B.E., M.S. Lond., F.R.C.S.: consultant ear, nose, and throat surgeon, Guy's/Evelina Hospitals, London.
STEPHENS, J. P., M.B. Camb., F.R.C.S.: senior surgical registrar, Norfolk and Norwich Hospital.
SUMMERS, H. A. H., M.B. Belf., D.P.H.: asst. county M.O.H. and district M.O.H., borough of Daventry and the rural districts of Daventry and Brixworth.

Colonial Service:

BIRD, A., M.D.: M.O., Windward Islands.
BURY, E. J., M.R.C.S., D.P.H.: D.D.M.S., western region, Nigeria.
CHARLES, E. D. B., M.D. McGill, M.P.H.: M.O.H., Jamaica.
COHEN, R. I., M.B. Lpool, F.R.C.S.: M.O., South Pacific Health Service.
DIDSBURY, BRIAN, M.B. Manc.: M.O., Malaya.
GOULDING, M. D., M.B.: M.O., Federation of Malaya.
HARRIES, J. R., M.B. Lond., M.R.C.P., D.C.H.: M.O. (special grade), Kenya.
HARRIS, B. P., M.A., M.D. Camb., D.T.M.&H.: senior M.O., Kenya.
HODGES, W. A. A., B.A., M.B. Camb., F.R.C.S.: M.O. (special grade), Tanganyika.
PARK, ROBERT, M.R.C.S.: senior M.O., Nyasaland.
PASQUAL, R. S. H., M.B. Edin.: M.O., Kenya.
REID, H. A., M.B. Edin., M.R.C.P.E., D.T.M.&H.: specialist physician, Malaya.
SEXTON, J. P., M.B. Edin., D.P.H.: regional senior health officer, northern region of Nigeria.
SINCLAIR-HALL, A. H., M.D. Manc., F.R.C.S.: senior specialist, Nigeria.
VERLEY, DORIS, M.B. Edin., D.A.: medical specialist (anæsthetist), Jamaica.
WATERS, I. R., M.R.C.S.: M.O., Nyasaland.
WELLS, R. H. C., M.B. Lond.: M.O., Federation of Malaya.

Manchester Regional Hospital Board:

CALDER, A. G. S., M.B. Edin., F.R.C.S.E.: consultant E.N.T. surgeon, Wigan and Leigh Hospitals.
DARK, J. F., M.B. Manc., F.R.C.S.: consultant thoracic surgeon, Baguley and Park Hospital, Manchester.
JACK, G. D., M.B. Edin., F.R.C.S.: consultant thoracic surgeon, Baguley and Park Hospital, Manchester.
PARKER, R. P., M.B. St. And.: asst. anæsthetist, Burnley and district hospitals.

The Terms and Conditions of Service of Hospital Medical and Dental Staff apply to all N.H.S. hospital posts we advertise, unless otherwise stated. Canvassing disqualifies, but candidates may normally visit the hospital by appointment.

Notes and News

ROYAL MEDICAL BENEVOLENT FUND

DURING 1951 the Royal Medical Benevolent Fund helped 8 new applicants, and the number of its beneficiaries is now over 600. Reporting on the year, Dr. R. Cove-Smith, the hon. secretary, says that during the year £41,467 was disbursed, including £21,865 in grants, £10,609 in annuities, £2028 as Christmas gifts, and £2020 as New Year gifts. Working expenses amounted to 6·6%. Investment income was £13,794 and subscription income £24,410; income-tax recovered under covenants totalled £5810. In addition, £18,114 was received in legacies and credited, as usual, to capital account. Dr. Cove-Smith observes that, with income-tax at 9*s.* 6*d.* in the pound, each guinea of covenant subscriptions represents an income of £2 to the Fund; and he asks all supporters to consider this method of subscription. The headquarters of the Fund are at 1, Balliol House, Manor Fields, Putney, London, S.W.15.

A NEW KIND OF CECIL HOUSE

WOMEN wandering about the streets of London in search of a cheap lodging are fortunately no longer as common as they were in 1925, when Mrs. Cecil Chesterton set out, with nothing in her pockets, to see what it felt like to be one of them. But there are still more than enough of them to disturb our peace of mind if we stop to think about it. The Cecil Houses, which she founded, still fill themselves every night, and the numbers turned away do not diminish. Those who get there in time can still get a clean and comfortable bed, a hot bath, and *facilities for* washing clothes, *for* a sum which has risen, with the change in the value of money, from 1*s.* to 2*s.* 3*d.*; a cot for a baby costs an additional 3*d.* They are asked no questions; they want, and are paying for, a night's lodging, and their private lives are respected. The only stipulation made is that they shall be sober.

Over the course of the years six Cecil Lodging Houses have been opened; some were closed for a time by bombing, and have since reopened—all but one, which is let temporarily for light industry until it can be rebuilt. In 1938 a new kind of Cecil House was opened—a residential club, in Gower Street, for 72 working girls who pay £2 a week, and must not be earning more than £5. This building was let during the war to the Canadian Legion but has been fulfilling its original purpose since 1947. Next year another new venture is to be launched—a residential club for 72 old ladies. The building is up, in Medlake Street, North Kensington; and it is delightful, from the roof garden and verandahs, and the nineteen dormitories, to the comfortable common-rooms, the convenient kitchen, and the central-heating installation in the basement.

Once launched, the Cecil Houses pay their way, and the new residential home will be no exception; but it has cost £65,000 to buy the site and build on it, and not all of this sum has been collected yet. Those who wish to contribute should send their subscriptions to the Hon. Treasurer, Cecil Houses (Inc.), 193, Gower Street, London, N.W.1.

A VOICE FROM THE PAST

Daniel Drake was born in New Jersey in 1785. At the age of 2 he took part in the migration to the western parts of the United States. In the turmoil of those pioneer days a boy's education was apt to be neglected, but Daniel was soon able to take the matter in his own hands; for, as he later wrote, "I could read and examine a dictionary for the meaning of words and here is the starting point of all improvement." And improvement thus started led to his apprenticeship at 15 with a doctor in Cincinnati, and carried him on to a place of distinction in the history of American medicine. He became a physician, teacher, and writer whose reputation spread far beyond the Ohio Valley where he spent most of his life.

Biographical facts, however impressive, give a poor picture of the man, but his written words do much to fill in the details—and Dr. Drake was a vigorous and prolific writer. His essays on medical education and the medical profession, first published in 1832, have now been reprinted.[1] Many of his pungent criticisms must have been unpopular at the time, and indeed some of them may touch a sore spot here and there even now. "The profession abounds in students and practitioners who are radically defective in spelling, grammar, etymology, descriptive geography, arithmetic, . . . and book-keeping." He also demanded "a competent knowledge of the elements of physical geography, general history, the art of composition, algebra, geometry, and mechanics." How his students must have quailed! He deals as devastatingly with the failings that he detected in the medical schools of the time; and his ideas on a proper medical training laid the foundations of modern American teaching methods. He wrote so entertainingly that he should be read again even if his lessons had all been learnt, which is by no means the case.

THE WORKS OF SIR ALMROTH WRIGHT

Dr. Leonard Colebrook, F.R.S., loving disciple of an unusual man, has prepared a bibliography of all the published works of Sir Almroth Wright,[1] and has appended to each title a short account of the contents. Most of these deal with immunisation, Wright's major interest, and it is impressive to see the vast field he ranged and the notable contributions he made to this subject. Two works on which Dr. Colebrook evidently sets a high value are *Prolegomena to the Logic which searches for the Truth*, and *Alethetropic Logic* (still unpublished) to which the *Prolegomena* was written as a foreword. The main work began to take shape, Dr. Colebrook says, in the 'nineties, when Wright had become interested in the physiological processes associated with emotional disturbances. This led him to reflect on the nature of belief, and the intellectual operations usually included in the word "logic." "It seemed to him that the modern development of psychology and physiology called for a new system of logic—one which was not concerned only with Reasoning, but took account also of all the processes by which we arrive at our Beliefs." Three contributions, whose shocking illiberality nowadays raises a smile, are concerned with the case against woman suffrage; perhaps it would have been kinder to leave them out.

SAFETY FOOTWEAR

IN industry injuries to the feet are a common cause of disablement. The Ministry of National Insurance found that in 1949 and 1950 such injuries accounted for about 4% of all successful claims for injury benefit. The British Standards Institution, in coöperation with other organisations, has issued a standard for men's safety boots and shoes (B.S. 1870/1952, price 2*s.* 6*d.*). Shoes made by this standard, which were demonstrated in London this week, have an external or internal steel toecap, weighing 2 oz. and designed to withstand a shock test of 150 foot-lb. or a dead weight of 3 tons.

Royal Medico-Psychological Association

Dr. W. Rees Thomas will deliver the Maudsley lecture to this association on Thursday, Nov. 6, at 2.15 P.M., at 1, Wimpole Street, London, W.1. He is to speak on The Unwilling Patient.

London Hospital

On Thursday, Oct. 9, at 4.15 P.M., at the Medical College, Prof. S. P. Bedson, F.R.S., will deliver the Schorstein lecture on Twenty-five Years' Progress in Virus Research.

Royal Free Hospital

Sir Henry Dale, O.M., F.R.S., will deliver the opening address of the 1952–53 session to the medical school on Friday, Oct. 3, at the Senate House, University of London, W.C.1, at 3 P.M.

Guy's Hospital

The biennial dinner for past medical and dental students will be held in the Connaught Rooms, Great Queen Street, London, W.C.2, on Friday, Oct. 3, at 7.30 p.m. Tickets (25*s.* exclusive of wines) are obtainable from Mr. O. Gayer Morgan, hon. secretary of the dinner, Medical School, Guy's Hospital, London, S.E.1.

Westminster Medical School

On Monday, Oct. 6, at 3.45 P.M. at Church House, Great Smith Street, S.W.1, Sir Raymond Evershed, P.C., the Master of the Rolls, will give the inaugural address.

---

[1] Practical Essays on Medical Education and the Medical Profession in the United States. By DANIEL DRAKE, M.D. Baltimore: Johns Hopkins Press. London: Oxford University Press. 1952. Pp. 103. 20*s.*

[1] Bibliography of the Published Writings of Sir Almroth Wright, M.D., F.R.S. London: Heinemann. 1952. Pp. 32. 6*s.*

Society of Chemical Industry

On Monday, Oct. 20, at 5.30 P.M., at the rooms of the Chemical Society, Burlington House, London, W.1, at a meeting of the crop protection panel of the agriculture group, Dr. J. M. Barnes will speak on Health Hazards in Crop Protection.

Rubber Products for Hospital Use

With the collaboration of the professional and industrial interests concerned, the British Standards Institution is preparing a series of standards for rubber products used in surgical and hospital practice, and the following have now been published:

B.S.1803—Surgical rubber gloves (price 1s. 6d.) deals with gloves made by dipping in rubber solution (both cold and hot vulcanised), or by dipping in latex. Recommendations are given for storing and sterilisation.

B.S.1883—Rubber ward-dressing gloves and porters' gloves (2s.) covers three types of gloves—namely, rubber-solution dipped, rubber-latex dipped, and those built up from sheet rubber. Methods of marking to show date of manufacture are laid down.

B.S.1884—Rubber post-mortem gloves (2s.) is similar in scope to B.S.1883.

B.S.1882—Rubber tubing for hospital use (2s.) includes specifications for pressure, drainage, stethoscope, and Paul's tubing. Transfusion tubing is still under consideration, and will be dealt with by an amendment slip to the present standard as soon as the work is completed. Exact methods o [illegible] ensions and tolerances, are specified, and [illegible] ical tests to ensure that the quality of rul [illegible] for each purpose.

Copies of these standards may be had from the sales branch of the Institution, 24, Victoria Street, London, S.W.1.

British Legion Homes

This year the British Legion has completed its post-war plan to provide 8 special homes. The 4 country homes for the aged at Westgate, Cromer, Ripon, and Bwlch, near Brecon, accommodate 220 men and women, 130 of whom are disabled. Every year more than 3000 men and women spend a fortnight at the convalescent homes at Southport, Weston-super-Mare, Sevenoaks, and Helen's Bay in Northern Ireland.

Institute of Child Health, London

Ten postgraduate lectures on Disease in the Young Animal and the Child are to be given at the Hospital for Sick Children, Great Ormond Street. The lectures will be held on Mondays, at 5.30 P.M., beginning on Oct. 13. Further particulars may be had from the secretary of the institute, Great Ormond Street, W.C.1.

Wessex Rahere Club

The autumn dinner of this club will take place at the Grand Spa Hotel, Clifton, Bristol, on Saturday, Oct. 25. Membership of the club is open to all Barts men practising in the West Country. Further details may be had from Mr. A. Daunt Bateman, the hon. secretary, 3, The Circus, Bath.

Vellore Christian Medical College, South India

Friends of Vellore are to hold their annual reunion on Wednesday, Oct. 8, at Caxton Hall, Westminster, S.W.1, at 3.30 P.M. The speakers will include: Dr. Margaret Brand, Mr. Paul Brand, Dr. Gwenda Lewis, and Dr. P. Koshy.

Association of Clinical Pathologists

The annual general meeting of this association will be held at the Westminster Hospital Medical School, London, S.W.1, from Oct. 2 to 4.

Hunterian Society

The annual party of this society is to be held at 41, Portland Place, London, W.1, on Thursday, Oct. 2, at 6 P.M., when recent additions to the museum will be shown.

Rations for Patients with Cœliac Disease

A new category of extra rations has been introduced for children with cœliac disease. In future children who are being treated on a wheat- or gluten-free diet may be allowed one extra ration of fats (butter, margarine, and cooking-fat), one extra meat ration, and one priority allocation of eggs a week. These allowances are alternative to, and not additional to, the extra rations at present granted. Medical certificates, in addition to providing the figures for a stool fat-analysis or fat-absorption test, should state that the patient is on a gluten-free diet. The Ministry of Food's medical advisers are prepared to give consideration to adults suffering from steatorrhœa who have been placed on a similar diet.

International Congress on Rheumatic Diseases

The eighth International Congress on Rheumatic Dis will be held at Geneva from Aug. 24 to 28, 1953. The follo subjects have been chosen for discussion: Connective Tis and Rheumatism; Steroids in the Treatment of Rheumati the End-results of Surgery for the Rheumatic Hip; a Occupational Reablement. Further particulars may be h from Prof. K.-M. Walthard, Institut de Physiatrie, Hôpit Cantonal, Geneva, Switzerland.

St. Thomas's Hospital

The old students' dinner will take place at the Trocade Restaurant, Piccadilly Circus, London, W.1, on Frida Oct. 17, at 7.30 P.M., when Mr. L. E. C. Norbury, will ta the chair. Tickets (29*s*. exclusive of drinks) can be obtain from the hon. secretaries, G. A. MacGregor, R.A.P., and C. E. Savage, R.A.S., St. Thomas's Hospital, S.E.1.

Illuminating Engineering Society

On Jan. 28, Prof. E. D. Adrian, O.M., P.R.S., will deliver th Trotter-Paterson lecture to this society. He will speak on th Nervous Reactions of the Retina. Dr. W. J. Wellwood Ferguson will deliver the presidential address on Oct. 1 Both meetings will be held at the Royal Institution, Albem Street, London, W.1, at 6 P.M.

Newsholme Lectures

Prof. W. M. Frazer, medical officer of health for Liverpool, is to deliver these lectures at the University of London in 195

Mr. A. S. Parkes, D.SC., F.R.S., head of the division of experimenta biology of the National Institute for Medical Research, Mill Hi London, leaves on Sept. 17 for a lecture tour in Latin Americ which has been arranged by the British Council.

The British Standards Institution has issued a draft Britis Standard for clinical maximum thermometers (B.S. CO(LBC) 332 comments on which should be sent before Oct. 9 to the Institutio 24, Victoria Street, London, S.W.1.

The Cambridge Instrument Company Ltd. are issuing to delegate at the European [illegible] monograph on th *Development of the* [illegible] L. Barron, M.I. to which Sir Alan L [illegible] a foreword. So additional copies ar [illegible] without charge t doctors who apply to the company, 13, Grosvenor Place, Londo S.W.1.

Births, Marriages, and Deaths

BIRTHS

ATKINSON.—On Sept. 1, at Bromley, Kent, to Mollie (née Mortl wife of Mr. W. J. Atkinson, M.D., F.R.C.S.—a daughter.

CLARKE.—On Aug. 29, at the Purey Cust Nursing Home, Yo to Catherine (née Waugh), wife of Mr. P. R. R. Clarke, F.R.C —a son.

FELIX-DAVIES.—On Aug. 29, in London, to Joan (née Kellett), wi of Dr. D. Felix-Davies—a son.

HICKS.—On Sept. 3, at Edgware General Hospital, Edgware, to Marie, wife of Dr. Frederick N. Hicks—a daughter.

HIGHTON.—On Aug. 25, to Dr. Roberta Highton (née Baker), wi of Dr. Thomas C. Highton, M.R.C.P., of Rotorua, New Zealan —a son.

LOTHIAN.—On Aug. 31, at Shoreham, Kent, to Joan (née Hamb wife of Dr. William Lothian—a son.

LUCAS.—On Aug. 25, at Princess Elizabeth Hospital, Nairob Kenya, to Dr. Shelagh Lucas (née Fair), wife of Mr. J. M. Lucas, M.R.C.V.S., Box 2141, Nairobi—a daughter.

MUNRO.—On Sept. 6, at Crayford, Kent, to Dr. Olive Munro, wife of Dr. Ian Munro—a daughter

ROBERTSON.—On Sept. 4, to Helen (née Preston), wife of Dr. Jam Robertson, 66, Gloucester Gardens, W.2—a son.

TASKER.—On July 25, at Northampton, to Anita, wife of Dr. J. R. Tasker—a son.

WOHL.—On Aug. 31, at the London Clinic, to Hilda (née Hoffman wife of Dr. M. Wohl—a daughter.

MARRIAGES

DEVITT—BROWNLEE.—On Sept. 6, at Pinner, Herbert P.-S. Devit M.R.C.S., to Carol Brownlee.

DEATHS

ANDREWS.—On Sept. 2, at Gorse, Blatchington, Seaford, He Arthur Andrews, M.R.C.S., formerly of Tonbridge, aged 8

INNES.—On Aug. 24, at Grantown-on-Spey, Inverness-shire, F Riddell Innes, M.B. Edin., formerly of the Christian Medi College, Vellore, S. India, and of Brisbane, Australia.

MCKIBBIN.—On Sept. 5, at his home, Frederick McKibbin, O.B.E. M.B. Belf., colonel, late R.A.M.C.

POLLARD.—On Sept. 3, at Pound Hill, Framfield, Sidney Pec Pollard, M.D. Camb., F.R.C.S.

SMALL.—On Aug. 25, at his residence, Kinghurst, Stoke Gabri Devon, Robert Small, M.R.C.S., D.P.H., D.T.M., formerly M.O. Mombasa.

WARDROP.—On Aug. 30, at his home, 45, Northumberland Roa Leamington Spa, John Glen Wardrop, M.D. Lond., aged 6

MILIARY TUBERCULOSIS IN CHILDREN*

ROBERT DEBRÉ
M.D. Paris
PROFESSOR OF PÆDIATRICS, UNIVERSITY OF PARIS

MILIARY tuberculosis has been much discussed for nany years by clinicians, pathologists, and radiologists. Acute miliary tuberculosis was described by the French nternist Empis (1865) as a clinical entity with high pyrexia, severe dyspnœa, and a fatal outcome. The diagnosis of *granulie* meant to the French physician this acute disease, with its regularly fatal prognosis. Then came, with routine radiography, the description, especially by Burnand and Sayé (1924), of less acute miliary tuberculosis, which could sometimes heal spontaneously—*granulies froides, granulies curables.* Following such observations, the interpretation of the clinical and radiological pictures, and their bearing on the prognosis, became somewhat confused, and it has been my task to make a clear-cut difference between those cases of miliary tuberculosis that can heal spontaneously and those that are as hopeless as tuberculous meningitis. I showed in 1934 that they could be distinguished both clinically and radiologically. I have kept the word *granulie* for the acute fatal form, calling the other one " subacute miliary tuberculosis," and its radiological picture *image granulo-réticulée.*

Streptomycin has changed the character of miliary tuberculosis, but this distinction has remained of value for the prediction of meningitis, which is now the main, almost the only, danger. The creation of centres for treating tuberculous meningitis has allowed a much wider observation of this form of tuberculosis, and I summarise here my experience during the last few years, in coöperation with H. E. Brissaud, Henriette Noufflard, S. Kaplan, and others, of the clinical picture of miliary tuberculosis in children, and of its evolution under streptomycin treatment.

ÆTIOLOGY

In the years 1947–49 and 1950, 170 cases of miliary tuberculosis were admitted to the Clinique Médicale des Enfants in Paris. In almost all these children miliary dissemination appeared very early in the history of the disease, almost simultaneously with primary tuberculosis. In only 8 of these 170 cases could there be found a past history of tuberculosis 1–6 years earlier: conversion of skin test, or bone tuberculosis. And skin tests are now so widely used as a routine in France that it is unlikely that many other cases of postprimary tuberculosis would have been missed in this group.

In almost all the cases there was nothing in the past history of the child suggesting tuberculosis; often there were recent contamination and recent proved conversion of the skin tests; and the symptoms for which the skin test was made were usually those for which the radiograph was made that showed miliary tuberculosis: pyrexia and loss of weight for several weeks or a few months without remission. In some cases there was a remission of a few weeks or months followed by recurrence of the pyrexia and discovery of miliary tuberculosis. If miliary tuberculosis in children appears usually as a severe form of primary or postprimary tuberculosis, the question arises: why does it occur in certain cases and not in the others? Does it occur more readily in certain groups of children or after heavier contamination?

Sex.—Of these 170 children, 69 were boys and 101 girls—a slight but significant difference, occurring only in the older age-group.

Age.—Fig. 1 shows the ages of the patients. Most cases fall in the younger age-group: 22 children were aged less than 1 year, and 61—i.e., more than a third—were aged less than 3 years. This is far from parallel to the tuberculin index even in France, and shows definitely that widespread miliary dissemination occurs more readily in infants and younger children.

Contamination.—Of 154 cases in which the inquiry had been thorough enough the contamination was found, unquestionably or with great probability, in 69. In about half these cases it was a very heavy familial contamination (in 19 cases by the father, 8 by the mother, 1 by both parents, and 4 by grandparents).

SYMPTOMS AND SIGNS

In nearly half my cases meningitis was present on admission, and in about a quarter the history was mainly that of the meningitis, miliary tuberculosis being only discovered by routine radiography of the chest and examination of the optic fundi.

In all the other cases miliary tuberculosis was diagnosed first, and the history was somewhat monotonous, being that of a systemic disease, with pyrexia, fatigue, anorexia, and loss of weight. The temperature is usually very high (102°–104°F) but sometimes moderate (100°–101°F). I have never seen an absolutely normal temperature. And this pyrexia had lasted many weeks, sometimes several months, before the right diagnosis was made. The physician often thinks of typhoid fever before he thinks of tuberculosis, in spite of the latter being much more common. In only a few cases was there severe dyspnœa with cyanosis. Usually nothing calls attention to the chest. On physical examination there are few signs. The spleen is enlarged in about half the cases. In many instances no meningeal signs are found; even though meningitis may be present, as shown by routine lumbar puncture.

In infants the diagnosis is difficult when contamination is unknown, because of the technical difficulties of radiography and of the examination of the optic fundi.

There are a few other circumstances in which miliary tuberculosis has been diagnosed: it may be discovered by routine radiography in a child with bone tuberculosis; and twice I have seen it associated with signs of a

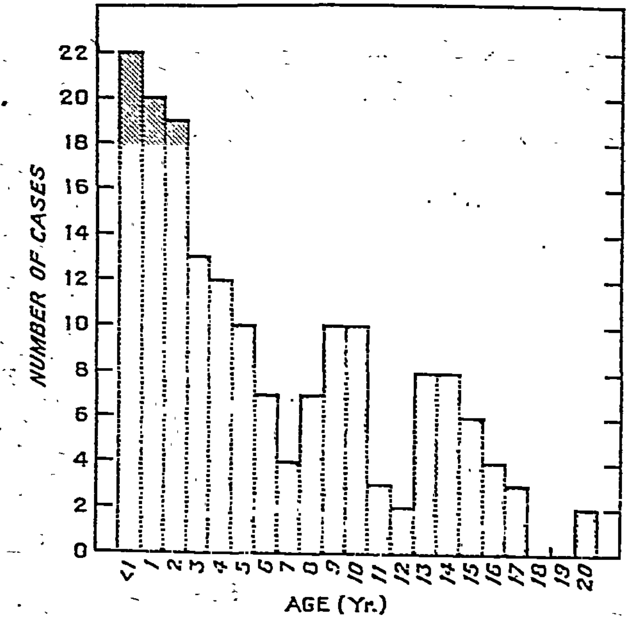

Fig. 1—Age-distribution of miliary tuberculosis.

---

* Lecture read at the meeting of the British Pædiatric Association at Windermere on May 1, 1952.

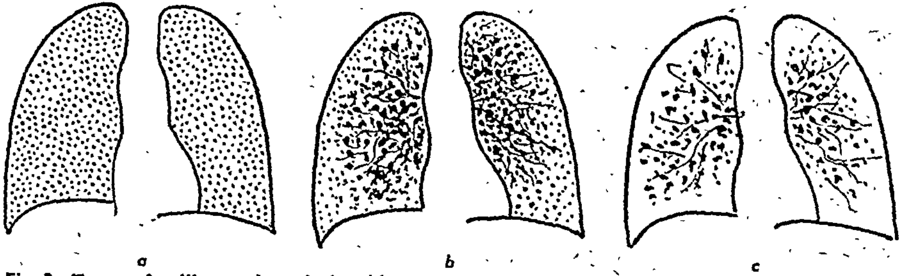

Fig. 2—Types of miliary tuberculosis of lungs: *a*, acute; *b*, subacute very dense; *c*, subacute more discrete.

cerebellar tumour (the tuberculoma was successfully removed in both cases).

The tuberculin test is usually the first to give the right orientation. It is well known that it can be negative in miliary tuberculosis even when the patient is not in too poor a condition. I have found a weak allergy (negative Pirquet and positive Mantoux at a more or less high dilution) in 12 cases, and complete absence of allergy (negative Mantoux at the higher concentrations of tuberculin) in 3 cases. Of these 3 cases 1 became positive after a month; the 2 others, which remained negative throughout the disease, both had positive gastric washing. Misleading as they are, such cases are the exception, and only mean that a negative skin test is not enough to reject the diagnosis of acute tuberculosis if there are good reasons to keep it in mind.

CHEST RADIOGRAPHY

Miliary tuberculosis can be completely missed at fluoroscopy or on a technically imperfect plate. A good plate, made with a rapid exposure from a distance of not more than 1 metre and with rather soft X rays during inspiration, will show either of the following two pictures:

(1) Fig. 2*a* shows the very acute form of miliary tuberculosis, the *granulie d'Empis*, made of innumerable tiny spots so small that no differences of size can be seen between them, and so numerous that they appear to be scattered throughout both lungs, no part of the lungs being clear of them. This type of miliary tuberculosis never heals by itself, and even with streptomycin treatment its evolution differs from that of the other kind.

(2) Figs. 2*b* and *c* show the other type of miliary tuberculosis. Here the spots are larger and unequal. Caseous diffuse pneumonia is excluded from present consideration. Though the borderline between these pictures and caseous diffuse pneumonia is sometimes difficult to trace, these are still very small spots though larger than in the first type. They do not stipple both lungs so uniformly as in the first type: they appear denser near the hilum, where the lung is thicker, and scarcer at the periphery. A kind of network can often be seen between the spots. In fig. 2*b* the spots are still very numerous though unequal in size and distribution, whereas in fig. 2*c* they are much less numerous. This is the picture that is often found in tuberculosis of lymph-nodes or of bones and joints. This is the type that can heal spontaneously and for which the term *granulie curable* has been used.

TUBERCLES OF THE CHOROID

Tubercles of the choroid were described and pictured by Bouchut (1869), chief physician at the Hôpital des Enfants Malades in Paris, shortly after the first ophthalmoscopes had been made. It has since been denied that they are at all common, and they have been somewhat forgotten of late. I have found them of great value both in diagnosis, because they can easily be observed without moving the child from the bed, and in prognosis.

The early lesion looks like a little pink or yellowish clear spot with hazy edges on the red fundus. Sometimes it is brilliantly white in the centre. It is no bigger than a quarter of the optic disc. There can be many such lesions in both eyes—miliary tuberculosis of the choroid. We have seen as many as 26 in one eye, anywhere in the choroid, even far from the centre and difficult to see (fig. 3). When they heal, black pigment appears on them, but some of the smaller tubercles can disappear completely.

In some cases larger tubercles can be found, and then there are only one or two of them. They have a white centre and a yellowish corona, and are surrounded by œdematous tissue. On six occasions I have seen a real tumour—tuberculoma of the choroid.

CORRELATION BETWEEN CHEST RADIOGRAM AND CHOROID

There is a definite correlation between the chest radiogram and the choroid. The accompany table shows that typical acute miliary tuberculosis (fig. 2*a*) is almost always associated with the presence of tubercles of the choroid (in 55 out of 58 cases), and that this tuberculosis of the choroid is then usually of the miliary type (in 41 out of 55 cases).

On the other hand, in subacute miliary tuberculosis the incidence of tubercles of the choroid is very different: in only 18 out of 39 cases in the very dense type (fig. 2*b*), or in 58 out of 106 including the more discrete type (fig. 2*c*).

INCIDENCE OF MENINGITIS

The main importance of the distinction of these types is its bearing on the incidence of meningitis (fig. 4):

Of 61 children with typical acute miliary tuberculosis (fig. 2*a*) 52 developed meningitis. Of the 9 children who did not 4 died very quickly with acute dyspnœa, and 3 developed what I have called a slight meningeal reaction because, in the absence of definite proof, I did not dare to consider it as actual tuberculous meningitis, but it might well have been. Only 2 can really be said to have escaped meningitis, and in 1 of these electro-encephalography showed definite changes in spite of the fact that the cerebrospinal fluid (C.S.F.) appeared normal.

In subacute miliary tuberculosis (figs. 2*b* and *c*), even when the radiogram shows extensive disease, the incidence of meningitis is much less: 51 of these 109 children did not get meningitis at any time.

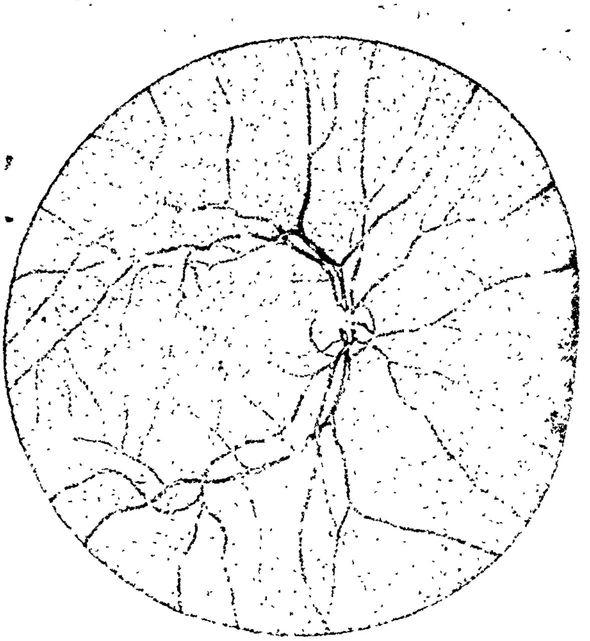

Fig. 3—Tubercles of choroid.

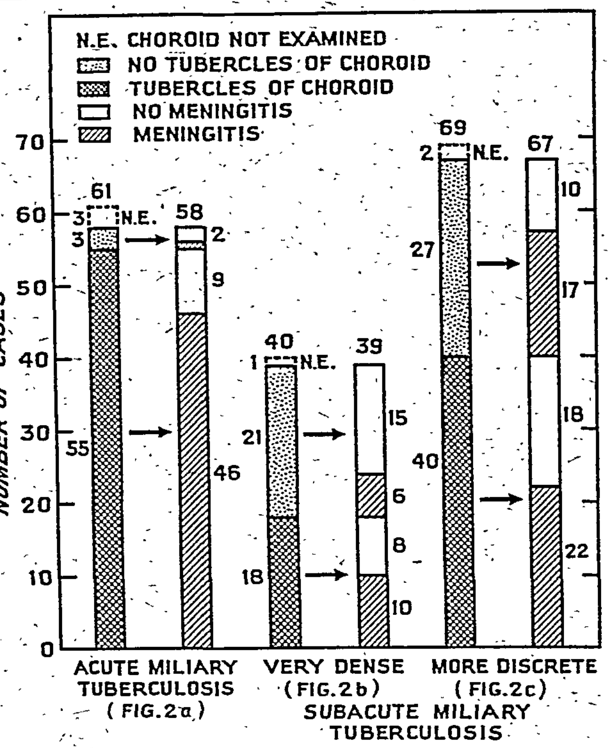

Fig. 4—Correlation of tubercles of choroid with meningitis.

This finding is all the more important because with streptomycin treatment meningitis is the main danger of miliary tuberculosis (see fig. 5):

Of 170 patients 108 either had meningitis on admission or developed it during or after streptomycin treatment. In this group the mortality-rate has been about 60%, much higher than the over-all mortality for tuberculous meningitis, which is 46% in my department.

On the other hand, only 9 patients died of the 62 who did not develop meningitis, making a mortality of about 15%.

This is to say that, on admission as well as throughout the course of the disease, and even after treatment has been discontinued, the main anxiety is about involvement of the meninges.

TUBERCULOUS MENINGITIS

As previously stated, meningitis is already present in nearly half the patients with miliary tuberculosis at the time of admission to hospital. Sometimes the history is that of a tuberculous meningitis, the chief complaint being vomiting and headache. Sometimes, on the other hand, miliary tuberculosis has been diagnosed and it is only on being questioned that the patient tells of a mild headache, or at a careful examination that he is found slightly drowsy and that meningitis is suspected. In many cases it is only by the routine lumbar puncture that the diagnosis can be made. It is therefore imperative not to start the treatment before making sure that the c.s.f. is not abnormal.

CORRELATION BETWEEN CHEST RADIOGRAM AND CHOROID

Type of miliary tuberculosis of lungs	No. of cases	Choroid				
		Not examined	No tubercles present	Tubercles present		
				Miliary*	Isolated†	Total
Typical acute (fig. 2*a*) ..	61	3	3	11	14	55
Subacute :						
Very dense (fig. 2*b*) ..	40	1	21	2	16	18
More discrete (fig. 2*c*) ..	69	2	27	5	35	40

* More than 3 tubercles in each eye.

† Less than 3 tubercles in each eye, or tuberculoma.

If the routine lumbar puncture, before treatment is started, shows a normal c.s.f., this does not mean that the patient will not develop meningitis at any time under treatment, but the chances of his doing so seem to decrease with length of treatment:

In 80 patients meningitis was present on admission.

In 11 patients meningitis was discovered in the first two months of treatment (but in 5 it was not proved that it did not exist on admission).

In 4 patients meningitis was discovered during the fourth month of treatment.

In 1 patient meningitis was discovered during the sixth month of treatment.

In 1 patient meningitis was discovered during the twenty-first month of treatment.

In the remaining 11 patients meningitis was discovered after completion of the treatment.

Therefore once treatment has been started, lumbar punctures are repeated, if not routinely, at least for very slight symptoms, especially in the first two months: the slightest headache or a new rise in temperature or loss of weight, even if it is moderate.

Usually the changes in the c.s.f. are typical enough to make the diagnosis eventually obvious, on repeated lumbar puncture. But in some cases the changes, though definite, are so slight that they are difficult to interpret, and in 3 cases I could neither rule out nor prove the presence of meningitis. Moreover, in 4 children with miliary tuberculosis tubercle bacilli were found on culture of the c.s.f., which was otherwise completely normal. In all 4 children, when the culture was reported as positive from three to six weeks later, a further lumbar puncture, in spite of the absence of any meningeal symptoms, showed typical changes in cells and albumin in the c.s.f. The clinical course of these cases of meningitis was that of any other tuberculous meningitis but on the whole more severe.

In the 17 cases in which meningitis developed during streptomycin treatment tubercle bacilli were found in the c.s.f. at the beginning of the meningitis in 12 cases, and were tested for their sensitivity to streptomycin in 9 cases. They were all sensitive, but in 3 cases a rather resistant strain developed at a later stage. It can be concluded that bacteriological resistance may be one of the factors to account for the bad prognosis of these cases of meningitis.

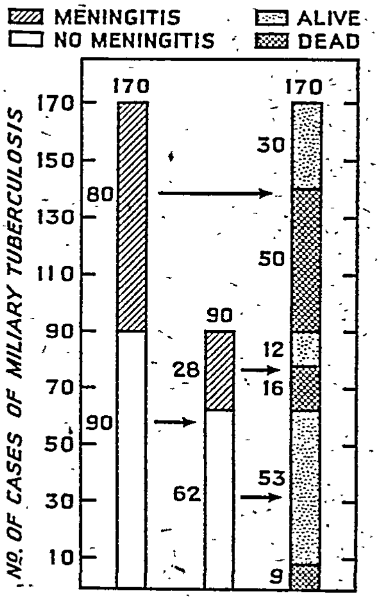

Fig. 5—Onset of meningitis and fate of patients.

CLINICAL COURSE WITHOUT MENINGITIS

In the absence of meningitis the clinical course of miliary tuberculosis treated with streptomycin is usually quite simple. Dyspnœa, if present, usually subsides quickly. The temperature begins to fall quite soon but does not become normal until the second or, more often, the third or fourth month of treatment. The patient

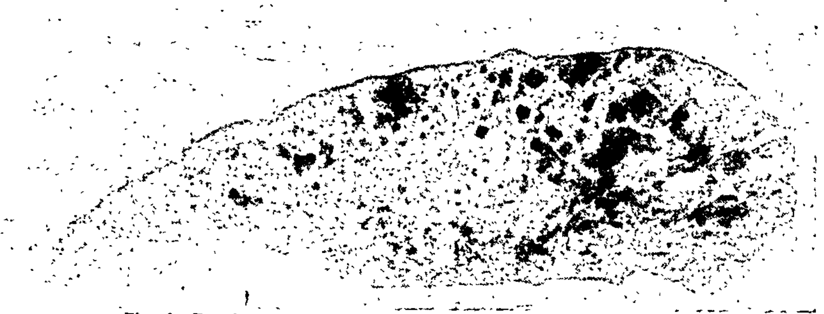

Fig. 6—Emphysematous bullæ of lung due to miliary tuberculosis.

usually starts gaining weight only after the temperature has started to drop. The erythrocyte-sedimentation rate (E.S.R.) returns to normal slowly. At the same time the lesions in the lungs and eyes clear up remarkably. Usually within a month there is already a dramatic improvement in the chest radiogram. The acute *granulie* may have almost disappeared, leaving only a thin reticulum. The larger spots become smaller, resembling for a while the more acute form. The complete clearing up, however, though it can be surprisingly quick (one or two months), usually takes at least three months and sometimes nine. Either it is complete or it leaves a very thin network pattern, which appears unchanged in subsequent radiograms.

Some of the tubercles of the choroid disappear completely; on the bigger ones a black pigmentation can be seen, and they leave a little scar that can be readily recognised. New tubercles, however, have been seen to develop during streptomycin treatment and then to heal on continuation of the same treatment.

COMPLICATIONS

After the chest and eye lesions have completely healed, and the general condition is good after the treatment has been stopped, certain dangers are still to be feared.

Meningitis can still develop. In 11 patients meningitis was discovered only after treatment had been discontinued; but 5 of these were early cases in which no lumbar puncture had been done, and it is likely that meningitis was present much earlier, perhaps from the very beginning, and that what had been taken for the onset of meningitis was only the first manifestation of a relapse. In the 6 other patients lumbar puncture had shown a normal C.S.F. during treatment, and they developed meningitis after treatment had been discontinued for several months in 4 cases, and for a few weeks in 2. It is worth emphasising that 3 were early cases which had been treated for less than three months, another 1 had been treated for three and a half months, another 1 for five months, and another 1 for ten months. With the present treatment lasting more than six months, continued long after the radiogram is back to normal, post-treatment meningitis has become very rare. Indeed, I have seen it only once in such circumstances.

Relapse of miliary tuberculosis is very rare, too. I have seen it twice:

The first case was in a girl, aged 13, admitted in February, 1947, with very acute miliary tuberculosis. After the completion of five and a half months' treatment she went home for two and a half months and then was readmitted with tuberculous meningitis; meanwhile her chest radiogram remained normal, and there were no new tubercles of the choroid. She was treated nearly a year for her meningitis, and then discharged with normal C.S.F. and in good condition; but she was readmitted ten months later with acute miliary tuberculosis both of the lungs and of the choroid, but with no relapse of meningitis. Treatment was resumed and proved as efficient as before. Now she has been off treatment for two years and is doing very well; but she is deaf.

The second case was in a boy, aged 4 years, who had tuberculous cervical lymph-nodes and acute miliary tuberculosis that cleared up very slowly in spite of high dosage of streptomycin and prolonged treatment with combined streptomycin, sulphones, and *p*-aminosalicylic acid (P.A.S.). Treatment was discontinued after more than eighteen months in spite of persistent pyrexia. Five months later the cervical lymph-nodes became enlarged again and, shortly after, miliary dissemination was found again both in the lungs and in the choroids. The child died of a late streptomycin-resistant meningitis.

These are the only 2 cases that I have seen of relapse in 170 cases of miliary tuberculosis.

Other Complications.—In other cases I have seen, after streptomycin treatment, bone-and-joint tuberculosis in 3 patients, tuberculous cervical lymph-nodes in 1, and discrete apical tuberculosis in 1. This, out of the 95 patients who are still alive, means an excellent prognosis as a whole. Of these 95 patients 21 are still being treated or have been off treatment for less than 1 year; 12 have been off treatment for 1–2 years; 35 for 2–3 years; 19 for 3–4 years; and 8 for 4–5 years.

CLINICAL FORMS

Fatal Acute Miliary Tuberculosis.—In the present series of 170 patients 9 died of miliary tuberculosis and not from meningitis. The main cause of death was acute asphyxia. I have seen it in 3 cases due not only to actual miliary lesions but also to rupture of emphysematous alveoli, causing either pneumothorax or acute mediastinal and subcutaneous emphysema (fig. 6). The other patients died of more or less rapidly progressive cachexia.

Miliary Tuberculosis with Localised Tuberculosis.—Tuberculosis of bones and joints or of lymph-nodes is seen with subacute miliary tuberculosis. I have seen 2 tuberculomas of the cerebellum; both were successfully removed under streptomycin treatment.

Late Miliary Dissemination.—In a few cases miliary dissemination took place from some unknown cause several years after the onset of the primary tuberculosis. I have twice seen a child, admitted with meningitis without miliary tuberculosis, have a typical miliary spread at the time of a relapse of the meningitis. One of these children is off treatment and in good condition, and the other is still being treated and doing well. In a third case miliary tuberculosis was found at necropsy in a child who had died of a relapse of tuberculous meningitis due to resistant tubercle bacilli.

TREATMENT

I give 0·02–0·04 g. daily per kg. of body-weight. I give more to small children (0·50 g., for instance), and never more than 1·50 g. to older children. This dose is given in three injections daily, continuously for at least eight months.

I always give P.A.S. too by mouth 0·30–0·50 g. per kg. of body-weight taken in 1–4 fractions a day, continuously until the streptomycin is discontinued.

This treatment has to be continued if the regression of the signs and symptoms (radiological picture, temperature, E.S.R.) takes longer than usual. In some such cases the treatment has lasted thirteen months.

After completion of a course of treatment, it has to be resumed in the following circumstances:

(1) If there is a relapse of miliary tuberculosis.

(2) If there is a secondary *tuberculous focus* (lymph-nodes, bones and joints, &c.).

(3) If meningitis develops. In this case streptomycin 20–4 mg. is immediately given by the intrathecal route, usually lumbar, twice a day for a few days (in addition to two intramuscular injections a day) and then once a day until the C.S.F. has been normal for two months. The intramuscular injections are discontinued at least two months after the intrathecal injections.

The recent introduction of isoniazid in the treatment of tuberculosis adds a new weapon to the struggle against this disease; but by no means does it exclude streptomycin and P.A.S., especially streptomycin, which remains the fundamental antituberculous drug.

INFECTIOUSNESS OF COMMUNICABLE DISEASES IN THE HOUSEHOLD

(MEASLES, CHICKENPOX, AND MUMPS)*

R. E. HOPE SIMPSON
M.R.C.S.

DIRECTOR, EPIDEMIOLOGICAL RESEARCH UNIT, PUBLIC HEALTH LABORATORY SERVICE, CIRENCESTER, GLOS

MEASLES, chickenpox, and mumps have similarities which link them in a natural group with a number of other diseases. Each is a characteristic communicable illness to which most people are liable, and each usually produces enduring immunity. The causal agent of each is an obligate parasite natural to man which passes direct from sufferer to susceptible, apparently without the need of an intermediate agency. Inapparent infections are rare, at least in measles and chickenpox, infection of a susceptible ordinarily leading to the manifest disease, and the carrier state does not seem to play an important part in distribution.

These properties, with some others, determine the way a disease behaves in a community, and in fact the three diseases resemble one another sufficiently closely in their epidemic and endemic behaviour to justify comparative investigation by similar methods. Nevertheless there are differences. Despite the broad similarity, just as each disease has its peculiar clinical picture, so it has its own epidemiological pattern due to consistent differences of degree in those very attributes which link the diseases together in a natural grouping. Both measles and mumps, for example, tend to attack exposed susceptibles, but measles habitually strikes more readily than mumps, and so it comes about that mumps works its way through a community more slowly than measles, leaving behind more susceptibles to be dealt with at second or third visits. This peculiarity is reflected in the age-distribution of any adequate collection of cases. Communities of various types may vary much in the age at which their members take these diseases, but in a single community over a given period the average age of attack will be somewhat younger for measles than for mumps.

The epidemic pattern depends in part on the natural characters of the parasite, in part on the behaviour of the human host. When investigating a particular property of the parasite it is therefore necessary, so far as possible, to reduce or eliminate any disturbing effects of human behaviour—the human community must be standardised for the purpose. The household has often proved the most suitable community in which to compare and contrast various properties of different human parasites under similar conditions.

Having studied a particular property in one type of community one can repeat the study in other types of human environment, and so, step by step, learn something both of the effect of human behaviour on the biology of the organism, and of those details of the host-parasite relationship with which deliberate human interference may be practicable and desirable. Moreover, the method is fruitful in assessing the results of such interference.

Distinctions between similar diseases may sometimes be qualitative, as when transmission is effected by sputal droplets in one disease and by fæcal contamination in another. More often the differences are quantitative and require numerical assessment and presentation.

* The word "infectious" is used in some parts of the English-speaking world synonymously with our use of the word "infective"; hence in such places "infectious diseases" would mean all those of microbic agency whether naturally communicable or not. For those which are communicable the word "contagious" is used (Dorland 1938). For transatlantic readers the initial word of the title of this paper should be: "Contagiousness."

TABLE II—INFECTIOUSNESS (EXPOSURE ATTACK-RATE AMONG SUSCEPTIBLES AT RISK IN THE HOME)

Age-group (yr.)	Measles	Varicella	Mumps

Infectiousness, the ability of a disease to spread in a community, is a measurable characteristic and should be susceptible of being expressed precisely. It is insufficient to recognise that measles is more infectious than mumps. How much more infectious is it? Is it more so than chickenpox? A means of measuring infectiousness not only adds to our knowledge of the biology of this interesting group of parasitic organisms but also provides an approach to the solution of some practical problems. Does infectiousness vary from time to time, and from place to place? What other attributes of a disease are quantitatively associated with its degree of infectiousness? Is change in infectiousness responsible for the waxing and waning of epidemic prevalence?

The present paper describes studies on the infectiousness of measles, chickenpox, and mumps in households in a semi-rural area of Gloucestershire—a town of some 11,000 inhabitants and the surrounding agricultural area to a radius of 6–8 miles containing a slightly larger population. The records for measles and chickenpox cover the four years from June 1, 1947, to May 31, 1951. Those for mumps include also a further seven months until Dec. 31, 1951.

A member of the epidemiological research unit visited all the cases and contacts several times. Much care was taken to ensure accuracy and to indicate which data were fully reliable and which only approximate. Approximately accurate data, though useful for certain purposes, can be most damaging when associated with more accurate data for other purposes. Close association with a general practice, the ready coöperation of the other general practitioners in the area, and long familiarity with the district gave unusually favourable opportunities. For example, the parent of a child with an attack of measles claimed that five years earlier the child had had a previous attack of measles diagnosed as such by the doctor. Reference to the contemporary notes of the doctor showed that the previous attack was one of rubella. In many such instances it was possible to increase the accuracy of the records.

Method of Calculating Infectiousness

PRINCIPLE

Measurement of infectiousness is based on the attack-rate. Attack-rates are assessed in different days, and to secure comparable figures it is important to define which way is being used. In one which has been much used an estimate is made of the proportion of susceptibles who become infected in homes into which the disease has been introduced; this gives a secondary attack-rate. Attractive because of its convenience and simplicity, this reckoning conceals several sources of error and should be reserved for diseases in which it is impossible to determine the details of spread inside the individual households—e.g., whooping-cough. An excellent example of the use of this method is to be found in the report of the Medical Research Council (1951) on the prevention of whooping-cough with vaccine. The results are not precisely comparable with those of the method used here and tend to give a consistently higher rate.

In determining infectiousness the *susceptible-exposure attack-rate*—i.e., the proportion of exposures of susceptibles leading to a transmission—should be used whenever possible. An exposure takes place each time that a susceptible—one giving no past history of the disease—is at risk with one or more infectious cases. Each susceptible in a household in which another occupant is ill with the disease is deemed to have undergone exposure unless he is simultaneously ill with the same disease. The desirability of counting in this way is clear if one considers families of different sizes. A solitary susceptible escaping an exposure in the home has no further opportunity to catch the disease there, whereas when two susceptibles are simultaneously at risk of whom only one takes the disease the other is exposed a second time. The larger the number of susceptibles the greater is the opportunity for several generations inside the family. Each exposure must therefore be recorded to allow those leading to a temporary escape equal value with those leading to a more permanent escape. Four examples are given to make the method clear:

I, A infects B, C, D, and E.

Exposures	4
Transmissions	4

II, A infects B, but C, D, and E escape. Then B infects C, D, and E.

Exposures	7
Transmissions	4

III, A infects B, but C, D, and E escape. B then infects C, but D and E again escape. Then C infects D, but E again escapes. E also escapes the infective stage of D, so escaping finally.

Exposures	10
Transmissions	3

IV, A fails to infect B, C, D, and E. Five weeks later B gets the disease and infects C and D, but E escapes. Here there are two distinct entries of the virus into the household:

(i)	Exposures	4
	Transmissions	0
(ii)	Exposures	4
	Transmissions	2

Table I shows these four examples set out on the epidemic sheet from which the exposure attack-rate in the home is compiled.

EFFECT OF FAULTY MEMORY

A person who mistakenly represents himself to be a susceptible produces a double error by falsifying both the

number of exposed susceptibles in the family and the proportion of escapes. In example III given above, for instance, if E is not susceptible but immune, the number of presumed escapes is raised from 3 to 7, a serious augmentation. The larger the family the greater is the error, because most immunes at risk will always escape, however often exposed. Increasing age brings forgetfulness of childhood ailments, a source of error which becomes considerable in the elderly. Against measles there appears to be no evidence of increasing immunity apart from an attack of the disease. Epidemics in areas unprotected by endemic disease affect the older equally with the younger members of the population, as was shown in the Solomon Islands and in the Faroe Islands (1846). The position is probably the same for varicella.

S.I., first day of swelling.

For measuring infectiousness the attack-rate is therefore calculated on susceptibles aged 14 or less. The rate in alleged susceptibles above that age is very different (table II), and one presumes that this disparity is due in large part to the fading memory of childhood illness. It is not unreasonable to suppose that of the 36 persons aged more than 14 representing themselves to be susceptible to measles only about 10 were so. In mumps the position is different; mumps is less infectious and therefore attacks on an average at a later age. The attack-rate among those aged more than 14 claiming to be susceptible does not differ materially from that in the younger group. At present there seems to be no knowledge of the effect of ageing on susceptibility. The figure for the infectiousness of mumps, 31·1%, reckoned on the susceptibles aged less than 14 differs but little from the attack-rate at all ages (32·1%). It is therefore probably unnecessary to make, as we have done, an adjustment of the sort used in measles and varicella to the figures for mumps.

PRIMARY AND SECONDARY CASES

From what has already been written it is seen to be important to distinguish clearly between primary (infecting) cases and secondary (infected) cases. During an epidemic three or four generations of the disease may occur in a family, the second-generation cases in their turn becoming primary to the tertiary, and the tertiary to the quaternary. A right estimate of the number of exposures and transmissions depends on a knowledge of the span of a generation, a measurement peculiar to each disease.

Point of Measurement

It is necessary to define a point in the course of the disease from which to measure the serial interval from case to case. Most diseases present several features that might be used for the purpose, and the principles on which to choose the most suitable have already been discussed (Hope Simpson 1948). The event on which to base a *measuring-point* must be regularly present, readily recognised, and constant in the time of its appearance in the cycle of the illness. In measles four events have been examined for suitability (table III):

(1) *Onset of symptoms of illness.*—This, though often used, is unsatisfactory because the serial intervals cover a wide range with a shallow mode.

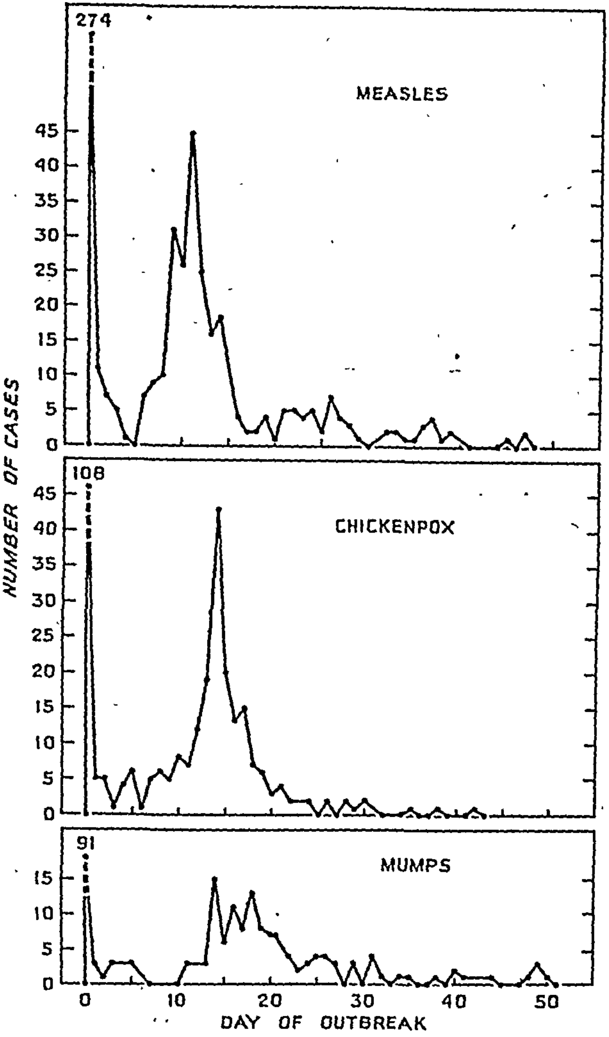

Fig. 1—Primary and secondary cases in outbreaks in households.

(2) *First appearance of conjunctivitis.*—This gives a satisfactory range and mode, but the symptom is often absent or unrecognised, or its day of onset is forgotten.

(3) *First appearance of rash.*

(4) *Day of maximum rash.*

Between these last two there is little to choose. Parents are perhaps less certain of the date of the first appearance. Some parents are more observant than others. We can ourselves confirm the day of fullest development more often than the day of first appearance of the rash. For these reasons we have chosen the day of fullest flowering of the rash. When, as occasionally happens, the rash remains equally florid for more than one day, the first day of maximum rash is used.

Table IV examines the onset and the first day of rash in chickenpox, and table V the onset and the first day of swelling in mumps. The days of measurement used in the present study are as follows:

Measles: maximum rash,
Chickenpox: first appearance of rash,
Mumps: first appearance of swelling.

The point of measurement in each case is midnight after the day of measurement.

First-generation Primaries

It is next necessary to distinguish between those cases in the home which are co-primary with the first case and have been infected outside the household, and second-generation cases infected by the primary case within the household. To do this, the first case in the home is *considered as occurring at the zero point,* and the intervals between the measuring-point in this and subsequent cases are tabulated. The experience of all the households combined shows a steep decline for the first few days owing to the decreasing number of co-primaries, succeeded by a rise towards the mode of the curve of secondary cases (fig. 1). The lowest point, where the decreasing primaries are intersected by the increasing secondaries, is taken as the division between first and second generations, and at this point primaries erroneously included as secondaries most nearly balance secondaries wrongly considered primary. A small error remains because there are inevitably more secondaries than primaries.

TABLE VIII—PERCENTAGE OF SECONDARY CASES ESCAPING TEMPORARILY

Disease	Secondary cases	Percentage escaping temporarily	
		Once	Twice
Measles	201	4·0	0·5
Varicella ...	172	8·1	0·6
Mumps	82	12·2	3·7

Cases which have had two escapes are also included among those which have escaped once.

The following are the intervals during which cases are considered co-primary with the first case in the household:

Measles: 6 days, Varicella: 7 days, Mumps: 10 days.

Second Generation

The second generation must be distinguished not only from the first as described above but also from subsequent

BLE IX—EXPOSURE ATTACK-RATE % AMONG FAMILIES WITH FFERENT NUMBERS OF SUSCEPTIBLES UNDER THE AGE OF 15

isease	No. of susceptibles in family				
	One	Two	Three	Four or more	Total
easles	140 (*77·9*)	68 (*76·0*)	24 (*70·0*)	16 (*70·0*)	248 (*75·6*)
aricella	104 (*75·0*)	80 (*60·0*)	48 (*48·6*)	15 (*45·5*)	247 (*61·0*)
umps	78 (*32·1*)	98 (*38·3*)	81 (*31·1*)	55 (*25·3*)	312 (*31·1*)

Rates are shown in parentheses.

TABLE X—INFECTIOUSNESS AND AGE-DISTRIBUTION

—	Measles	Varicella	Mumps
fectiousness (%)	75·6	61·0	31·1
ean age at which infection takes place (yr.)	5·6	6·7	11·5
andard deviation of age distribution	4·73	5·45	10·50
ge by which 90% of cases have had the disease	8 yr. 4 mos.	10 yr. 8 mos.	29 yr.

enerations. Mistaken inclusion of tertiaries reduces the roportion of escapes, and mistaken inclusion of second-eneration cases among tertiaries reduces the proportion f transmissions. Epidemic studies are of great assistance n solving this problem. Fig. 2 shows accumulated epi-emics with the first case of each recorded at zero point. t is easy to find the mode of generation after generation. rom these figures the following intervals have been hosen:

	First generation (days)	*Second generation (days)*	*Tertiaries (days)*	*Quaternaries (days)*
easles ..	1–6	7–18	19–30	31–42
aricella ..	1–7	8–21	22–35	36–49
umps ..	1–10	11–30	31–50	51–70

(Both days are included in the intervals.)

Certain interesting relationships emerge from this study. It will be seen that the generation-time is twice the interval during which cases are considered to be co-primary with the first case. Further, the generation-time is identical with the mean interval between the modes of successive generations, and indeed this forms the simplest method of estimating it.

Here is a biological measurement of great interest, susceptible of precise estimation, differing consistently from disease to disease in a manner peculiar to each parasite. Domiciled in man for millennia, the causal organism of measles has burst into reproductive activity and sent forth a fresh colony on the average every twelfth day. The figure of twelve days used here for measles is too long, but for present purposes it is impossible to split the day into portions. The reproductive cycle of varicella is almost exactly fourteen days. For mumps the data are as yet insufficient to give a precise figure, and twenty days must be considered as tentative.

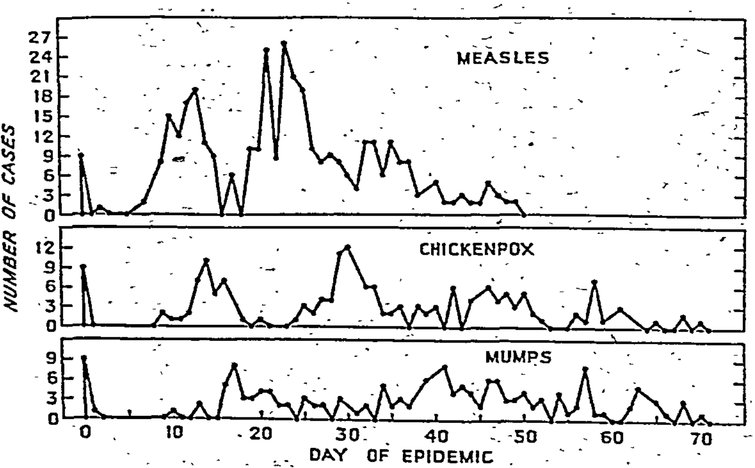

Fig. 2—First, second, and subsequent generations of cases in epidemics.

The methods used here differ from those used by Wilson et al. (1939), whose paper should be consulted for details of previous usages. The choice of method makes a considerable difference, especially when one is studying attack-rates in families with differing numbers of susceptibles at risk. To compare our figures with those of Wilson et al. we have re-analysed them in table XII by the methods which they used.

Results

Table II shows the infectiousness of the three diseases, the figures for each representing the experience of almost the same families. Measles is evidently the most infectious in the community provided by the household. Mumps is not half as infectious as measles and only just over a half as infectious as varicella. Fig. 3, based on tables VI and VII, shows the infectiousness of the three diseases throughout the seasons, a three-monthly moving average being used. Tests of significance show that the variation in each is not more than would be expected by chance. The degree of infectiousness in the three diseases is also reflected in the proportion of secondary cases that escape once or twice before finally coming down (table VIII).

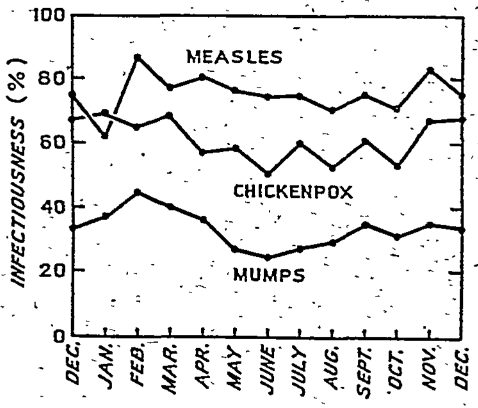

Fig. 3—Infectiousness of measles, chickenpox, and mumps in different seasons.

EFFECT OF SIZE OF FAMILY ON INFECTIOUSNESS

Table IX shows the infectiousness of the three diseases in families with 1–4 or more susceptibles at risk. The numbers of families with more than 3 susceptibles at risk are not large enough to be representative.

INFECTIOUSNESS AND AGE OF ATTACK

In diseases which confer life-long immunity the degree of infectiousness is reflected in the age at which a person is most likely to be attacked. The more infectious the disease the younger is the age at which an attack is likely to be received. Table X, which shows the age-distribution and the infectiousness of measles, varicella, and mumps, brings out the closeness of this inverse relationship.

INFECTIOUSNESS AND SEASONAL PREVALENCE IN MEASLES

During the period of this study measles in this area was mainly a disease of spring and summer, 78·6% of the 663 cases in the epidemic studies having fallen during the months from May to August (table XI). In case these figures were unrepresentative, drawn as they were largely from studies of total epidemics in various parts of the area, the fairness of the picture was tested by analysing the measles seen in the same period in a local general practice among some 4000 patients. Of the 229 cases of measles encountered in the practice more than 75% fell in the months from May to August; hence the epidemic figures may be taken as representing the local trend of measles during that period.

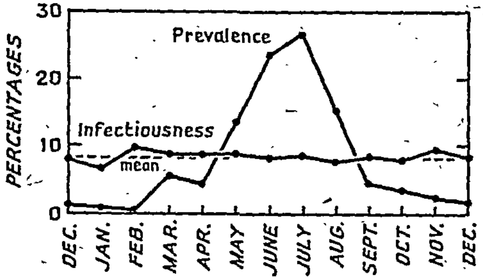

Fig. 4—Comparison of infectiousness and prevalence of measles.

Was the autumn decline in prevalence due to diminished infectiousness of the disease? Comparison of the seasonal infectiousness with the seasonal prevalence in table XI and fig. 4 shows a vivid contrast between the uniformity of the infectiousness and the variation in the prevalence. There is no seasonal waxing and waning in infectiousness such as might explain the vagaries of these epidemics.

RELIABILITY AND UTILITY OF THE PRESENT METHOD

The simple method presented here of assessing infectiousness can be adapted to the study of virus mutation and other factors involving secular changes in infectiousness. The measurement given is absolute and not merely relative, 100% infectiousness representing a disease which attacks every exposed susceptible in the home at the first opportunity. Measles approaches quite near to saturation, and experience suggests that whooping-cough will give an even higher figure. It has been shown above how the method can be used to study seasonal variation in infectiousness; and, in view of its possible usefulness in other spheres, it is well to inquire if the figures produced possess the requisite stability. Were the investigation to be repeated in another part of the country, for example, or here at another time, would different figures emerge? Although further research is needed to decide this, our experience suggests that sufficiently stable figures can be obtained. The measles cases analysed here can be arranged in a form to compare with the admirable studies of Wilson et al. (1939) at Providence, Rhode Island. Reference to table XII shows that their figures fall close to ours in both age-groups.

TABLE XI—SEASONAL PREVALENCE AND INFECTIOUSNESS IN MEASLES

(The three percentage columns show the proportion of the total occurring in each month)

—	Infectiousness in epidemic studies			Prevalence

(See also fig. 4.)

Several workers have suggested that infectiousness alters during the course of an epidemic and is at a different level in interepidemic periods. This matter can also be investigated simply and directly by the present methods: it would demand a simultaneous collection of records from a wide area and would need to be continued for several years.

Summary

It is possible to give a quantitative expression of the infectiousness of certain diseases by assessing the incidence of cases resulting from every exposure of a susceptible in the home (susceptible-exposure attack-rate). Infectiousness in the diseases studied was:

Measles: 75·6%, Varicella: 61·0%, Mumps: 31·1%.

The mean reproductive cycle of the virus of measles is twelve days, that of varicella fourteen days, and that of mumps about twenty days. Cases are reckoned as co-primary with the first case in the household if they fall within a period of half the reproductive cycle. Subsequent generations are reckoned by adding on to this half-cycle a period equal to one reproductive cycle for each generation. Details are given of the methods used.

TABLE XII—COMPARISON OF THE SECONDARY ATTACK-RATE IN MEASLES IN DIFFERENT AREAS AND AT DIFFERENT TIMES

Age-group (yr.)	Secondary attack-rate	
	Providence, U.S.A., 1929–34 (Wilson et al. 1939)	Cirencester, 1947–51
Less than 1	40·6	40·0
Less than 15	81·1	80·1
15 or more	16·7	16·3

The age-distribution of these diseases shows a close inverse relationship with the infectiousness.

The summer prevalence of measles in these areas during the period under review was not due to any increase of infectiousness that could be shown in the home attack-rate.

A numerical expression of infectiousness should prove of value in the study of various problems concerning infectious disease.

It is a pleasure to acknowledge the great help received from every member of the unit during the five years of its existence, and the grant from the Medical Research Council which made the work possible. I have also had help and advice from many people, and I wish especially to mention that received from Prof. A. Bradford Hill. I am glad also to acknowledge the willing coöperation of the school-teachers in this area, and of my general-practitioner colleagues, and the patients who form the subject of this work.

PHYSICIAN TO THE WREXHAM GROUP OF HOSPITALS

SINCE the advent of A.C.T.H. and cortisone reports have been published emphasising the danger of their side-effects. One of these alleged effects is the activation of healed or quiescent peptic ulcers, leading on occasion to bleeding or to perforation (Beck et al. 1950, Habif et al. 1950, Smyth 1951, Mandel et al. 1951, Sloan et al. 1951, Gray et al. 1951). Even more alarming are the records of perforation or of massive hæmorrhage in A.C.T.H.-treated patients with no previous history of ulceration (Habif et al. 1950, Gray et al. 1951). In such cases A.C.T.H. seems to have produced an ulcer.

Two explanations are offered for this untoward effect (Spiro et al. 1950, Gray et al. 1951):

(1) An increase in peptic activity as the result of administration of A.C.T.H. or of cortisone is shown both by a rise in the concentration of pepsin in the gastric juice and by increased excretion of uropepsin in the urine. The effect is not immediate but becomes manifest a few days after the start of treatment. It appears both in normal and in ulcer patients.

(2) At the same time there is a rise in gastric acidity, which is also slow, for the increase is not well marked until therapy has been given for 7–14 days. This effect also is seen in both normal and ulcer patients. When treatment is stopped, gastric acidity returns to normal.

So far Gray et al. (1951) have reported this increased gastric acidity only for A.C.T.H.; but it seems not unlikely that cortisone produces a similar effect, since it also increases peptic activity. Gray et al. comment:

> "The necrosing and erosive properties of acid-pepsin-gastric juice are well established. There is no reasonable doubt that the continuous stimulation or overproduction over a period of days or weeks of highly acid gastric juice rich in pepsin may result in a reactivation, perforation, or hæmorrhage from peptic ulcer."

They used fairly large doses, 100–160 mg. of A.C.T.H., or 250 mg. of cortisone, daily. This is more than most patients receive as a routine nowadays. However, the reported ulcer catastrophes cannot all be dismissed as due to excessive dosage; for, although one patient bled after receiving 4000 mg. of A.C.T.H. in twenty-one days, another perforated and died after having only 375 mg. in five days (Smyth 1951).

The activation of healed or of quiescent peptic ulcers, and the apparent production of ulceration in normal stomachs, are serious indictments of A.C.T.H. and cortisone—more particularly of A.C.T.H., since almost all the published reports of catastrophes refer to its use. Probably about 1 in 5 of the adult population of these islands has at one time or another had a peptic ulcer and would therefore seem to be at risk if given A.C.T.H. or cortisone. Physicians may well hesitate to administer these drugs, however pressing the indications for their use, to anyone who has a previous history of dyspepsia; they know how difficult it is to exclude the possibility of ulcer having caused the symptoms. Preliminary barium-meal radiography may show a scarred and deformed duodenal cap, but it may not reveal the scar of a healed gastric ulcer; and even when no previous ulcer exists, there is still the possibility that the treatment may cause one to appear. To make matters worse, the perforation of a peptic ulcer in a patient under treatment with A.C.T.H. or with cortisone may be attended by minimal symptoms and signs, owing to the masking effect of these drugs. The diagnosis may therefore be delayed, or even missed altogether, with fatal results (Smyth 1951).

There are indications, however, that the risk of ulcer activation is not really so great as might appear from the foregoing. Large numbers of people in Britain and elsewhere have now been treated with A.C.T.H. and with cortisone, yet the published reports of gastric accidents are relatively few. Even if the recorded catastrophes form only a small proportion of those that have taken place, there seems at present no indication that the situation is so grave as to cause widespread disquiet among those clinicians in this country who are using these drugs. Are A.C.T.H. and cortisone in fact as bad for peptic ulcers as a reading of the relevant reports might lead one to suppose? Whenever a new drug appears, the initial wave of enthusiasm is nearly always quickly succeeded by a trough of doubt. A.C.T.H. and cortisone were received initially, especially by the lay press, with even more than the usual acclaim, but a recent description of them as merely "a glorified aspirin" seems equally lacking in proportion. It would be a pity if such potentially valuable drugs were to be withheld from patients who might benefit from them, because of exaggerated fears about their toxic effects on the stomach.

The present investigation was started in the hope that it might throw some light upon the extent of this particular danger.

METHOD

Only patients with gastric ulcers have been included in this study. The healing, or otherwise, of gastric ulcers can be judged objectively by X rays, whereas that of duodenal ulcers as a rule cannot. Subjective clinical assessment of ulcer activity is notoriously unreliable.

Eighteen patients with uncomplicated gastric ulcers were divided into three groups. One group was treated with A.C.T.H. and one with cortisone, and the third was used as control. No selection was exercised, and all that the patients had in common was a chronic gastric ulcer, with a history of dyspeptic symptoms for several months or years.

As soon as the presence of an ulcer had been radiologically confirmed in the hospital outpatient department, the patient was put on the inpatient waiting-list and admitted as soon as possible. It was unfortunately impracticable to give A.C.T.H. and cortisone effectively to outpatients. However, while the patients were in hospital, no restriction was placed on their activities. They were allowed to smoke, were given no drugs other than A.C.T.H. or cortisone, and were kept on an almost normal diet. It was impossible to give a completely unlimited diet, because most patients were already accustomed to some self-imposed dietary restrictions which they were reluctant to abandon altogether; moreover the control group might well have complained that they were being kept in hospital unnecessarily. However, the diet given was merely the routine "post-ulcer régime," which consists simply of snacks between the main meals and the prohibition of grossly irritant articles of diet.

During the inpatient period A.C.T.H. and cortisone were given to patients in the appropriate groups by intramuscular injection at six-hour intervals. After two or three weeks of such treatment the patients were sent home with instructions to remain away from work and to continue the "post-ulcer" dietary régime, and were seen in the outpatient department at intervals until radiography showed complete healing of the ulcer or, in the case of those ulcers that failed to heal, until some other form of treatment was adopted.

RESULTS

The "radiological healing-time" of the ulcer has been arbitrarily assessed as the number of days which elapsed between the initial outpatient radiogram showing an ulcer and the final radiogram showing complete healing. The figure thus obtained is necessarily inexact, because

TABLE I—A.C.T.H.-TREATED PATIENTS

Case no.	Age (yr.)	Sex	History of ulcer (yr.)	Total dose of A.C.T.H. (mg.)	Period of administration (days)	Symptomatic improvement under treatment	Radiological healing-time	Remarks
1	45	M	20	980	15	Worse	..	Gastrectomy
2	55	F	3	440	12	Moderate	..	Eventually healed on routine treatment
3	55	M	2	980	27	Well marked	..	,,

radiography could only be done relatively infrequently (usually about once a fortnight). However, this is unimportant when dealing, as here, with a chronic lesion taking several weeks to heal, because differences of a few days one way or the other are of minor consequence.

The results in the three groups are summarised in tables I–III.

A.C.T.H.

There were originally five patients in this group, but one has been excluded because of doubt about whether the original radiogram did in fact show an ulcer. A second patient refused, for irrelevant reasons, to continue the injections after the first three days. As will be seen from table I, two of the remaining three patients said they felt better after the course of injections, but their radiograms showed no decrease in the size of the ulcer. One patient was apparently made worse:

Case 1.—*A lorry-driver, aged 45, had had intermittent* dyspepsia for twenty years. Radiography on March 22, 1951, showed a chronic gastric ulcer on the lesser curvature. He was admitted to hospital on April 25, 1951, and further radiography on May 4, 1951, still showed the ulcer, though it was smaller. A.C.T.H. 12·5 mg. six-hourly was given from May 5 to May 11, 1951, when the dose was increased to 20 mg. six-hourly. By May 17, 1951, he was complaining of increased pain; so the dose was reduced to 10 mg. six-hourly, and A.C.T.H. was finally omitted two days later. The patient was then put to bed on a light gastric diet, but despite this he continued to complain of severe pain and asked for operation. On May 28, 1951, a partial gastrectomy was done. The ulcer, which was simple and surrounded by considerable scar tissue, adhered to but did not actually penetrate the pancreas. Uneventful recovery followed.

There seems to be little doubt that this man's ulcer, which appeared to be healing before he came into hospital, was made worse by the A.C.T.H. and might well have perforated had the injections been continued.

In view of the uniformly poor results in these three patients, and the reported catastrophes after the use of A.C.T.H., it seemed unjustifiable to submit any more patients with gastric ulcers to the risk of A.C.T.H. injections.

TABLE II—CORTISONE-TREATED PATIENTS

Case no.	Age (yr.)	Sex	History of ulcer (yr.)	Total dose of cortisone (mg.)	Period of administration (days)	Symptomatic improvement under treatment	Radiological healing-time (days)	Remarks
4	51	M	5	300.	24	Well marked	48	..
5	41	M	10	2200	23	,,	26	Relapsed 2 mos. later
6	41	M	5	1850	20	,,	55	..
7	50	M	$^{3}/_{12}$	2250	23	Moderate	57	..
8	66	F	10	1650	17	Well marked	..	Gastrectomy
9	50	M	3	2650	28	,,	33	..
10	50	F	1	2450	25	,,	..	Gastrectomy
11	44	M	$^{3}/_{12}$	2150	23	,,	51	..

Cortisone

By contrast, this group of eight patients did unexpectedly well. With two exceptions the patients showed progressive clinical and radiological improvement, both during the period of cortisone injections and afterwards, to the point of complete healing of their ulcers. Two patients, however, failed to get radiological healing.

Case 8.—A married woman, aged 66, had had intermittent dyspepsia for many years. Radiography on Dec. 12, 1951, showed a deep chronic gastric ulcer on the lesser curvature. She was admitted to hospital on Dec. 13, 1951, and cortisone 25 mg. was given six-hourly between Dec. 13 and Dec. 27, 1951. Then the dosage was tapered off and the drug finally discontinued on Dec. 30, 1951. During this period the patient gradually lost all her symptoms, but radiography on Dec. [illegible], 1951, showed no diminution in the size of the ulcer. She was discharged from hospital and observed at outpatients. Two months later the ulcer was still present; so in March, 1952, a successful partial gastrectomy was done. The ulcer was simple, but associated with much scarring and adherent to the pancreas.

Case 10.—A married woman, aged 50, had had dyspepsia for a year. Radiography on Jan. 14, 1952, showed a chronic gastric ulcer on the lesser curvature. She was admitted to hospital on Jan. 19 and given cortisone 25 mg. six-hourly from Jan. 22 to Feb. 13. Then the dosage was tapered off and the drug finally discontinued on Feb. 16. During this time the patient became symptomless, but radiography on Feb. [illegible] and 21 showed no change in the size of the ulcer. A month later a partial gastrectomy was done because malignancy was suspected. The patient died shortly after operation. The ulcer was simple.

TABLE III—CONTROLS

Case no.	Age (yr.)	Sex	History of ulcer (yr.)	Symptomatic improvement in hospital	Radiological healing-time (days)	Remarks
12	45	M	10	Well marked	63	..
13	24	M	3	,,	35	..
14	61	F	10	Moderate	..	Gastrectomy
15	37	M	5	Well marked	48	..
16	41	F	2	,,	31	..
17	36	F	1	,,	53	..
18	73	F	$^{3}/_{12}$	,,	19	..

Although both these patients became symptom-free while on cortisone, their ulcers did not show radiological improvement. It is therefore possible that the cortisone may have delayed healing; it did not, however, seem to make the ulcers any worse.

Controls

All but one of these seven patients showed progressive clinical and radiological improvement to the point of complete healing, although they received no treatment other than the "post-ulcer régime." The exception was an elderly lady with a large ulcer on the lesser curvature. Although her symptoms improved and the ulcer decreased in size, after four months it was still visible on radiography. Gastrectomy was successfully done. The ulcer was simple.

DISCUSSION

The good results obtained in the controls confirm the experience of previous observers that gastric ulcers have a strong tendency to heal spontaneously, though the healing may only be temporary. Stolte (1950), for example, obtained radiological healing, usually in about [illegible] weeks, in twenty-one of twenty-four gastric-ulcer [illegible] patients treated only with placebos. It therefore follows that, if a drug is given to such patients, and if as a result some of them show appreciable delay in the progressive healing of their ulcers, it must be assumed that the drug is doing harm, even though there is no actual worsening of the condition.

The three A.C.T.H.-treated patients were all radiologically unimproved after the drug had been given, and one of them was symptomatically worse. A case against A.C.T.H. has already been made by three recorded episodes in which a gastric ulcer was made worse by the administration of A.C.T.H. (Sandweiss et al. 1950, Smyth 1951, Gray et al. 1951), and this case seems to be strengthened by the present findings. It would be foolhardy to persist in using A.C.T.H. for patients with active, or even quiescent, gastric ulcers.

The case against cortisone, however, does not seem so strong. There is no published record of a gastric ulcer having been made worse by cortisone, and in fact there is only one report of such deterioration in a duodenal ulcer (Lubin et al. 1951). It is also worth noting that the gastric-ulcer patient recorded by Smyth (1951) as having been made worse by A.C.T.H. subsequently received a course of cortisone without ill effect. On the other hand, S. J. Gray (personal communication) has had a patient who, after several months of cortisone treatment in fairly heavy dosage, developed a gastric ulcer for the first time.

In the present series six of eight cortisone-treated patients progressively healed their ulcers in an average time of 45 days. This compares favourably with the six similar controls, whose ulcers healed in an average time of $41\frac{1}{2}$ days. It therefore does not seem that cortisone, in contrast to A.C.T.H., materially interferes with healing in most gastric ulcers.

This apparent difference between the effect of cortisone and that of A.C.T.H. on gastric ulceration is perhaps less surprising than might appear at first sight. Copeman (1952) says:

> "Twenty-six different steroid substances have been isolated by Kendall from the adrenal cortex, one of which is cortisone. The administration of corticotropin to a patient stimulates the production of all twenty-six substances, and more side-effects are therefore to be expected than after cortisone alone."

Perhaps the malign effect of A.C.T.H. on gastric ulceration is in part due to the action of one or more of the other twenty-five cortical steroids; but it would be unwise to assume, on the present available evidence, that cortisone itself is entirely blameless.

It must be emphasised that any tentative conclusions to be drawn from the data presented here apply only to *gastric* ulcers. Many workers believe that gastric ulcer and duodenal ulcer are different diseases; the evidence has recently been summarised by James and Pickering (1949). So perhaps they react differently to A.C.T.H. and cortisone. Certainly reports of activation of duodenal ulcers by A.C.T.H. are far more numerous than reports of activation of gastric ulcers. This may simply be due to the fact that duodenal ulcers are more common, but it might also be that duodenal ulcers are more likely to be adversely affected by A.C.T.H. There are some theoretical grounds for believing that this is so. If, as seems probable, both A.C.T.H. and cortisone increase pepsin and acid secretion in the stomach, this may do less harm to gastric than to duodenal ulcers. Hollander (1938) and Hunt (1950) suggest that there is a hypothetical alkaline, as well as an acid, component in the gastric juice of patients with peptic ulcer. Hunt further believes that gastric-ulcer patients have a supernormal central reactivity in the secretory mechanism of this hypothetical alkaline component. Without stretching hypothesis too far, it might be conjectured that gastric-ulcer patients can therefore more easily than duodenal-ulcer patients compensate, to some extent, drug-induced increases in the acidity and peptic activity of their gastric juices.

CONCLUSION

On the evidence presented here, and in the light of previously published work, it seems reasonable to suggest that patients with active gastric ulcers, or with a past history of gastric ulcer, should not be given A.C.T.H. The administration of cortisone to such patients may be justifiable if it is strongly indicated for some concomitant disease, provided that the risk of possible ulcer activation is borne in mind. The appearance or worsening of gastric symptoms would be an imperative signal to discontinue the drug, or at least to reduce the dosage.

SUMMARY

The alleged activation of peptic ulcers by A.C.T.H. and by cortisone has been recorded. This effect has been attributed to the fact that these drugs increase the acidity and peptic activity of gastric juice.

Three hospital patients with active uncomplicated gastric ulcers were given A.C.T.H., eight were given cortisone, and seven were used as controls. No other significant treatment was given to any of the patients.

All three A.C.T.H.-treated patients failed to improve radiologically while on this treatment, and one of them became symptomatically worse. In contrast, six of the eight cortisone-treated patients progressively improved radiologically, and their ulcers healed; none of them was made worse. Six of the seven controls progressively improved and their ulcers healed radiologically. In the cortisone-treated and controls the rates of healing in the successful cases did not differ much.

It is suggested that this apparent difference between the effect of A.C.T.H. and that of cortisone on active gastric ulceration may be due to the fact that A.C.T.H. stimulates the secretion of adrenal cortical steroids other than cortisone.

It is inadvisable to give A.C.T.H. to patients with active or healed gastric ulcers, but it may be justifiable to administer cortisone, provided that a careful watch is kept for signs of ulcer activation. This conclusion applies only to gastric ulceration, and it would be unwise to assume that it is equally true for duodenal ulceration.

I am grateful to my colleagues, Dr. P. R. C. Evans and Mr. R. S. Ninian, for allowing me to treat some patients under their care, and to Dr. J. N. Hunt for his helpful advice in the preparation of this paper.

C-REACTIVE PROTEIN IN RHEUMATIC FEVER

ALAN G. S. HILL
M.C., M.B. Edin., M.R.C.P.E.

From the Department of Medicine, University of Edinburgh, and the Rheumatic Unit, Northern General Hospital, Edinburgh

IN many cases the activity of rheumatic fever can be readily established on purely clinical grounds; in others, however, the situation is less clear, and assistance is sought from laboratory findings, particularly the erythrocyte-sedimentation rate (E.S.R.). Among such findings the presence of C-reactive protein in the blood has been said to provide "probably the most sensitive test for the presence of rheumatic activity that we now possess" (Anderson and McCarty 1950).

C-reactive protein is an abnormal constituent of the blood and other body-fluids, and can be detected during the acute stages of many infective and non-infective conditions. It forms a precipitate with the C, or somatic, polysaccharide of the pneumococcus, a reaction first observed by Tillett and Francis (1930). In investigating the value of determination of C-reactive protein in rheumatic fever Anderson and McCarty (1950) used as their test reagent a specific antiserum prepared in rabbits by immunisation with purified human C-reactive protein. Wood and McCarty (1951) compared the sensitivity of such an antiserum with that of C polysaccharide in detecting the C-reactive protein, and concluded that the antiserum was more efficient and was the reagent of choice in assessing rheumatic activity.

As it is difficult to obtain enough material containing C-reactive protein in sufficient concentration to produce an antiserum, the present investigation was planned to explore the value of the less sensitive C-polysaccharide test in rheumatic fever. Single or multiple determinations of C-reactive protein were made in 15 cases. The main objects were to correlate fluctuations in the concentration of C-reactive protein with changes in the clinical condition and E.S.R., and to investigate the relation of such fluctuations to treatment with salicylate.

METHODS

The technique used in testing serum for C-reactive protein (hereafter called C protein) has been described by Hill (1951). Briefly, it involves a ring test in which a 1 in 10,000 dilution of C polysaccharide, prepared by the method of Goebel et al. (1943), is layered over undiluted serum, cleared when necessary by Seitz filtration. To enable results to be recorded in a roughly quantitative way an arbitrary grading of reactions from +4 downwards is used.

Experience in applying this test to rheumatoid arthritis has shown that precipitation due to C-polysaccharide antibody can sometimes lead to confusion; such reactions can be differentiated from those produced by C protein by repeating the test with citrated serum; there is no precipitation in the absence of calcium ion when C protein is the reactive agent, but there is precipitation when C-polysaccharide antibody is responsible (Abernethy and Avery 1941).

The E.S.R. was measured in Westergren tubes and read at the end of 1 hour.

RESULTS

The accompanying table summarises the results of the initial tests for C protein in 13 cases of rheumatic fever. All 6 of the acute febrile cases had a very strong (+4) reaction. In the subacute cases the reactions were +2, +3, and +4. C protein could not be detected in serum from any of the 4 convalescent patients. The relation of C protein to rheumatic activity illustrated by these initial tests was studied in more detail in several cases, the patient's serum being retested at intervals throughout the illness.

REPRESENTATIVE CASES

Case 1.—A woman, aged 45, was admitted eight days after the onset of acute rheumatic fever. She had acute febrile polyarthritis and gave a history of a previous attack of rheumatic fever at the age of 25. She was treated with salicylate and became afebrile after two days. Fig. 1 shows that C protein, initially present in high concentration, disappeared between the third and fifth days after clinical recovery. Convalescence was uneventful and C protein remained absent. The E.S.R. fell to normal rather more slowly.

Case 2.—A man, aged 25, was admitted with acute febrile polyarthritis on the fourth day of his illness. He had no history of a previous attack of rheumatic fever. C protein was present in high concentration in the initial specimen of serum. Treatment with salicylate was started on the day after admission but was interrupted after six days. Fig. 2 shows that a clinical relapse followed the withdrawal of salicylate, and that the fall in C-protein titre which had already started was quickly reversed, a new peak being reached three days after the return of symptoms. Fever and joint pain were again controlled when treatment was started again, and the fall in C-protein titre was resumed, the tests finally becoming negative. A second interruption of treatment was again followed by a relapse, mild on this occasion, and by a return of C protein. Changes in E.S.R. followed a similar trend but tended to lag behind those in C-protein concentration.

RESULTS OF TESTS FOR C PROTEIN IN 13 CASES OF RHEUMATIC FEVER

Clinical condition	No. of cases	C protein	
		Present	Absent
Acute febrile	6	6	0
Subacute—			
Occasional mild fever	1	1	0
Afebrile	2	2	0
Convalescent	4	0	4
Total	13	9	4

Case 3.—A boy, aged 13, had an attack of tonsillitis six weeks before admission. Flitting joint pains started two or three weeks later but seem to have been only moderately severe. The boy had no history of a previous attack of rheumatic fever. On admission he was afebrile and his only complaint was of slight pain and stiffness in the hands and elbows. C protein was not detected in serum taken on the

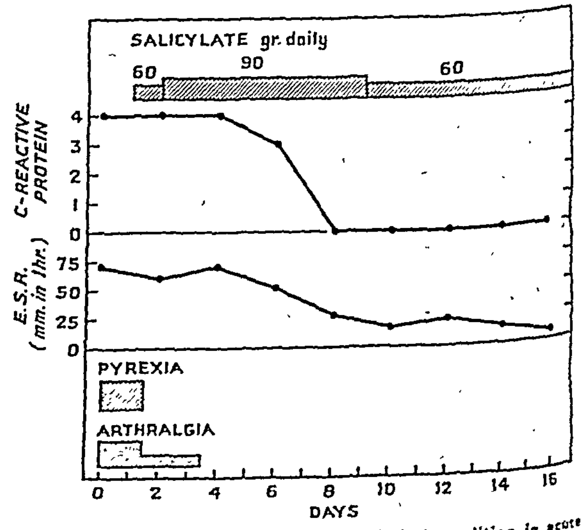

Fig. 1—Changes in C protein, E.S.R., and clinical condition in acute rheumatic fever in which recovery was prompt and uneventful (case 1).

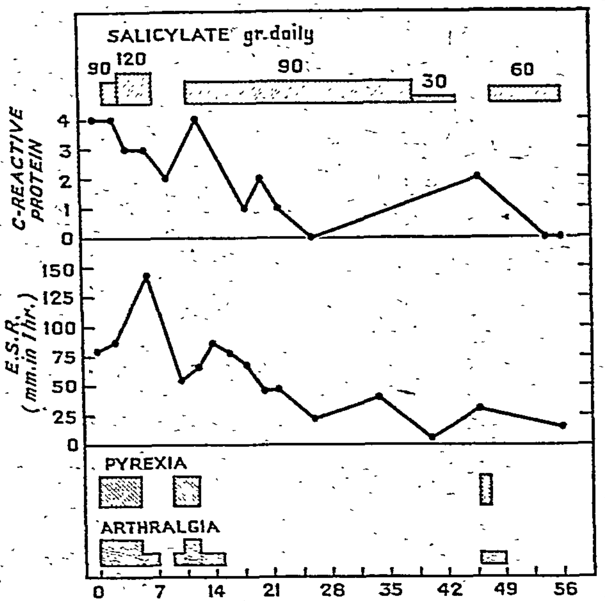

Fig. 2—Changes in C protein, E.S.R., and clinical condition in acute rheumatic fever in which withdrawal of salicylate was followed on two occasions by clinical relapse (case 2).

first day in hospital, though the E.S.R. was raised (47 mm. in 1 hr.). He was given a small daily dose of salicylate for eleven days. Two days after this had been stopped there was a recurrence of joint pain with swelling. C protein was found in serum collected three days later (fig. 3). A further rise in E.S.R., presumably related to this relapse, was recorded a few days after the first appearance of C protein. Treatment with salicylate was restarted on the third day of the relapse, and C protein disappeared, but it subsequently reappeared in low concentration in a single specimen. This brief reappearance remained unexplained: there were no clinical signs of renewed rheumatic activity at the time, and salicylate was still being administered.

Case 4.—A boy, aged 14, had subacute rheumatic fever pursuing a protracted course and showing only occasional mild pyrexia, but with persistent evidence of carditis. The continuation of activity despite treatment with high doses of salicylate was further emphasised by the appearance of periodical crops of nodules. C protein remained present for many months (fig. 4) but in a concentration lower than that encountered in the more acute cases, providing evidence of its value as a sensitive index of rheumatic activity.

The results of E.S.R. and C-protein determinations were most often divergent in early convalescence. In one case, for example, the E.S.R. six weeks after clinical recovery was 73 mm. in 1 hr., though clinical evidence of residual activity was lacking and C protein was not detected. A month later the E.S.R. was 19 mm. in 1 hr., and after a further month it had fallen to 1 mm. in 1 hr. In most cases, however, the interval between the first negative test for C protein and the first normal E.S.R. did not exceed a few days.

A strongly positive test for C protein in the absence of rheumatic activity was encountered in one case only:

The patient, a man aged 41, had a typical attack of acute rheumatic fever, during which his serum gave a strong reaction for C protein. As the symptoms subsided, C protein disappeared. The E.S.R. remained rapid, however, and C protein reappeared after having remained absent for seven weeks. This reappearance could not be explained by any obvious recrudescence of rheumatic activity, and further investigation revealed a bronchial carcinoma.

In testing for C protein by the method used in this investigation it is necessary, as we have said, to consider C-polysaccharide antibody as an alternative cause of precipitation with the test solution. Weak reactions persisting after treatment of the serum with citrate, and accordingly attributed to antibody, were observed in two cases of rheumatic fever: (1) serum from one patient, collected during an acute attack, contained both C protein and antibody, the reaction being reduced in intensity but not wholly inhibited by citration; and (2) in the second case a reaction uninfluenced by citrate first appeared several weeks after the end of an acute attack. Only one case (not included in the table) gave a strong (+3) reaction of the antibody type; the patient had old-established rheumatic heart-disease, and there was no suggestion of current or recent acute rheumatic activity.

Though the number of cases in the present series is small, the incidence of strong antibody reactions was substantially lower than that we encountered in rheumatoid arthritis.

DISCUSSION

The first detailed study of C protein in rheumatic fever was made by Rothbard et al. (1948) in the course of an investigation of the immunological changes in patients with infections due to hæmolytic streptococci. Using the C-polysaccharide test they detected C protein in 97·6% of their patients in whom rheumatic fever developed.

Anderson and McCarty (1950) tested for the presence of C protein with specific antiserum in 45 cases of rheumatic fever and found that the test provided the most consistently positive laboratory finding in the presence of rheumatic activity. Though changes in the amount of C protein present tended roughly to parallel changes in the E.S.R., the E.S.R. often remained raised during the early recovery period after C protein had disappeared. The total leucocyte-count was not an accurate guide.

In the present series a similar rough parallelism was found between C-protein titres and the E.S.R., but again there was a tendency for the E.S.R. to remain above normal during early convalescence after the C protein had disappeared. The combination of a normal E.S.R. with a positive C-protein reaction, which Anderson and McCarty (1950) occasionally found, was not encountered, but the persistence of C protein for long periods in cases of smouldering rheumatic activity was exemplified by case 4. The reaction for C protein was always positive when the rheumatism was active. In the closeness of this relationship rheumatic fever differs from rheumatoid arthritis: occasional undoubtedly active cases of rheumatoid arthritis do not give a positive reaction (Hill 1951).

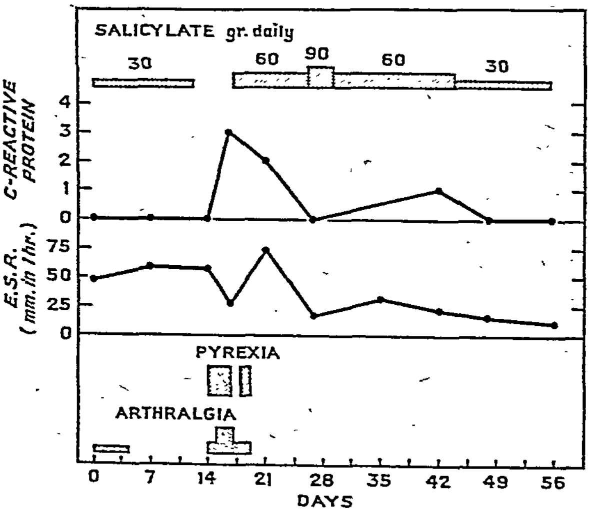

Fig. 3—Changes in C protein, E.S.R., and clinical condition in rheumatic fever, quiescent when first observed but relapsing on withdrawal of salicylate (case 3).

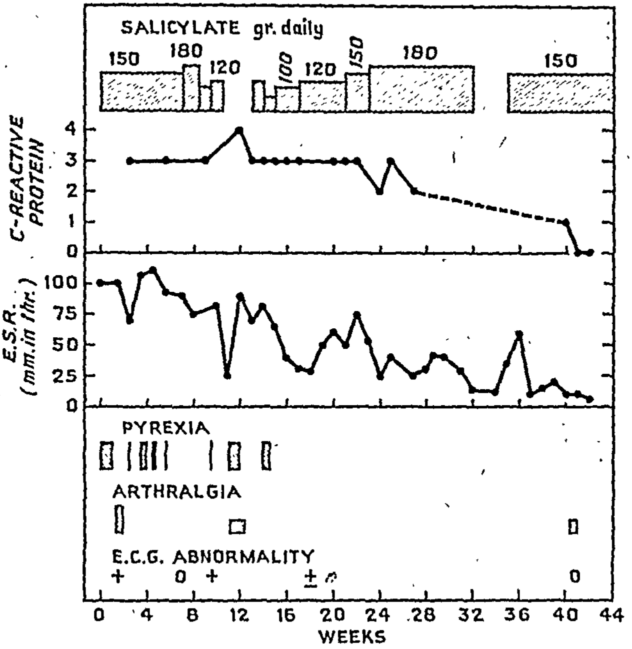

Fig. 4—Changes in C protein, E.S.R., and clinical condition in subacute rheumatic fever pursuing a protracted course with persistent evidence of carditis and showing no apparent response to salicylate (case 4).

The value of tests for C protein in rheumatic fever lies particularly in the characteristic rapidity with which this abnormal substance can appear in or disappear from the blood, and in the close correlation of such changes with variations in the patient's clinical state. This lability was clearly evident in some cases of rheumatoid arthritis, particularly where the disease was temporarily modified by a course of A.C.T.H. or of cortisone. In such cases C protein disappeared soon after the symptoms had been suppressed, and reappeared equally promptly when treatment was stopped (Hill 1951). The influence of these hormones on C-reactive protein in rheumatic fever has been reported by McEwen et al. (1950). Suppression of the clinical manifestations of rheumatic fever by salicylate seems to be regularly accompanied by the disappearance of C protein; when salicylate was clinically ineffective (case 4), C protein was, however, uninfluenced.

In using the C-polysaccharide test for detecting C protein the possible introduction of false positive results by C-polysaccharide antibody must be considered, but this difficulty is likely to be encountered less often in rheumatic fever than in rheumatoid arthritis. As a test reagent C-protein antiserum is preferable to C polysaccharide not only because it avoids this difficulty but also by virtue of its greater sensitivity. Wood and McCarty (1951) showed that antiserum can detect C protein in a concentration less than a tenth of that required to produce a visible reaction with the polysaccharide. The greater sensitivity of the antiserum test is likely to prove of particular value in helping to establish the existence of smouldering rheumatic activity when the clinical signs are equivocal. Despite these considerations the technique which uses the more readily available polysaccharide can provide useful information: the sensitivity of the test is enhanced by careful clarification of each serum before testing, and the specificity of a positive reaction can be confirmed by a control test with citrated serum.

SUMMARY

The presence of C-reactive protein in the serum of 13 cases of rheumatic fever has been studied, the C polysaccharide of the pneumococcus being used as the test reagent.

Positive reactions were obtained in all active cases, and changes in the concentration of C-reactive protein faithfully mirrored fluctuations in the activity of the disease. Though these changes tended to parallel variations in the E.S.R., the E.S.R. often remained high during early convalescence after C protein had disappeared. A clinical response to treatment with salicylate was closely followed by the disappearance of C-reactive protein.

I should like to express my thanks to Dr. J. J. R. Duthie for advice and encouragement during this investigation, and to Dr. J. A. Strong for permission to study cases under his charge. Part of the work was done during tenure of a Nuffield fellowship in rheumatic diseases.

SHOCK IN BOTULISM TREATED WITH DEXTRAN AND BLOOD

JØRGEN PEDERSEN
M.D. Copenhagen
SENIOR ASSISTANT PHYSICIAN

ANKER CHRISTENSEN
M.D. Copenhagen
ASSISTANT PHYSICIAN

EPIDEMIHOSPITALET, BLEGDAMSHOSPITALET, COPENHAGEN

BOTULISM is a type of food-poisoning caused by the toxin of *Clostridium botulinum*. Under normal conditions it is rare, but it might be used in biological warfare.

The *mortality* from botulism is high, averaging 50% according to published reports, but it varies. In the U.S.A. there have been some very severe poisonings due to *Cl. botulinum* type A (Hall 1936). In France, on the other hand, about 1000 cases, mainly due to type B, were reported during the occupation, with a mortality of about 2% (Legroux et al. 1947).

The principal *symptoms* are general weakness, abdominal pain, vomiting, internal and external ophthalmoplegia, dryness of mucosæ, paralysis of the pharyngeal muscles, and, finally, respiratory and cardiac paralysis.

The *treatment* consists in the injection of the type-specific antitoxic serum: the administration of antibiotics; feeding through a *duodenal tube*; the parenteral administration of fluid, glucose, and electrolytes; and the administration of oxygen, clearing of the pharynx and bronchi, tracheotomy, and treatment with a mechanical respirator as the case indicates.

Treating a small family epidemic in the autumn of 1951, we noticed that 4 of our 6 patients were in a state of severe shock on admission. These 4 patients received dextran and blood-transfusions, apparently with a favourable result. Since shock does not seem to have been emphasised previously as a sign in this disease, we report our experience here.

THE OUTBREAK

Our 6 patients had luncheon together on Oct. 21, 1951, at noon; 5 were admitted in the afternoon or evening of Oct. 22, and 1 on the morning of Oct. 23. The poisoning was due to home-made pickled herrings, no doubt infected with *Cl. botulinum* by contact with earthy potato peel at an early stage of the preparation. The herrings ontained botulinus toxin type B. Of the 6 patients were fairly weak, 1 slightly, and 1 not at all.

ILLUSTRATIVE CASE-RECORD

Case 1.—A man, aged 43, was admitted at 4 P.M. on Oct. 22. eneral malaise had come on in the late evening of Oct. 21, welve hours after the luncheon. About 6.30 A.M. on Oct. 22 e felt ill, dizzy, and nauseated, and vomited eight times. e then had blurred vision, and later diplopia and much ryness of buccal and pharyngeal mucosa. The symptoms rew worse during the day, and shortly before admission he as feeling very ill, and dizziness and vomiting came on when e tried to get up.

On examination he was weak and pale, with a small soft ulse. On sitting up for auscultation he became still paler nd his pulse small, rapid, and almost imperceptible. This tate was relieved by lying down. Examination of his eyes y Dr. H. Skydsgaard showed loss of accommodation and iplopia due to paresis of the external ocular muscles. No ther signs of cranial nerve pareses were seen, particularly o ptosis, nasal tone, hoarseness, or dysphagia. His faucial ucosa was dry. His heart beat was regular, pulse-rate 100, eart sounds normal, and blood-pressure 85/50 mm. Hg. His ngs were normal on auscultation, and his respirations were 6 per minute. His abdomen was diffusely tender, with some uscular guarding. The reflexes of the arms were normal, and hose of the legs too brisk, if anything.

Treatment and Progress.—Shortly after admission the atient received carbon and magnesium sulphate by mouth nd botulinus antitoxin (types A and B) 50 ml. intramuscuarly. The antitoxin was repeated next morning. The patient as made to lie flat, and his pulse-rate and blood-pressure ere observed for a few hours. When the pulse became faster, he blood-pressure fell, and the patient grew cool, dextran litre was administered by intravenous drip, followed by a lood-transfusion of 500 ml. He then improved somewhat, nd at 9 P.M. his blood-pressure was 110/80 mm. Hg and pulse-ate 100. Seven times in the night the patient vomited copious atery matter and complained of an uncomfortable feeling n the abdomen. Next morning his general condition was fair, ut his blood-pressure had again dropped somewhat; so nother blood-transfusion of 500 ml. was given. During the ext few days, the condition was characterised by slight espiratory difficulty, but not actual paralysis; much dryness f the mouth and pharynx; and mydriasis, diplopia, and cular fatigue. On Oct. 24 the patient was too ill to be further xamined for diplopia. He took ample fluid but could not wallow much food, because of the dryness of the mucosa. He was subfebrile, and from Oct. 25 received prophylactic enicillin 150,000 units twice daily for five days. His temperaure reached its peak on the evening of Oct. 26. Since his erum-potassium level was low, he was given a solution of otassium sodium chloride 250 ml. by mouth on Oct. 25 nd 500 ml. on Oct. 30 and Nov. 1. On Oct. 28 he developed n itching serum exanthem, which subsided in two days. He radually improved and was discharged on Nov. 8, feeling ather tired, and with slightly reduced vision and some ryness of the throat.

Laboratory Tests.—The patient's blood was not tested for otulinus toxin. His urine contained no albumin, blood, pus, r sugar. A white-cell count showed 6800 leucocytes per .mm., with a pronounced shift to the left, suggesting intoxiation. Radiography of the chest on Oct. 24 showed no bnormality. Electrocardiograms made daily from Oct. 24 o Nov. 2 showed slight flattening of TII. on Oct. 27 and 29 nd a constantly negative or iso-electric TIII. Examination of he blood gave the following additional information:

	Oct. 23	*Oct. 24*	*Oct. 26*	*Oct. 27*	*Oct. 29*	*Nov. 1*
Serum-chloride (m.eq.)	95	97	..	..	..	..
Serum-bicarbonate (m.eq.)	28	26	..	..	..	..
Serum-sodium (mg. per 100 ml.)	305	..	332	..	..	..
erum-potassium (mg. per 100 ml.)	14	13·2	12·9	..	..	14·4
lood-urea (mg. per 100 ml.)	79	57	56	44	44	..
b (%)	94	100	101	104	102	..
ed cells (million)..	4·59	4·61	4·52	4·81	5·20	..

DISCUSSION

The diagnosis of botulism must be considered as stablished beyond doubt. The symptoms were typical, nd botulinus toxin was found in the blood of 3 out of the 4 patients in which it was sought. No attempt at neutralisation with type-specific antitoxin was made, because not enough serum was available. As mentioned above, examination of the herrings showed that the infection was of type B.

BLOOD-PRESSURES AND PULSE-RATES BEFORE AND AFTER TREATMENT WITH DEXTRAN AND BLOOD-TRANSFUSIONS

Case no.	Age (yr.)	On admission		24 hours later		Treatment during first 24 hours	
		Blood-pressure (mm. Hg)	Pulse-rate	Blood-pressure (mm. Hg)	Pulse-rate	Dextran (ml.)	Blood (ml.)
1	43	85/50	100	110/80	90	..	1000
2	11	80/50	136	110/75	120	1000	1100
3	51	110/90*	126	130/90	92	1500	500
4	36	90/70	140	105/65	92	1000	1500
5	50	100/80	80	120/85	84	..	..
6	39	110/80	80	125/85	84	..	..

* Normally a systolic blood-pressure of about 200 mm. Hg.

The principal symptoms were severe weakness, dryness of the mucosæ, and visual disturbances. Four patients were in a state of shock on admission, 3 had dysphagia, and 2 slight air-hunger on swallowing, but none developed pharyngeal or respiratory paralysis. One patient had attacks of laryngeal spasm, and another tonic convulsions in his limb muscles, with tetany position of the hands.

Although the disease was benign in the sense that pharyngeal or respiratory paralysis did not develop, 4 patients were severely affected by the initial shock. The brief incubation periods (12, 18, 16, 19, 20, and 20 hours) also indicate severe poisoning.

The patients' shock on admission was striking. They were pale, weak, and cool, with low blood-pressure and fast pulse-rate. This is shown by the accompanying table and by the case-history, which shows also that the infusions of dextran and blood produced much improvement in blood-pressure, pulse, and general condition. We have found some published reports from which it must be presumed that the patients were in a state of shock, particularly in extremis, but we have never seen this point emphasised. Treatment by venesection, on the other hand, was not uncommon. Thomas et al. (1951) report a case in which a blood-transfusion was given to a boy, aged 13, who died of botulism after a botulinus infection in a relatively small gunshot wound of the leg. We feel that shock is rather common in severe botulism, and that it is due to direct action of the toxin on the organs regulating the circulation (cf. diphtheria). From our experience we recommend blood-transfusion and feel that the symptomatic treatment should be on the lines prevailing at present in other neurotoxic poisonings, such as barbituric-acid poisoning.

All our patients had slightly reduced serum-potassium levels, the lowest value being 11·9 mg. per 100 ml. From the second to the seventh day after admission the average serum-potassium level was 13·5 mg. per 100 ml., although 5 patients received potassium by mouth. The potassium balance does not seem to have been studied in this disease, and the cause of the reduction is unknown. It can hardly be due to loss of potassium, because it occurred also in a patient who did not vomit. Nor does a decreased intake of potassium seem to be the explanation.

Electrocardiograms were made daily from Oct. 23 to Nov. 2, and transitory changes were observed in 5 cases. These changes consisted almost exclusively in flattening to the extent of negativity of TII between the seventh and twelfth days.

A few workers—e.g., Joly (1944), Mouquin et al. (1944), and Dyggve (1946)—have previously reported electrocardiographic changes in single cases. These changes were extrasystoles, depression of the S-T segment, negative or iso-electric T waves, and splitting of
